# Universal Approximation with Quadratic Deep Networks 

Fenglei Fan, Student Member, IEEE, and Ge Wang, Fellow, IEEE

#### Abstract

Recently, deep learning has been playing a central role in machine learning research and applications. Since AlexNet, increasingly more advanced networks have achieved state-of-the-art performance in computer vision, speech recognition, language processing, game playing, medical imaging, and so on. In our previous studies, we proposed quadratic/second-order neurons and deep quadratic neural networks. In a quadratic neuron, the inner product of a vector of data and the corresponding weights in a conventional neuron is replaced with a quadratic function. The resultant second-order neuron enjoys an enhanced expressive capability over the conventional neuron. However, how quadratic neurons improve the expressing capability of a deep quadratic network has not been studied up to now, preferably in relation to that of a conventional neural network. In this paper, we ask three basic questions regarding the expressive capability of a quadratic network: (1) for the one-hidden-layer network structure, is there any function that a quadratic network can approximate much more efficiently than a conventional network? (2) for the same multi-layer network structure, is there any function that can be expressed by a quadratic network but cannot be expressed with conventional neurons in the same structure? (3) Does a quadratic network give a new insight into universal approximation? Our main contributions are the three theorems shedding light upon these three questions and demonstrating the merits of a quadratic network in terms of expressive efficiency, unique capability, and compact architecture respectively.

Index Terms-Artificial Intelligence, machine learning, deep learning, artificial neural networks, second-order networks, approximation theory

## I. Introduction

0Ver recent years, deep learning has become the mainstream approach for machine learning. Since AlextNet [1], increasingly more advanced neural networks [2-6] are being proposed, such as GoogleNet, ResNet, DenseNet, GAN and variants, to enable practical performance comparable to or beyond what the human delivers in computer vision [7], speech recognition [8], language processing [9] game playing [10], medical imaging [11-13], and so on. A heuristic understanding of why these deep learning models are so successful is that these models representate knowledge in hierarchy and facilitate high-dimensional non-linear functional fitting. It seems that deeper structures are correlated with greater capacities to approximate more complicated functions.

The generic representation power of neural networks has been rigorously studied since the eighties. The first result is that a network with a single hidden layer can approximate a

[^0]continuous function at any accuracy given an infinite number of neurons [14]. That is, the network can be extremely wide. With the emergence of deep neural networks, studies have been performed on theoretical benifits of these deep models over shallow ones [15-22]. One way [15, 19] is to construct a special kind of functions that are easy to be approximated by deep networks but hard by shallow networks. It has been reported in [16] that a fully-connected network with ReLU activation can approximate any Lebegue integrable function in the $L 1$-norm sense, provided a sufficient depth and at most $d+4$ neurons in each layer, where $d$ is the number of inputs. Through a similar analysis, it is reported in [22] that ResNet with one single neuron per layer is a universal approximator. Moreover, it is demonstrated in [15] that a special class of functions is hard to be approximated by a conventional network with a single hidden layer unless an exponential number of neurons are used.

In our preivious studies [23-25], we proposed quadratic/second-order neurons and deep quadratic neural networks. In a quadratic neuron, the inner product of a vector of data and the corresponding weights in a conventional neuron is replaced with a quadratic function. The resultant quadratic neuron enjoys an enhanced expressive capability over the conventional neuron. For example, a single quadratic neuron can implement the famous XOR logic [23]. Furthermore, each quadratic neuron can be viewed as a generalized fuzzy logic gate, and a deep quadratic network is nothing but a deep fuzzy logic system [25]. Note that high-order neurons [26-27] were taken into account in the early stage of artificial intelligence, but they are not connected into deep networks and suffer from combinatorial explosion of parameters due to high order terms. In contrast, our quadratic neurons of a limited number of parameters (tripled that of a conventional neuron) performs the utility of high-order neurons in a deep network architecture. For this type of novel quadratic deep networks, we developed a general backpropagagtion algorithm [24] to make them trainable, paving the way for quadratic neurons to be applied for deep learning.

However, how quadratic neurons improve the expressing capability of a deep quadratic network has not been studied up to now, preferably in relation to that of a conventional neural network. In this paper, we ask three basic questions regarding the expressive capability of a quadratic network: (1) for the one-hidden-layer network structure, is there any function that a quadratic network can approximate
much more efficiently than a conventional network? (2) for the same multi-layer network structure, is there any function that can be expressed by a quadratic network but cannot be expressed with conventional neurons in the same structure? (3) Does a quadratic network give a new insight into universal approximation? If the answers to these questions are favorable, quadratic networks should be signficantly more powerful in many machine learning tasks.

In this paper, we present three theorems addressing the above three questions respectively and positively, thereby establishing the intrinsic advantages of quadratic networks over conventional networks. More specifically, these theorems characterize the merits of a quadratic network in terms of expressive efficiency, unique capability, and compact architecture respectively. We answer the first question with the first theorem, given the network with only one hidden layer, there exists a function that a quadratic network can approximate it with a polynomial number of neurons but a conventional network can only do the same level approximation with a exponential number of neurons. Regarding the second question and the second theorem, any radial function can be approximated by a quadratic network in a structure of no more than four neurons in each layer but the function cannot be approximated by a conventional network in the same structure. As far as the third theorem is concerned, for any multivariate polynomial function, denoted as $P\left(x_{1}, x_{2}, . ., x_{i}, \ldots, x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, whose degrees of inputs $x_{1}, \ldots, x_{N}$ are $\max _{k}\left\{n_{1}(k)\right\}, . ., \max _{k}\left\{n_{N}(k)\right\}$ respectively. there is a quadratic network with the width of $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and the depth of $\max _{k}\left\{n_{j}(k)\right\}+N$ that computes $P\left(x_{1}, x_{2}, . ., x_{i}, \ldots x_{N}\right)$ exactly.

