Abstract—We develop a modeling and simulation framework capable of massively parallel simulation of multicellular systems with spatially resolved stochastic kinetics in individual cells. By the use of operator-splitting we decouple the simulation of reaction-diffusion kinetics inside the cells from the simulation of molecular cell-cell interactions occurring on the boundaries between cells. This decoupling leverages the inherent scale separation in the underlying model to enable highly horizontally scalable parallel simulation, suitable for simulation on heterogeneous, distributed computing infrastructures such as public and private clouds. Thanks to its modular structure, our framework makes it possible to couple just any existing single-cell simulation software together with any cell signaling simulator. We exemplify the flexibility and scalability of the framework by using the popular single-cell simulation software eGFRD to construct and simulate a multicellular model of Notch-Delta signaling over OpenStack cloud infrastructure provided by the SNIC Science Cloud.

I. INTRODUCTION

One important insight gained in computational systems biology is that intrinsic molecular noise in cellular regulatory networks can have important consequences for the functioning of the system [11], [22], [27], [32]. This has led to the development of a wide range of methods and simulation software capable of simulating the stochastic dynamics of intracellular kinetics, both in a well-mixed and in a spatial setting [14].

In the case that one can assume a well-mixed system, i.e. when the rate of chemical reactions can be assumed to be independent of the spatial location of the molecule, Gillespie’s Stochastic Simulation Algorithm is a popular algorithm to generate trajectories of the involved chemical species, who are assumed to follow a continuous time discrete space Markov process. As long as the well-mixed assumption holds, this type of modeling has proven very useful, in cell biology but also in other fields where this algorithm was not primarily intended [28].

This work has been funded by the Swedish research council (VR) under award no. 2015-03964 and by the eSCIENCE strategic collaboration of eScience.

Cellular regulation kinetics are inherently spatial though, with reactions frequently taking place in a diffusion-limited regime where the spatial homogeneity assumption breaks down. One popular alternative that simulates stochastic kinetics with spatial resolution is the Reaction Diffusion Master Equation (RDME) [11]. On an even finer scale, molecules are assumed to be continuously diffusing hard spheres and interact according to Smoluchowski diffusion limited theory. The Green’s Function Reaction Dynamics (GFRD) framework [25] is a popular simulation software in that setting. There is therefore a well established hierarchy for single-cell modeling techniques, with ordinary differential equation (ODE) based methods on the coarser end of the spectrum and detailed particle dynamics methods on the other end.

However, in complex multicellular systems, cells do not act in isolation of each other, on the contrary, they interact with each other in many different ways. Through direct contact, where cells physically push or pull each other, changing position and shape over time, and through chemical signaling, where signals are mediated by receptor molecules at the surface of the cells, that trigger a cascade of intracellular reactions when activated, modulating the cell’s genetic regulatory networks. Unless simulations are able to capture both these intricate cell-cell interaction mechanisms as well as discrete, spatial stochastic molecular regulation, modelers are missing out on important details.

Several studies have focused on coupling single-cell and multicellular interactions. Cell mechanics have been modeled with agent-based models [30], center based models [19], vertex based models [1] or cellular Potts models [17]. These models have been coupled with ODEs [7], [13], boolean networks [3], and more recently the RDME framework [12]. Non-spatial deterministic models remain the preferred framework due to their relatively low complexity and low computational cost. Similar to the insights gained from using stochastic models in the single-cell setting though, enabling the use of more detailed stochastic models of chemical kinetics coupled with sophisticated models of cell mechanics interactions could bring significant insight to these models.

Contrary to methods used for single-cell models, for multicellular systems there is no unifying underlying mathematical theory that would provide an analytical solution to be com-

pared with. Also, there is no well-established model hierarchy, and models are often only compared qualitatively to each other [21]. So far, cell mechanics models have often been coupled with coarse, simple internal cell dynamics, such as *ad hoc* rules, ordinary and delayed differential equations, or simple stochastic dynamics [15]. It remains, however, unclear how much information is lost in using these coarse approximations. In other words, using more detailed models and software for simulating intracellular reaction networks, such as GFRD [25], Smoldyn [2] or URDME [9], could uncover new insights. Handling such detailed simulation remains highly challenging due to their prohibitive computational cost.