For the first theorem, it is commonly known that a conventional neural network with one hidden layer is a universal approximator. Hence, the best thing we can do to justify quadratic networks is to find a class of functions that can be more efficiently approximated by a quadratic network than with a conventional network. As related to the second question, the precious studies show that any function of $n$-variables that is not constant along any direction cannot be represented by a fully-connected ReLU network with no more than $n-1$ neurons in each layer [16]. Breaking this network width lower bound, our second theorem states that when a radial function is not constant in any direction, the network width $=4$ is sufficient for a quadratic network to approximate the function accurately. Our third theorem is most interesting that a general polynomial function $\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$ can be exactly expressed by a quadratic network of width $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and depth $\max _{k}\left\{n_{j}(k)\right\}+N$. Therefore, by the Weierstrass theorem, the quadratic network is a universal approximator. Different from the analyses of conventional neural networks as universal approximators [14,16] that are of either infinitely wide or infinitely deep, for a given polynominal model the depth and width of our quadratic network are both finite for a perfect model representation, which we call the size-
bounded universal approximator. Noticably, by expressing each polynomial term/factor globally a quadratic network matches the functional structure better, avoiding brute-force piecewise linear fitting into a target function.

In the next section, we introduce some preliminaries. In the third section, we describe our three theorems, and include the corresponding lemmas and proofs. Numerical examples are also used for illustration. Finally, in the last section we discuss relavant issues and conclude the paper with some conjectures and future work.

## II. Preliminaries

Quadratic/Second-order Neuron: The $n$-input function of a quadratic/second-order neuron before being nonlinearly processed is expressed as:

$$
\begin{align*}
h(\mathbf{x}) & =\left(\sum_{i=1}^{n} w_{i r} x_{i}+b_{r}\right)\left(\sum_{i=1}^{n} w_{i g} x_{i}+b_{g}\right)+\sum_{i=1}^{n} w_{i b} x_{i}^{2}+c \\
& =\left(\mathbf{w}_{r} \mathbf{x}^{T}+b_{r}\right)\left(\mathbf{w}_{g} \mathbf{x}^{T}+b_{g}\right)+\mathbf{w}_{b}\left(\mathbf{x}^{2}\right)^{T}+c \tag{1}
\end{align*}
$$

where x denotes the input vector, and the other variables are defined in [23]. Our definition of the quadratic function only utilizes $3 n$ parameters, which is more compact than the general second-order representation requiring $\frac{n(n+1)}{2}$ parameters. While our quadratic neuron design is unique, other papers on quadratic neurons are also in the later literature; for example, [28] proposed a type of neurons with paraboloid decision boundaries. It is underlined that the emphasis of our work is not only on quadratic neurons individually but also deep quadratic networks in general.

One-hidden-layer Networks: The function represented by a one-hidden-layer conventional network is as follows:

$$
\begin{equation*}
f_{1}(\mathbf{x})=\sum_{l=1}^{k} t^{l} \sigma_{l}\left(\sum_{i=1}^{n} w_{i}^{l} x_{i}+b^{l}\right)=\sum_{l=1}^{k} t^{l} \sigma_{l}\left(\mathbf{w}^{l} \mathbf{x}+b^{l}\right) \tag{2}
\end{equation*}
$$

In contrast, the functions represented by a one-hidden-layer quadratic networks is:

$$
\begin{equation*}
f_{2}(\mathbf{x})=\sum_{l=1}^{k} t^{l} \sigma_{l}\left[\left(\mathbf{w}_{r}^{l} \mathbf{x}^{T}+b_{r}^{l}\right)\left(\mathbf{w}_{g}^{l} \mathbf{x}^{T}+b_{g}^{l}\right)+\mathbf{w}_{b}^{l}\left(\mathbf{x}^{2}\right)^{T}+c^{l}\right] \tag{3}
\end{equation*}
$$

In our Theorem 1 below, we will compare the representation capability of a quadratic network and that of a conventional network assuming that both networks have the same one-hidden-layer structure.
$L$-lipschitz Function: A $L$-Lipschitz function $f$ from $\mathbf{R}^{n}$ to $\mathbf{R}$ is defined by the following property:

$$
|f(\mathbf{x}-\mathbf{y})| \leq L\|\mathbf{x}-\mathbf{y}\|
$$

Radial Function: A radial function only depends on the norm of its input vector, generically denoted as $f(\|\mathbf{x}\|)$. The functions mentioned in Theorems 1 and 2 are all radial functions. By its nature, the quadratic neuron is well suited for modeling of a radial function. On the other hand, a general function can be regarded as the mixtures of radial functions, such as radial basis function networks can be used for universal
approximation.
Fourier Transform: For a function $f: \mathbf{R}^{d} \rightarrow \mathbf{R}$, its Fourier transform is:

$$
F(\mathbf{w})=\int_{\mathbf{R}^{d}} \exp [-2 \pi i(\mathbf{w} \cdot \mathbf{x})] f(\mathbf{x}) d x
$$

Euclidean Unit-volume Ball: In a $d$-dimensional space, Let $R_{d}$ be the radius of a Euclidean ball $B_{d}$ such that $R_{d} B_{d}$ has the unit volume.

The First Kind Bessel Function: The first kind Bessel function $J_{v}$ of an order $v$ is denoted as:

$$
J_{v}(x)=\sum_{m=0}^{\infty} \frac{(-1)^{m}}{m!\Gamma(m+v+1)}\left(\frac{x}{2}\right)^{2 m+v}
$$

Lesbegue-integrable Function: A nonnegative measurable function is called Lesbegue-integrable if its Lesbegue integral is finite. For an arbitrary measurable function, it is integrable if its positive part and negative part are both Lebesgue integrable.

Bernstein Polynomial: $l_{n, m}=C_{n}^{m} x^{m}(1-x)^{n-m}, 0 \leq$ $m \leq n$. The $n$-th Bernstein polynomial of $f(x)$ in $(0,1)$ is defined as

$$
B_{n}(x)=\sum_{m=0}^{n} f\left(\frac{m}{n}\right) l_{n, m}(x)
$$

The Bernstein Polynimials are used before to prove the Weirestrass theorem.

## III. Three Theorems

First, we present three theorems, and then give their proofs.

Theorem 1: For an activation function $\sigma(\cdot)$ with $|\sigma(x)| \leq$ $K\left(1+|x|^{\kappa}\right), x \in \boldsymbol{R}$, and constants $K, \kappa>0$, and for some universal constants $c>0, C>0, C^{\prime}>0, c_{\sigma}>0$, there exist a probability measure $\mu$ and a radial function $\tilde{g}: \boldsymbol{R}^{d} \rightarrow \boldsymbol{R}$, where $d>C$, that is bounded on $[-2,2]$ and supported on $\|\boldsymbol{x}\| \leq C^{\prime} \sqrt{d}$ satisfying:

1. $\tilde{g}$ can be approximated by a single-hidden-layer quadratic network with $C^{\prime} c_{\sigma} d^{2.5}$ neurons, which is denoted as $f_{2}$.
2. For every function $f_{1}$ expressed by a single-hiddenlayer conventional network with at most $c e^{c d}$ neurons, we have:

$$
E_{x \sim \mu}\left(f_{1}(\mathbf{x})-f_{2}(\mathbf{x})\right)^{2} \geq \delta
$$

for some positive constant $\delta$.
Theorem 2: For any Lesbegue-integrable radial function $f(\|\boldsymbol{x}\|):[-1,1]^{n} \rightarrow \boldsymbol{R}$, and any $\epsilon$, there exists a fullyconnected ReLU quadratic network with no more than four neurons in each layer such that the correponding function $F(x)$ expressed by this network satisfies:

$$
\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}|f(\|\mathbf{x}\|)-F(\mathbf{x})| d x \leq \epsilon
$$

Theorem 3: For any multivariate polynomial $P\left(x_{1},, . ., x_{i}, \ldots x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, which degrees of input components $x_{1}, \ldots, x_{i}, \ldots, x_{N}$ in the $k$-th term are $n_{1}(k), n_{2}(k),, . ., n_{i}(k), \ldots, n_{N}(k)$ respectively. there is a
quadratic network of width $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and depth $\max _{k}\left\{n_{j}(k)\right\}+N$ that computes $P\left(x_{1}, . ., x_{i}, \ldots x_{N}\right)$ exactly.

## A. Proof of Theorem 1

Key Idea for Proving Theorem 1: The proof combines the observation from [15] and the utility of quadratic neurons to approximate a radial function. For convenience and consistency, we use some definitions and notations in [15]. The form of functions represented by a single-hiddenlayer conventional network is $f(\mathbf{x})=\sum_{l=1}^{k} t^{l} \sigma_{l}\left(\mathbf{w}^{l} \mathbf{x}+b^{l}\right)$. It is observed that the distribution of the Fourior transform of $f(\mathbf{x})$ is supported on a finite clollections of lines. The support covered by the finite lines are sparse in the Fourier space, especially for a high dimensionality and high frequency regions, unless an exponential number of lines are involved. Thus, a possible target function to be constructed should have major components at high-frequencies. A suitable candidate has been found in [15]:

$$
\tilde{g}(\mathbf{x})=\sum_{i=1}^{N} \epsilon_{i} g_{i}(\|\mathbf{x}\|)
$$

where $\epsilon_{i} \in\{-1,1\}, N$ is a polynomial function of $d$, $g_{i}(\|\mathbf{x}\|)=\mathbf{1}\left\{\|\mathbf{x}\| \in \Delta_{i}\right\}$ are radial indicator functions over disconnected intervals. Although the constructed $\tilde{g}$ is hard to approximate by a conventional network, it is easy to approximate by a quadratic network, because Eq. (1) contains square terms that can be rewritten as $h(\mathbf{x})=\beta \sigma\left(\|\mathbf{x}\|^{2}+\gamma_{i}\right)$ to compute the norm and then the radial function. Consequently, it is feasible for a single-hidden-layer quadratic network to approximate the radial function with a polynomial number of neurons. Note that $\tilde{g}(\mathbf{x})$ is discontinuous, and cannot be perfectly expressed by a neural network with continuous activation functions. Here we use a probability measure $\mu$. With $\mu, \tilde{g}$ can be approximated by $f(\mathbf{x})$ represented by a network in the sense of $E_{x \sim \mu}(f(\mathbf{x})-\tilde{g}(\mathbf{x}))^{2}$.

Proposition 1 in [15] has demonstrated that $\tilde{g}$ cannot be well approximated by a single-hidden-layer conventional network with a polynomial number of neurons. We put his proposition here as Lemma 1 for readability and coherence of our paper.

Lemma 1: For a fixed dimension $d$, suppose that $d>C$, $\alpha>C$ and $N \geq C \alpha^{1.5} d^{2}$, and $k$ an integer satisfying $k \leq$ $c e^{c d}$ with universal constants $c, C>0$, there exists a function $\tilde{g}(\boldsymbol{x})=\sum_{i=1}^{N} \epsilon_{i} g_{i}(\boldsymbol{x})$, where $\epsilon_{i} \in\{-1,1\}, i=1,2, \ldots, N$ such that for any function of the form: $f_{1}(\boldsymbol{x})=\sum_{l=1}^{k} t^{l} \sigma_{l}\left(\boldsymbol{w}^{l} \boldsymbol{x}+b^{l}\right)$ with $\left|\sigma_{l}(x)\right| \leq K\left(1+|x|^{\kappa}\right)$ for some $K$, $\kappa$, we have

$$
\left\|f_{1}-\tilde{g}\right\|_{L_{2}(\mu)} \geq \delta / \alpha
$$

where $\delta$ is a universal constant.
To illustrate $\tilde{g}$ is approximatable with a quadratic network, we know from Lemma 12 of [15] that a continuous Lipschitz function $g$ can approximate $\tilde{g}$, what is remained for us to do is to use a quadratic network with a polynomial
number of neurons to approximate $g$.

Lemma 2: Given a proper activation function $\sigma$, there is a constant $c_{\sigma} \geq 1$ (depending on $\sigma$ and other parameters) such that for any L-Lipschitz function $f: \boldsymbol{R} \rightarrow \boldsymbol{R}$, which is constant outside a bounded interval $[r, R]$, and any $\delta$, there exist scalars $a,\left\{\alpha_{i}, \beta_{i}, \gamma_{i}\right\}, i=1, \ldots, w, w \leq c_{\sigma} \frac{(R-r) L}{\delta}$ with which we have

$$
h(\mathbf{x})=a+\sum_{i=1}^{w} \alpha_{i} \sigma\left(\beta_{i}\|\mathbf{x}\|^{2}-\gamma_{i}\right)
$$

satisfies

$$
\sup _{x \in \mathbf{R}}|f(\|\mathbf{x}\|)-h(\mathbf{x})|<\delta
$$

Proof: Without loss of generality, we assume that the nonlinear activation function is ReLU: $\sigma(z)=\max \{0, z\}$. However, our proof is also applicable to other nonlinear activation functions.