Given this diversity in both single-cell and multicellular simulation frameworks, there is a need for tool to easily combine different software into complex simulations that includes single-cell resolution and cell-cell signaling. Due to the computational cost, such a framework needs to be able to leverage modern distributed computing environments such as cloud infrastructure to seamlessly scale simulations in parallel. This would make quantitative comparative studies of various model couplings possible, allowing modelers to determine more easily how much detail is needed in their simulations.

The aim of this paper is therefore to provide such a unifying framework making it possible to construct composite multicellular models from state-of-the-art single-cell simulators and from multicellular modeling frameworks. To accommodate as many current and future modeling approaches as possible, the framework needs to be as flexible and general as possible. To achieve this, the only assumption we make regarding our models is that they are possible to split in an operator split fashion. Unlike other multiscale agent-based platforms (such as Chaste [20] or BSim [16]) our framework is independent of any language or technology, and focuses on combining different tools into massively parallel simulations rather than to provide new tools for individual components of a simulation. Rather than a new simulation software, or a generic workflow library, our framework is a tool to compare various combinations of models, systematically and reproducibly, using existing simulation software [25], from the computational biology field on the one hand, and from parallel computing on the other hand [6].

The rest of the paper is organized as follows: first, we introduce our framework and its components. We then move on to the scaling study and detail our simple biological test-model and how we have implemented our framework. We examine both strong and weak scaling of our algorithm. We conclude by emphasizing the advantages of our approach and open the way for future developments.

II. A PARALLEL FRAMEWORK FOR MULTISCALE SIMULATION OF CELLS

Our main objective is to design a general framework that makes it possible to a) combine different existing tools for single cell reaction kinetics simulation and multicellular mechanics models into multi-fidelity multicellular simulations, and b) enable to simulate the resulting model in parallel

Figure 1: The Orchestral Framework. Blue nodes represent simulation modules, while red nodes represent translation scripts. Every timestep, the internal cell dynamics are simulated (χ) and the result of these simulations is translated to initialize the simulation of cell signaling (S). This simulation is then run as well and the results are translated to update the cell’s internal state. The central node (O) executes and distributes the execution of every program the right order.

across a range of platforms. The simulations should permit the inclusion of spatial details in single cells, and should be pluggable to allow for the use of different simulation software for the different parts of a simulation (multiscale simulation).

Three main design assumptions are critical to meet these requirements. First, we assume that a multicellular simulation can be broken down into principal parts, or simulation modules, e.g: intracellular dynamics, cell signaling, and mechanics. Second, we assume that each such simulation module can be simulated one after the other, for a short timestep Δt , such that the numerical solution converges with $\Delta t \rightarrow 0$. This is true for operator splitting and co-simulation schemes under reasonably non-restrictive conditions, and a commonly employed strategy in multiphysics simulation. This assumption enables parallelism, since by decoupling internal cell dynamics from boundary interactions over the timestep Δt , it allows us to update cells in an embarrassingly parallel fashion. The amount of parallelism enabled depends on the size of the timestep, as will be illustrated in the numerical experiments.

Third, we assume that the simulation software used to implement the different simulation modules can be called from the command line, with a single input file and a single output file as arguments (SISO). This assumption makes our framework agnostic to specific technology, software or library to handle the simulation modules. Literally any command line simulator can be used, provided the two above-mentioned assumptions are fulfilled.

Figure 1 illustrates the architecture of our proposed framework. Blue nodes represent our two simulation modules, one for internal spatial details (χ), and the other for external cell interactions (S). Red nodes are the programs responsible for providing cell interactions with summarized internal spatial

data and for updating internal dynamics with information from cell-cell interactions, essentially coupling the simulation modules together. The green node in the center is in charge of executing these modules in the right order and as efficiently as possible. For every timesteps, each module is executed once, in the order following the thick arrow. The simulation ends once all the timesteps have been executed.

We point out that all the above requirements are very weak assumptions that are easily satisfied. On the one hand, the splitting should work provided the coupling implemented by the user (i.e. the way data are summarized and shared between simulation modules) is correct and makes sense, physically speaking. On the other hand, even if simulation software do not always provide a SISO interface, it is very simple and straightforward to wrap them into a small script that would ensure compatibility.

In the following subsections we describe the main components of the framework. Our implementation is available at <https://bitbucket.org/Aratz/orchestral/>.

A. Simulation modules

In this paper, we restrict the scope to study simulation modules for intracellular dynamics and cell-cell signaling.

1) *Internal cell dynamics module*: This module focuses on simulating chemical kinetics inside cells, e.g. the interaction between proteins and genes. In this paper it will be denoted by the Greek letter χ . There is a wide range of models that can be used here, from ordinary differential equation models to more detailed particle based algorithms. One important remark here is that the role of the internal dynamics module is to update the internal state of independent cells. All types of molecular interactions involving more than one cell will be handled in the next module. This makes the update of cell internal dynamics across a cell population embarrassingly parallel over the splitting timestep Δt .

2) *Cell signaling module*: Here pairwise signaling is considered, that is, all molecular interactions involving exactly two cells. This can for example be binding of a ligand in one cell to a receptor at an adjacent cell. All pairs being independent, this step is also naturally embarrassingly parallel. We will use the letter S to represent this module.

B. Translation scripts

The translation scripts connect the simulation modules. Before a simulation module is run, an input file is generated by the translation script from the data computed previously by the other simulation modules (Figure 1). The translation scripts ensure compatibility between the simulation modules. If such a module is replaced by a new one using a different data format, the only action needed in this case is then to update the translation scripts.

Specifically, when translating from an internal dynamics model to a signaling model ($T_{\chi \rightarrow S}$), the script takes a pair of cells as input. The script can then be used to filter out molecules that are close to the common boundary of the two cells and put them in the signaling model input file. When

translating from a signaling model to an internal dynamics model ($T_{S \rightarrow \chi}$), the script takes an unspecified number of signaling pairs as parameters, which depends on the number of neighbors of the target cell. Typically, this script is used to propagate new molecules from the signaling model back into the internal dynamics model.

C. Orchestration

Finally, the main module of our framework is the orchestrator, which is responsible for executing simulation modules and translation scripts, and for efficiently distributing the computations across the computing grid. Again, this module is completely independent from the simulation modules. Replacing a simulation module does not affect the orchestrator, and replacing the orchestrator (for instance to fit the computing cluster of the user's choice better) does not affect the implementation of the simulation modules.

Figure 3: Configuration file. This file contains all the information necessary to run the four modules, i.e. command line syntax and parameters, as well as global simulation parameters.