If $(R-r) L<\delta$, then $h(\mathbf{x})$ can be trivially constructed by setting it to be a 0 function. Otherwise, we have $R-r \geq \delta / L$, We assume that there is an integer $m$ satisfying $m \delta / L<R-r \leq(m+1) \delta / L$, dividing $[r, R]$ into $(m+1)$ intervals $[r, r+\delta / L],[\delta / L, 2 \delta / L], \ldots,[i \delta / L,(i+$ 1) $\delta / L], \ldots,[r+m \delta / L, R]$. We set $\beta_{i}=1, \gamma_{i}=(r+i \delta / L)^{2}, i=$ $0, . . m, \gamma_{m+1}=R^{2}, a=h(r)$, and

$$
\alpha_{i}=\left(f\left(\sqrt{\gamma_{i+1}}\right)-f\left(\sqrt{\gamma_{i}}\right)\right) /\left(\gamma_{i+1}-\gamma_{i}\right)
$$

Then, by such construction, the lemma holds. Here, the number of the used neurons is $w$, which is no more than $\left[\frac{(R-r) L}{\delta}\right]+1=c_{\sigma} \frac{(R-r) L}{\delta}$, where $[\cdot]$ is the floor function.

As we know, Eq.(1) represents a quadratic network with a single hidden layer. Lemma 2 confirms that a Lipschitz radial function $f$ can be well expressed by such a singlehidden layer network.

Lemma 3: There are a universal constant $C>0$ and $\delta \in(0,1)$, for $d \geq C$ and any choice of $\epsilon_{i} \in\{-1,1\}, i=1,2, \ldots, N$, there exists a function $f_{2}$ expresssed by a single-hidden-layer quadratic network of a width of at most $c_{\sigma} \frac{N \alpha \sqrt{d}}{\delta}$ and with the range $[-2,+2]$ such that

$$
\left\|f_{2}-\tilde{g}\right\|_{L_{2}(\mu)} \leq \frac{\sqrt{3}}{\alpha d^{\frac{1}{4}}}+\delta
$$

Proof: In Lemma 2, we make the following substitions: $R=2 \alpha \sqrt{d}, r=\alpha \sqrt{d}, L=N, h=g$. Thus, $g(\|\mathbf{x}\|)$ is expressible by the a single-hidden-layer quadratic network with at most $c_{\sigma} \frac{N \alpha \sqrt{d}}{\delta}$ neurons. Coupled with Lemma 12 of [15], Lemma 3 is immediately obtained.

Proof of Theorem 1: By the combination of Lemmas 1 and 3, the proof for Theorem 1 is straightforward. In Lemma 1, by choosing $\alpha=C, N=C \alpha^{1.5} d^{2}$, we have

$$
\left\|f_{1}-\tilde{g}\right\|_{L_{2}(\mu)} \geq \delta_{1}
$$

Fig. 1. Classification of two concentric rings with conventional and quadratic networks. To succeed in the classification, a conventional network requires at least 6 neurons (Left), and a quadratic network only taks one neuron.

Let $\delta \leq \frac{\delta_{1}}{2}-\frac{\sqrt{3}}{C d^{\frac{1}{4}}}$, to approximate $\tilde{g}$ we need the number of quadratic neurons being at most

$$
c_{\sigma} \frac{N \alpha \sqrt{d}}{\delta}=c_{\sigma} \frac{C^{3.5} d^{2.5}}{\delta} \leq C^{\prime} c_{\sigma} d^{2.5}
$$

such that

$$
\left\|f_{2}-\tilde{g}\right\|_{L_{2}(\mu)} \leq \frac{\sqrt{3}}{C d^{\frac{1}{4}}}+\delta \leq \frac{\delta_{1}}{2}
$$

Therefore, we have $\left\|f_{1}-f_{2}\right\|_{L_{2}(\mu)} \geq \frac{\delta_{1}}{2}$. The proof is completed.

Classification Example: To demonstrate the exponential difference between the conventional and quadratic networks claimed by Theorem 1, we constructed an example for separation of two concentric rings. In this example, there are 60 instances in each of the two rings representing two classes. With only one quadratic neuron in a single hidden layer, the rings were totally separated, while at least six conventional neurons are required to complete the same task, as shown in Fig. 1.

## B. Theorem 2

Key Idea for Proving Theorem 2: It was proved in [16] that an $n$-input function that is not constant along any direction cannot be well approximated by a conventional network with no more than $n-1$ neurons in each layer. However, when such a function is radially defined, it becomes feasible to approximate the function by a quadratic network with width=4, which breaks the lower width bound $n-4$ claimed in [16].

To compute a radial function, we need to find the norm and then evaluate the function at the norm. With a quadratic neuron, the norm is natrually found. With respect to the norm, the radial function is intrinsically univariate. Therefore, heuristically speaking, a quadratic network with no more than $n-1$ neurons in each layer could approximate a radial function very well, even if the function is not constant along any direction.

The trick of approximation by a deep conventional network is adopted here to study a deep quadratic network, in
the same spirit to approach a function via composition layer by layer. Specifically, we use one quadratic neuron for the squared norm of an input vector, and a neuron to form a truncated-parabola function as a building block of the radial function. In every interval, a truncated-parabola function can approximate a piecewise constant function in the $L_{1}$ sense. Also, two neurons are needed to store the truncated-parabola function by the pair of neurons. We encapsulate these four neurons in total three layer as a module. By connecting these modules properly, we can express a piecewise trapezoid-like function and approximate any univariate function accurately.

Assume that the the input variable is $\mathbf{x}$, an interval is $\|\mathbf{x}\| \in\left[a_{i}, a_{i+1}\right]$, the network utilizes the ReLU function as the activation function, and $t=\|\mathbf{x}\|$, we use $R_{i, j}$ to represent the output of the $j$-th neuron in the $i$-th layer (we ignore the neuron that computes the square of norm.), then we have

$$
\begin{gathered}
1^{\text {st }} \text { layer }:\left\{\begin{array}{l}
R_{i, 1}=\frac{b_{i}}{C_{i}}\left(t^{2}-a_{i}^{2}\right)\left(a_{i+1}^{2}-t^{2}\right)^{+} \\
R_{i, 2}=K^{+} \\
R_{i, 3}=K^{-}
\end{array}\right. \\
2^{\text {nd }} \text { layer }:\left\{\begin{array}{l}
R_{i+1,1}=\left(b_{i}-\frac{b_{i}}{C_{i}}\left(t^{2}-a_{i}^{2}\right)\left(a_{i+1}^{2}-t^{2}\right)^{+}\right)^{+} \\
R_{i+1,2}=K^{+} \\
R_{i+1,3}=K^{-}
\end{array}\right.
\end{gathered}
$$

$$
3^{\text {rd }} \text { layer }:\left\{\begin{array}{l}
R_{i+2,1}=\left(b_{i}-\left(b_{i}-\frac{b_{i}}{C_{i}}\left(t^{2}-a_{i}^{2}\right)\left(a_{i+1}^{2}-t^{2}\right)^{+}\right)^{+}\right) \\
R_{i+2,2}=K^{+} \\
R_{i+2,3}=K^{-}
\end{array}\right.
$$

where $C_{i}=\left[\left(a_{i}+\delta\left(a_{i+1}-a_{i}\right)\right)^{2}-a_{i}^{2}\right]\left[a_{i+1}^{2}-\left(a_{i}+\right.\right.$ $\left.\left.\delta\left(a_{i+1}-a_{i}\right)\right)^{2}\right],(\cdot)^{+}$signifies the ReLU function, $R_{i+2,1}=$ $L_{i}$ is the expected output for the interval $\|\mathbf{x}\| \in\left[a_{i}, a_{i+1}\right]$, $K^{+}=\sum_{b_{i}>0} L_{i}$ and $K^{-}=\sum_{b_{i}<0} L_{i}$ As shown in Fig. 2, the output $\bar{R}_{i+2,1}$ is a truncated-parabola piecewise function. Also,

$$
R_{i+2,1}=\left\{\begin{array}{l}
\frac{b_{i}}{C_{i}}\left(t^{2}-a_{i}^{2}\right)\left(a_{i+1}^{2}-t^{2}\right)  \tag{4}\\
t \in\left[a_{i}, a_{i}+\delta\left(a_{i+1}-a_{i}\right)\right] \\
b_{i} \\
t \in\left[a_{i}+\delta\left(a_{i+1}-a_{i}\right), \sqrt{a_{i+1}^{2}+a_{i}^{2}-\left(a_{i}+\delta\left(a_{i+}\right.\right.}\right. \\
\frac{b_{i}}{C_{i}}\left(t^{2}-a_{i}^{2}\right)\left(a_{i+1}^{2}-t^{2}\right) \\
t \in\left[\sqrt{a_{i+1}^{2}+a_{i}^{2}-\left(a_{i}+\delta\left(a_{i+1}-a_{i}\right)\right)^{2}}, a_{i+1}\right]
\end{array}\right.
$$

where we have:

$$
a_{i+1}-\sqrt{a_{i+1}^{2}+a_{i}^{2}-\left(a_{i}+\delta\left(a_{i+1}-a_{i}\right)\right)^{2}}<\delta\left(a_{i+1}-a_{i}\right)
$$

In this way, each module will correspond to a truncatedparabola function over a unique interval. By decreasing $\delta$, our truncated-parabola function would approximate the target piecewise constant function with increasing accuracy. Since piecewise constant functions can approximate any Lesbegueintegrable function in the $L_{1}$ sense, a deep quadratic network with four neurons in each layer can express any Lesbegueintegrable radial function. Our final network structure is shown

Fig. 2. Four layer netwotk with ReLU activation for modeling a truncatedparabola function, which can be used to approximate a piecewise constant function over any interval.
in Fig. 3. A blue rectangle is a neuron, and a red rectangle forms a layer. Depending on the interval width, our network can be very deep.

In the following, we will prove Theorem 2 formally. In the proof, the closeness between two functions is measured in the $L_{1}$ sense, and for convenience we partially adopted the notations used in [16].

Notations: For a Lesbegue-integrable radial function $f(\|\mathbf{x}\|)$, suppose that $\|\mathbf{x}\|$ is supported on $\left[R_{1}, R_{2}\right]$, we define:

$$
f^{+}(t)= \begin{cases}\max \{f(t), 0\} & t \in\left[R_{1}, R_{2}\right] \\ 0 & t \notin\left[R_{1}, R_{2}\right]\end{cases}
$$

$$
f^{-}(t)= \begin{cases}\max \{-f(t), 0\} & t \in\left[R_{1}, R_{2}\right] \\ 0 & t \notin\left[R_{1}, R_{2}\right]\end{cases}
$$

$$
\left.\left.\imath_{i+1}-a_{i}\right)\right)^{2} S^{+}=\left\{(\mathbf{x}, y),\|\mathbf{x}\| \in E, 0<y<f^{+}(\|\mathbf{x}\|)\right\}
$$

$$
S^{-}=\left\{(\mathbf{x}, y),\|\mathbf{x}\| \in E, 0<y<f^{-}(\|\mathbf{x}\|)\right\}
$$

Because $f(t)$ is Lesbegue integrable, $S^{+}$and $S^{-}$are measurable. Then, there exits a series of cylindrical tubes $J_{+, i}, J_{-, i}$ having the property:

$$
\begin{equation*}
m\left(S^{ \pm} \triangle \bigcup_{i} J_{ \pm, i}\right)<\frac{\epsilon}{4} \tag{5}
\end{equation*}
$$

where $m(\cdot)$ is the Lesbegue measure. For cylindrical tubes $J_{ \pm, i}$, we assume $J_{ \pm, i}=X_{ \pm, j} \times\left[0, b_{i}^{ \pm}\right]$, where $X_{ \pm, i}=\left\{\mathbf{x} \mid a_{i}<\|\mathbf{x}\|<a_{i+1}\right\}$, and $b_{i}^{ \pm} \geq 0$ is the corresponding height of a cylindrical tube. Then, we define the corresponding indicator function as $\phi_{ \pm, i}=\mathbf{1}\left\{\mathbf{x} \in X_{ \pm, i}\right\}$, and we have the following lemma.