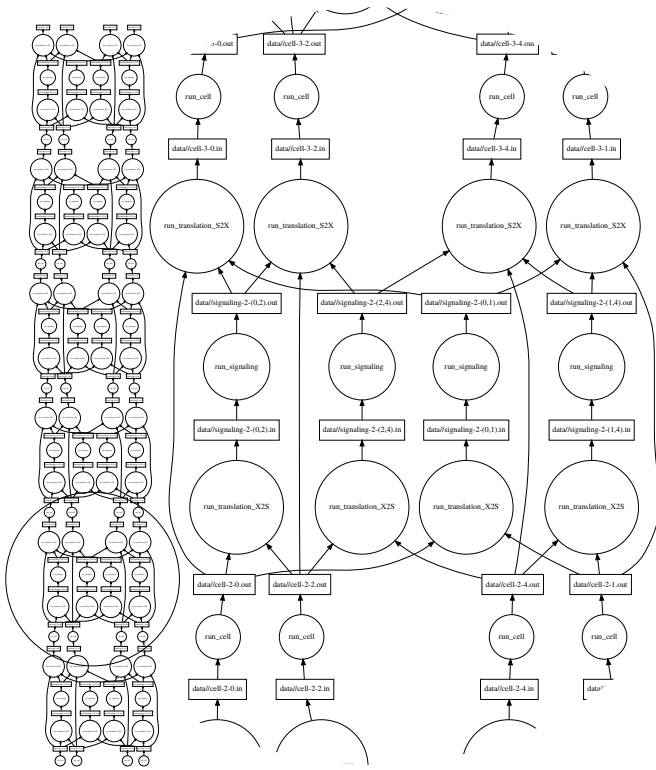

Figure 4: Task graph generated by Dask, for a model involving four cells and six timesteps. Round nodes are computation and translation steps, while rectangular nodes are input and output files.

We chose to use Dask [6], a python library for parallel and distributed computing. However, we point out that this is only one of many available alternatives, and that switching to any other library could be done very easily. In Dask, tasks can be described and hierarchized as a directed acyclic graph (DAG) using a simple Python dictionary, which makes the code very simple to understand. Switching between local

multicore simulation and distributed computations on a high performance cluster or a cloud is done by changing a single line in the orchestrator and updating the configuration file so that the data are written in the appropriate shared area. Figure 4 shows an example of such a graph for one of our simulations, where circles are tasks and rectangles are input and output files.

The orchestrator takes two input files as parameters. The first file describes the cell network, i.e. the position of each cell, the id of their neighbors, and model specific simulation parameters. An example of such a file, in json format, is given in Figure 2. The data is encoded as a dictionary, where unique cell identification numbers are associated to their parameters. It is possible to fine tune the parameters so as to have various models for each cell. Only position and neighbors are used by the orchestrator, all other parameters are fed to the internal dynamics module when the simulation is launched.

The second file is a configuration file that provides the syntax of the command line programs used to execute the simulation modules and translation script, as well as global simulation parameters, such as the number of time steps to run. An example of such a file is given in Figure 3. Each command line is written so that it is easy to format it using Python's format method by simply feeding the simulation parameters to this function. Changes to the format of the configuration file only mandates updates of the orchestrator module, but not the simulation modules or translations scripts.

III. RESULTS

In order to demonstrate the usefulness of our framework and to test its scalability, we implement a simplistic but biologically realistic model of cell-cell signalling based on the single-cell simulation software eGFRD [25]. The objective here is to provide a proof-of-concept model useful to study parallel scalability and to demonstrate how to use the framework. We conduct strong scaling experiments on a modern multicore machine and weak scaling experiments over a virtual cluster deployed in an OpenStack community cloud.

Figure 5: eGFRD single-cell simulation screenshot [25]. Cyan spheres represent Delta molecules while purple spheres represent Notch molecules. The green sphere in the center is a bound DNA promoter site.

Parameter	Value
Diffusion Constant, D	$1 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$
Transcription, t_D	$1 \times 10^2 \text{ s}^{-1}$
DNA binding, k_a	$1 \times 10^{-18} \text{ m}^3 \text{ s}^{-1}$
DNA unbinding, k_d	$2.5 \times 10^1 \text{ s}^{-1}$
Delta to $NICD$, k_N	1 s^{-1}

Table I: Model parameters used for our simulations. Since the focus of this paper is on performance rather than on biological realism, it is important to stress that these parameters were not chosen to be realistic, but rather so that the model would exhibit some interesting behavior to demonstrate the utility of our approach.