Fig. 3. Quadratic network with three neurons in one layer to approximate a component radial function.

Lemma 4: For any $f(\|\boldsymbol{x}\|)$ and $\epsilon$, the weighted sum of the indicator functions, which represent the cylindrical tubes, satisfies:
$\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}\left|f(\|\mathbf{x}\|)-\left(\sum_{i} b_{i}^{+} \phi_{+, i}-\sum_{i} b_{i}^{-} \phi_{-, i}\right)\right| d \mathbf{x} \leq \frac{\epsilon}{2}$.
Proof: Lemma 4 is evident by Eq. (5).
By stacking the modules gradually, we reconstruct the target function over more and more intervals until the approximation is complete. As we discussed, the function generated by our composite three layer modules is positive. If the correspoding cylindrical tube is positive, then it can be used to approximate $b_{i}^{+} \phi_{+, i}$ directly. If the correspoding cylindrical tube is negative, we need to substract the output of the module when its output is transmitted into the next layer. The network will eventually produce a function with many trapezoid-like pieces. We denote such a function is $F(\mathbf{x}), F^{+}(\|\mathbf{x}\|)$ and $F^{-}(\|\mathbf{x}\|)$ are the positive and negative parts of $F(\mathbf{x})$, which are actually $K^{+}$and $K^{-}$. Then, we have

$$
\begin{aligned}
& \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{+}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{+} \phi_{+, i}\right| d \mathbf{x} \\
& +\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{-}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{-} \phi_{-, i}\right| d \mathbf{x} \\
& \leq(2 \delta) \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}\left(\sum_{i} b_{i}^{+} \phi_{+, i}+\sum_{i} b_{i}^{-} \phi_{-, i}\right) d \mathbf{x} .
\end{aligned}
$$

Because $f(\mathbf{x})$ is Lebegue-integrable, its cover $\sum_{i} b_{i}^{ \pm} \phi_{ \pm, i}$ is Lebegue integrable as well. Therefore, $\sum_{i} b_{i}^{ \pm} \phi_{ \pm, i}<\infty$. Let us denote $\sum_{i} b_{i}^{+} \phi_{+, i}+\sum_{i} b_{i}^{-} \phi_{-, i}=C$ and $\delta=\frac{\epsilon}{4 C}$, we can approximate $\sum_{i} b_{i}^{ \pm} \phi_{ \pm, i}$ by our quadratic network up to a given accuracy $\epsilon$.

$$
\begin{aligned}
& \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{+}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{+} \phi_{+, i}\right| d \mathbf{x} \\
& +\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{-}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{-} \phi_{-, i}\right| d \mathbf{x} \\
& \leq \frac{\epsilon}{2}
\end{aligned}
$$

## Lemma 5:

$$
\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}| | F(\|\mathbf{x}\|)\left|-\left(\sum_{i} b_{i}^{+} \phi_{-, i}-\sum_{i} b_{i}^{-} \phi_{-, i}\right)\right| d \mathbf{x} \leq \frac{\epsilon}{2}
$$

Proof: Because of Eq. (6), we apply the triangle inequality:

$$
\begin{aligned}
& \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F(\|\mathbf{x}\|)\left|-\left(\sum_{i} b_{i}^{+} \phi_{-, i}-\sum_{i} b_{i}^{-} \phi_{-, i}\right)\right| d \mathbf{x} \\
& \leq \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{+}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{+} \phi_{+, i}\right| d \mathbf{x} \\
& +\int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]} \| F^{-}(\|\mathbf{x}\|)\left|-\sum_{i} b_{i}^{-} \phi_{-, i}\right| d \mathbf{x} \\
& \leq \frac{\epsilon}{2}
\end{aligned}
$$

Proof of Theorem 2: For any radial function $f(\|\mathbf{x}\|)$ whose support is bounded and any given closeness $\epsilon$, there is a network with no more than four neurons in each layer of the quadratic network as shown in Fig. 3. Applying the triangle inequality again, with Lemmas 4 and 5, the function represented by the quadratic network satisfies:

$$
\begin{aligned}
& \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}|f(\|\mathbf{x}\|)-F(\mathbf{x})| d \mathbf{x} \\
& \leq \int_{\|\mathbf{x}\| \in\left[R_{1}, R_{2}\right]}\left|f(\|\mathbf{x}\|)-\left(\sum_{i} b_{i}^{+} \phi_{-, i}-\sum_{i} b_{i}^{-} \phi_{-, i}\right)\right| d \mathbf{x} \\
& +\left|F(\|\mathbf{x}\|)-\sum_{i} b_{i}^{+} \phi_{-, i}-\sum_{i} b_{i}^{-} \phi_{-, i}\right| d \mathbf{x} \\
& \leq \frac{\epsilon}{2}+\frac{\epsilon}{2}=\epsilon
\end{aligned}
$$

Analytic Example: The function to approximate is $f(\|\mathbf{x}\|)=\cos \left(\frac{3 \pi}{200}\|\mathbf{x}\|^{2}+\frac{\pi}{2}\right)$, where $\mathbf{x}$ is supported on $\|\mathbf{x}\| \in[0,10 \sqrt{(2)}]$, as shown in Fig. 4(left). We approximate $f(\|\mathbf{x}\|)$ by stacking three modules with 9 layers in total, as shown in Fig. 4(right). The resultant function $F(\|\mathbf{x}\|)$ is:

$$
\begin{aligned}
& F(\|\mathbf{x}\|)=-\left(1-\left(1-\left(\frac{1}{597.3}^{2}\|\mathbf{x}\|^{2}\left(\frac{200}{3}-\|\mathbf{x}\|^{2}\right)\right)^{+}\right)^{+}\right)^{+} \\
& \quad+\left(1-\left(1-\left(\frac{1}{1022.5 .3}\left(\|\mathbf{x}\|^{2}-\frac{200}{3}\right)\left(\frac{400}{3}-\|\mathbf{x}\|^{2}\right)\right)^{+}\right)^{+}\right)^{+} \\
& \quad-\left(1-\left(1-\left(\frac{1}{1042.5 .3}\left(\|\mathbf{x}\|^{2}-\frac{400}{3}\right)\left(200-\|\mathbf{x}\|^{2}\right)\right)^{+}\right)^{+}\right)^{+}
\end{aligned}
$$

which divides $[0,10 \sqrt{(2)}]$ into three pieces $\left[0, \sqrt{\frac{200}{3}}\right],\left[\sqrt{\frac{200}{3}}, \sqrt{\frac{400}{3}}\right],\left[\sqrt{\frac{400}{3}}, 10 \sqrt{2}\right]$, and $b_{1}=b_{2}=$ $b_{3}=1$. If the support of $f(\|\mathbf{x}\|)$ is divided into more intervals, the closeness of $f(\|\mathbf{x}\|)$ and $F(\|\mathbf{x}\|)$ will be further improved.

## C. Theorem 3

Key Idea for Proving Theorem 3: For universal approximation by neural networks, all the current strategies are based on piecewise approximation in terms of $L_{1}, L_{\infty}$, or other distances. For such piecewise approximation, the functional space is divided into numerous hypercubes, which

Fig. 4. By stacking three modules, the network (right) approximates a predefined radial function.
are intervals in the one-dimensional case, according to a specified accuracy to approximate a target function in every hypercube. With quadratic neurons, we can instead use a global approximating method, which can be much more efficient. At the sam time, the quadratic network structure is neither too wide nor too deep, which can be regarded as a size-bounded universal approximator, in contrast to [14][16]. In [14], a single-layer network may have an infinite width. On the other hand, in [16] the network width is restricted to be no more that $d+4$ but network depth goes infinity.

Let us denote a general $N$-input polynomial consisting of $M$ terms as $P\left(x_{1}, . ., x_{i}, \ldots, x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, which degrees of input variables $x_{1}, x_{2}, x_{i} \ldots, x_{N}$ being $\max _{k}\left\{n_{1}(k)\right\}, . ., \max _{k}\left\{n_{N}(k)\right\}$ respectively. We claim that $P\left(x_{1}, x_{2}, . ., x_{i}, \ldots x_{N}\right)$ can be exactly expressed by a quadratic network with the width of $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and the depth of $\max _{k}\left\{n_{j}(k)\right\}+N$. Because any continous function can be well approximated by a polynomial, our quadratic network is thus qualified as a novel universal approximator. Since every term of the polynomial globally works over the whole input space, the expression made by a quadratic network is in a global sense. Furthermore, the width and depth of such a network-based universal approximator are respectively on orders of of $M$ and $N$ respectively, which do not go infinity. We underline that the quadratic network as a universal approximator enjoys its size-boundedness, which means a great potential of parameter sparsity and performance robustness [29]. In the rest of this section, we assume that ReLU is employed in quadratic networks without loss of generality. First, let us use one-dimensional case to illustrate the essential arguements for Theorem 3. Then, we extend the results to the general case.

Warming-up: One-dimensional case: We denote a general univariate polynomial of degree $N$ as $P_{N}(x)=\sum_{k=1}^{N} c_{k} x^{k}+c$. When ReLU is used, two ReLU neurons can be combined in parallel as the identical operation: $g(x)=\operatorname{Re} L U(g(x))-\operatorname{Re} L U(-g(x))$. We take such a pair of neurons as a unit and assume that $O_{i, j}$ is the output of the $j$-th unit in the $i$-th layer. In our following construction, there are $i$ units in the $i-$ th layer. We can show that $P_{N}(x)$ can be expressed by a quadratic network with

Fig. 5. Size-bounded qraquatic network compuates any univariate polynomial function.
depth of $N+1$ and width of no more than $2 N$. Specifically, we construct

$$
\begin{aligned}
& O_{1,1}=x \\
& O_{2,1}=x(x+1)=x^{2}+x, \quad O_{2,2}=x \\
& O_{3,1}=x\left(x^{2}+x+1\right)=x^{3}+x^{2}+x, O_{3,2}=x^{2}+x, O_{3,3}=x
\end{aligned}
$$

:

$$
O_{k, 1}=\sum_{p=1}^{k} x^{p}, O_{k, 2}=O_{k-1,1}, \cdots, O_{k, k}=O_{k-1, k-1}
$$

$$
O_{k+1,1}=x\left(O_{k, 1}+1\right), O_{k+1,2}=O_{k, 1}, \cdots, O_{k+1, k+1}=O_{k, k}
$$

$$
O_{N, 1}=\sum_{p=1}^{N} x^{p}, O_{N, 2}=\sum_{p=1}^{N-1} x^{p}, \cdots, O_{N, j}=\sum_{p=1}^{N-j+1} x^{p}, \cdots
$$

The quadratic network defined by the above equations is diagrammed in Fig. 5, which is neither too wide nor too deep and can perfectly express any univariate polynomial function. As shown in Fig. 5, only the output of the first unit in each layer is new that is generated by updating equation $O_{k+1,1}=$ $x\left(O_{k, 1}+1\right)$. In contrast, outputs of other units remain the same as the output in the previous layer. In the $N$-th layer, we compute the sum of different terms. With $O_{N, j}, j=1,2 \ldots N$, it is easy to express any term in a polynomial of degree $N$. For $P_{N}(x)=\sum_{k=1}^{N} c_{k} x^{k}+c$, in the $(N+1)$-th layer (output layer), we perform the following calculation to make the network produce $P_{N}(x)$ :

$$
P_{N}(x)=\sum_{k=1}^{N} c_{k}\left(O_{N, N+1-k}-O_{N, N-k}\right)+c
$$

Lemma 6: Any univariate polynomial of degree $N$ can be perfectly computed by a quadratic network with depth of $N+1$ and width of no more than $2 N$.