A. Setup

1) *Model*: The model implemented is a simplified model of the Notch signaling pathway [24]. The cells' membranes contain *Notch* receptors and *Delta* ligands (molecules binding to the receptor). When cells are in contact, *Notch* and *Delta* proteins can bind and this will release *Notch*'s intracellular domain (*NICD*) into the cell. *NICD* will then diffuse into this cell and potentially influence gene expression. In our model, *NICD* acts as a repressor of *Delta*, i.e. it suppresses the creation of new *Delta* protein. A single DNA molecule is placed in the center of each cell, modeling the *Delta* promoter. When not occupied by *NICD*, it transcribes *Delta* at a rate t_D . *Delta* proteins then diffuse in the cells. Figure 5 shows a snapshot of this system when simulated with eGFRD, where each molecule is approximated by a hard sphere diffusing in a cube representing the cell. DNA is shown in green in the center of the cube, while *Delta* molecules are cyan and *NICD* molecules are purple. *NICD* molecules modulate *Delta* transcription upon binding to DNA.

To model cell-cell signalling, we assume that when *Delta*

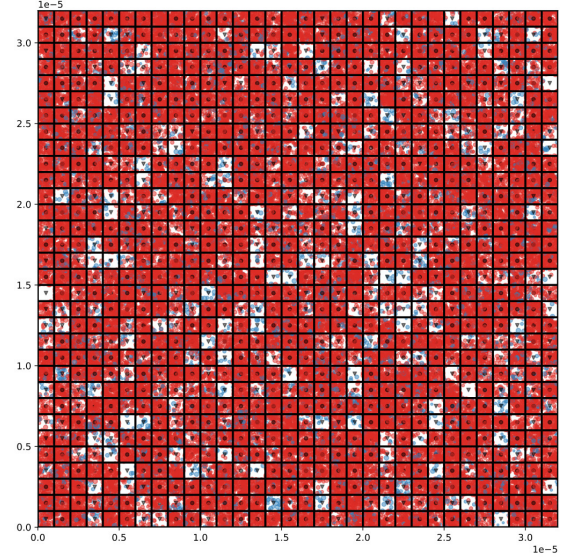

Figure 6: Snapshot of a patch of 1024 cells simulated by our algorithm after 10 timesteps. Red circles represent Delta molecules, while blue circles represent NICD molecules. DNA is represented by black circles (free DNA) and black triangles (suppressed DNA). As can be seen, DNA suppression causes the cell to stop producing Δ and to become empty.

molecules are within a distance ϵ of the cell membrane (boundary of the cube), they can be mirrored to the cell on the other side of the membrane and turn into NICD at rate k_N . NICD then diffuses inside the receiving cell and potentially associates to DNA at rate k_a . This binding turns off *Delta* transcription. NICD unbinds from DNA in bound state at rate k_d . Except DNA, all species degrade at the same rate d . The parameter values used in our simulation are summed up in Table I. These values are We tuned the model to illustrate our framework with interesting features. In the case one would want to perform a more detailed modeling study, one would need to take values from the literature.

We model cells as identical cubes, arranged in a 2D layer. Hence, each cell has at most four neighbors.

The chemical reaction turning *Delta* into *NICD* is handled by the signaling model, while all other reactions are handled as internal cell dynamics. Coupling is done by transferring all *Delta* molecules within ϵ of a *single* face of the cube to the associated signaling model. Coupling in the other direction is done by simply reporting the molecules from the signaling model back into the appropriate cell.

Figure 6 shows the output of a simulation of 1024 cells after 10 timesteps, each red dot is a *Delta* molecule, each blue dot is a *NICD* molecule, and DNA is shown in black, either in free state (circles) or bound state (triangles). Suppressed cells show a loss in *Delta* production and appear as white, while

cells with a free DNA promoter continue to produce *Delta* and remain red. Under some specific parameter regimes, this model is known to exhibit a so-called checkerboard pattern, where free cells are arranged in a regular pattern. The more noisy the system becomes, the less regular the pattern [26].

2) *Implementation:* We implement the single-cell model using eGFRD [25]. We use its custom simulation feature to both describe our model and set up reading and writing input and output files. The signaling model is implemented with a custom made python script. All translation scripts are implemented as python scripts.

B. Scaling

A key feature of the framework, as implemented using Dask, is the ability to seamlessly leverage a wide range of parallel and distributed computing resources. To demonstrate this flexibility we here tested the performance and scalability when executed on a single high-end multicore machine and b) using variable-size virtual distributed Dask-clusters deployed over cloud infrastructure as a service (IaaS) in the SNIC Science Cloud (SSC) [31]. For the multicore machine, a single node of the Rackham system provided by the Uppsala Multidisciplinary Center for Advanced Computational Science (UPPMAX) was used. The used node had two 10-core Xeon E5-2630 V4 processors running at 2.2 GHz (turbo 3.1 GHz). The SSC is a community cloud based on OpenStack, and in the same manner as public cloud providers such as AWS and Azure, it provides general infrastructure as a service (IaaS) to the Swedish research community.

We adapted the MOLNs orchestration toolkit [8] from the StochSS [10] suite to deploy virtual Dask clusters of variable sizes (<https://github.com/ahellander/molns/orchestral-dask>). MOLNs deploy an SSHFS shared filesystem which we use to share all the intermediate input-output data files of the simulation.

We begin with a strong scaling study on a single node, where we study the computation time as a function of increased number of cores with a fixed model size. We simulate an 8×8 grid of cells for ten seconds simulation time. We set up Dask to use the threaded single machine scheduler and ran the simulation on 1, 4, 8, 12, 16 and 20 cores. Figure 7 shows the parallel efficiency for splitting timesteps Δt of 0.1, 0.5 and 1.0 second, respectively.

Using a single core, the simulation took between 40 and 140 minutes. Using the full 20 cores of the shared memory node, the simulation took between 2 and 8 minutes, depending on Δt , thus demonstrating the usability of our framework for modeling purposes. Our framework hence shows very good parallel efficiency for all timesteps, with at slightly more than 80% parallel efficiency, with maximum efficiency obtained with $\Delta t = 0.5$. This can be explained by the fact that with $\Delta t = 1.0$, the task granularity is coarse due to the relatively low number and long duration of the tasks. With $\Delta t = 0.1$, on the other hand, the tasks become too short and the scheduling overhead of Dask leads to a loss of performance.

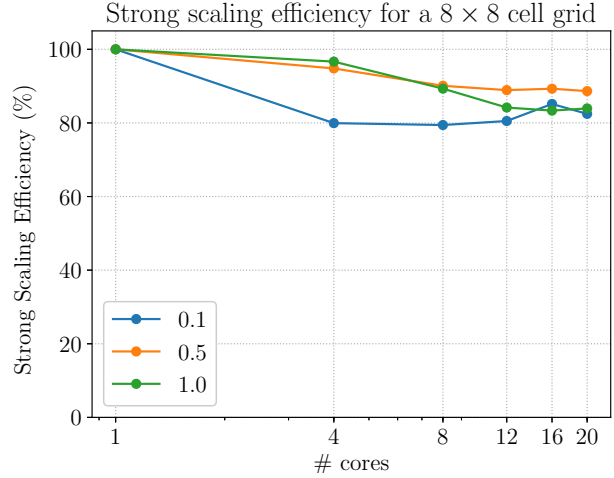

Figure 7: Single node strong scaling study of a 64-cell grid. The simulation is run for 10 seconds, with timestep length set to 1.0, 0.5 and 0.1 second. Our framework scales smoothly up to all 20 cores of our machine, maintaining about 80% strong scaling efficiency for all setups.

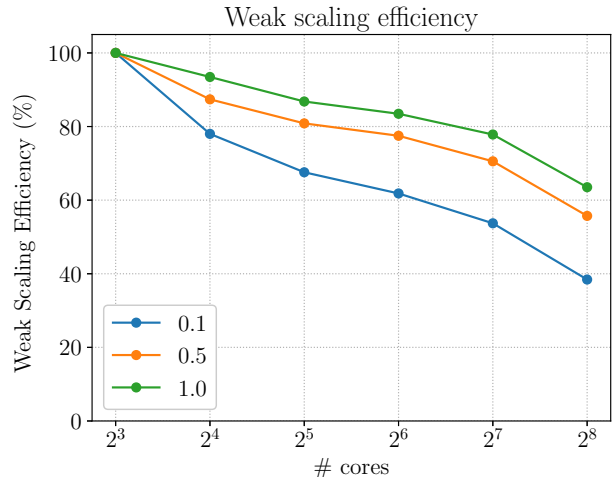

Figure 8: Weak scaling study. Each simulation consists of 100 cells per node and are run for 10 timesteps. We study three cases with timestep length ranging from 0.1 to 1.0. The results confirm the performance of our framework up to the limits of our cluster.

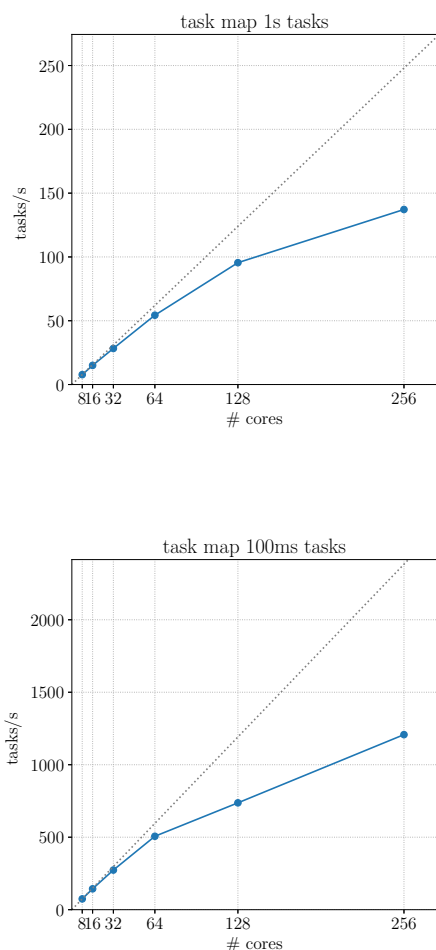

Figure 9: Weak scaling baseline benchmark focusing on Dask performance for deterministic map tasks of 1s processing time (top) and 100ms processing time (bottom).

Next we assessed the weak scaling properties of our implementation. We used *ssc.xlarge* VM instances each with 8 VCPUs and 16GB RAM and kept the number of cells simulated per core in the cluster constant as we scaled the size of the distributed cluster. We start from a grid of 100 cells for one VM (8 VCPUs), up to 3200 cells on 32 VMs (256 VCPUs). We run the simulation for 10 timesteps.

Again, our experiments demonstrate good parallel efficiency, with more than 50% efficiency across all tested timesteps on 16 VMs. Using 32 VMs, the efficiency drops as we approach the hardware limits of the cluster underlying the private cloud. It should be noted that the weak scaling properties depends on Δt , with the efficiency decreases with decreasing timestep. This is explained by the fact that as the timestep is reduced, the simulation tasks become shorter and shorter and scheduling and communication overheads limit scalability for the distributed system. In fact, to establish a baseline performance of Dask as deployed on the SSC virtual infrastructure we ran a publicly available Dask weak scaling

benchmark¹ measuring the throughput for simple deterministic tasks. In this benchmark, each task consists of simply incrementing an integer, and waiting for a small delay (1s, 100ms). The gray line shows the ideal performance. As can be seen, Dask over SSC VMs achieve close to ideal scaling up to 64 VCPUs, or 8 VMs, for both task granularities, with 74% and 54% efficiency for 128 and 256 cores respectively for 1s tasks. For 100ms task, the corresponding figures are 57% and 47% respectively. These results are consistent with results in the published benchmark with clusters deployed over the Google container platform.

The weak scaling efficiency of our multicellular simulations with Orchestral shown in Figure 8 should be seen in this context. For $\Delta t = 0.1$, individual tasks associated with updating the internal state of cells by running eGFRD vary due to stochasticity and particle counts in individual cells, but upon manual inspection in the Dask status UI they are found to vary in the interval 500ms – 2s, with the signaling module tasks taking around 300 – 600ms/task. This means that Orchestral achieves a weak scaling efficiency close to the ideal case (for this orchestrator and cloud infrastructure combination), demonstrating the lightweight nature of our framework.

IV. DISCUSSION AND CONCLUSION

In this paper, we have presented a new framework for constructing and simulating high-fidelity models of multicellular systems from existing frameworks for single-cell simulation. The driving motivation for Orchestral is a need to be able to conveniently combine the many existing frameworks for single-cell resolution reaction-diffusion models with the diverse landscape of models of cell mechanics. When combining these modeling levels, they need to be coupled via molecular cell-cell signaling. Orchestral provides a model for implementing such coupling, and for simulating the resulting model massively in parallel over a wide range of distributed computing environments. This is important, since the models resulting from integrating single-cell simulation with multicellular simulation become very computationally expensive. In this paper, we demonstrated the potential of Orchestral by turning the popular single-cell simulation software eGFRD [25] into a multicellular model where cells signal each other via a simplistic model of the Notch-Delta pathway over adjacent boundaries of individual cells.

The parallel scalability was demonstrated both in a strong scaling experiment on a shared memory system, and in weak scaling experiments over a multi-tenant science cloud IaaS infrastructure. The experiments serve to highlight the dependency of parallel efficiency on the splitting time step Δt , since this timestep determine the task sizes and hence latency requirements of the combination of underlying orchestrator and infrastructure. Since the choice of timestep depends on the needed and attained accuracy of the simulation (which is model dependent) it is not easy to *a priori* determine what type of computing platform is most suitable to accelerate

¹<http://matthewrocklin.com/blog/work/2017/07/03/scaling>

simulation. In future work, we plan to study this accuracy/performance trade-off for specific combinations of models and single-cell simulation software, in order to equip orchestral with highly performant orchestrator implementations for a range of timestep requirements and computing infrastructure.

Orchestral is primarily aimed at modelers with basic scripting experience. Due to its modular design, it is easy to reuse existing parts and patterns from a previous successful set up. Our framework puts no constraint on the technology used by the solvers, the translation scripts, or the orchestrator. All these modules are independent programs and can be exchanged at will. Indeed, replacing one simulation module only introduces the requirement to adapt the translation scripts to the file format of the new solver. In general, this is usually easily done as it mostly entails filtering and reformatting the data.

Finally, the orchestrator engine is also easily replaceable for a user with experience in distributed parallel computing. It is our intention for Orchestral to evolve with the help of the community to support a wide range of orchestrators tuned to specific platforms, for example optimized for shared memory desktop computers, for traditional HPC batch computing schedulers, and for virtual clusters deployed in private and public clouds. Writing a new orchestrator does not require any specific knowledge about the actual simulation modules or translation scripts. Therefore, programmers can focus on performance, without worrying about model compatibility. We found Dask to provide a good balance between simplicity, portability and performance, and chose to use it to implement the orchestrator that ships with Orchestral. There are however many alternatives available [4], [29], [5], [34], [23], [33], [18], which could potentially help us to push performance for low-latency requirements on distributed infrastructures. In fact, Orchestral could be used to create a comparative benchmark of all these libraries.

Here we have presented a proof of concept of our framework based on eGFRD as single-cell simulator. Future work on the modeling side involves exploring and comparing new combinations of simulators, in particular adding a module for cell-mechanics.

Finally, within our setup it is already possible to use different models to update different areas of the cell population, e.g. to use highly detailed simulation modules (such as eGFRD) at the boundary of a tissue (or generally where cells are actively engaged in signaling) and coarser modules (such as the RDME or even well-mixed models) in areas with less activity. In the future we will explore adaptive multiscale methods to switch between such models automatically.