Proof: It is evident from the above construction process.
The following lemma shows that any univariate function $f(x)$ continuous in $[0,1]$ can be approximated with a Bernstein polynomial up to any accuracy, which is the Bernstein version
of the proof for the Weierstrass theorem.
Lemma 7: Let $f(x)$ is a continuous function over $[0,1]$, we have

$$
\lim _{n \rightarrow+\infty} B_{n}(x)=f(x)
$$

Proof: It is well known; please refer to Chapter [30].

Corollary 1: Any continuous univariate function supported on $[0,1]$ can be approximated by a quadratic network up to any accuracy.

Extension: High-dimension Case: The general form of a multivariate polynomial can be expressed as: $P\left(x_{1}, . ., x_{i}, \ldots x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$. Each term $\prod_{j=1}^{N} x_{j}^{n_{j}(k)}$ is a product of every variable up to its power $x_{j}^{n_{j}(k)}$. Thus, a natural strategy of approximating a multivariate polynomial is to construct a network shown in Fig. 5 for every possible factor $x_{j}, x_{j}^{2}, \ldots, x_{j}^{\max _{k}\left\{n_{j}(k)\right\}}$. As shown in Fig. 6, every yellow module contains all the factors of the corresponding variable. The width is bounded by $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}$ while the depth by $\max _{k}\left\{n_{j}(k)\right\}$. Because our quadratic unit can compute the product of two inputs by setting the irrelevant parameters to zero, we can use $N$ layers in total, due to $N$ inputs and $2 M$ neurons in each layer, to construct every term in $P\left(x_{1}, x_{2}, \ldots, x_{i}, \ldots x_{N}\right)$. In the case of computing a component $\prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, since one quadratic unit computes the product of two elements in $\prod_{j=1}^{N} x_{j}^{n_{j}(k)}$ at a time, by repeatly invoking neurons $N-1$ times the final unit will output $\prod_{j=1}^{N} x_{j}^{n_{j}(k)}$. If there are $M$ terms, we need $M$ additional units ( $2 M$ neurons) in every layer. In addition, we need $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right.$ neurons to keep the power terms generated by the yellow modules in Fig. 6. Consequently, to express $P\left(x_{1}, . ., x_{i}, \ldots x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, we can always construct a quadratic network with width of $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and depth of $\max _{k}\left\{n_{j}(k)\right\}+N$.

Proof of Theorem 3: By integrating the above arguments, we claim that for a general multivariate polynomial $P\left(x_{1}, \ldots, x_{i}, \ldots x_{N}\right)=\sum_{k=1}^{M} \prod_{j=1}^{N} x_{j}^{n_{j}(k)}$, there must be a quadratic network with width of $\sum_{j}^{N} 2 \max _{k}\left\{n_{j}(k)\right\}+2 M$ and depth of $\max _{k}\left\{n_{j}(k)\right\}+N$ that can express $P\left(x_{1}, . ., x_{i}, \ldots x_{N}\right)$ exactly.

Corollary 2: Any continuous multivariate function whose variates are supported on $[0,1]^{N}$ can be well approximated by a quadratic network of finite size.

## IV. DISCUSSIONS AND CONCLUSION

Recently, major efforts have been made to develop and understand deep neural network for not only high accuracy but also great robustness. To achieve this goal, many techniques [31-36] have been developed based on structure diversity, distilled knowledge, randomizaiton, pruning/dropout, lowrank approximation, and so on. Some of these methods are

Fig. 6. Quadratic network of finite size to approximate any multivariate polynomial.
dedicated to compress an established network model without compromising its performace significantly. Encouraged by our Theorems 1, which shows an exponential advantage of the quadratic network over the conventional counterpart in terms of the network complexity, we believe that there are important tasks particularly suitable for use of quadratic networks, leading to a significantly more compact architecture for comparable or better accuracy and robustness than the conventional network. Therefore, quadratic networks could be used in the setting with memory restriction, for example, in mobile applications or other embedded systems.

Representing multivariable functions in desirable ways is pivotal in applications of deep learning, including unsupervised, semi-supervised, and supervised learning [37]. From this point of view, we need to consider expressibility and complexity when evaluating the quality of a neural network [38]. Expressibility means how rich a family of functions is that can be expressed by the neural network. Complexity means the number of consumed neurons, which should be, in a good sense, as small as possible. Theorem 1 has shown that the complexity of the quadratic network is intrinsically lower than that of the conventional network in representing radial functions. Regarding "Expressibility", quadratic networks actually provide a new paradigm, as suggested by Theorem 2. Given a $n$-input function that is not constant along any direction, the conventional network with width less than $n-1$ fails to do good approximation in terms of the $L_{1}$ distance. We do not consider the failure surprising since such a $n$-input function is by definition on a $n$-dimensional manifold, and compressing it with less than $n$ neurons is subjec to the dimensionality curse (in the opposite sense of the conventional meaning). In contrast, a quadratic network can only use four neurons per layer to approximate any multivariate radial function, which breaks the limit associated with the conventional network.

Most importantly, our Theorem 3 shows that quadratic
networks standout in both expressibility and efficiency. By calculating a quadratic function of input variables, quadratic neurons create second-order terms naturally. Second-order terms serve as nonlinear building blocks that are different from nonlinearity generated with nonlinear activation. By combining quadratic neurons, the quadratic network can compute any polynominal exactly. Accurately forming every term of a polynomial allows global computation and high efficiency relative to the popular piecewise methods. In our quadratic network construction, both the depth and width are limited, while all previous universal approximators can be either too wide or too deep to achive a high approximation accuracy. This fact suggests that quadratic networks could potentially minimize the number of neurons and free parameters for superior machine learning. It is surprising that although every quadratic neuron possesses the number paramters three times as many as that of a conventional neuron, quadratic networks can use less parameters than the conventional counterparts, at least in some important cases such as radial functions.

As we know, deep learning generalizes well in many applications. Some researchers questioned that quadratic networks may lead to overfitting because the added neural complexity may not be necessary. With our above proved theorems, we refute that since quadratic networks de facto are more compact and more effective than the conventional counterpart in major circumstances, quadratic networks could improve the generalization ability, according to Occam's razor principle. Since general features are either quardratic or can be expressed as combinations or compositions of quadratic features, quadratic deep networks will be universal, instead of being restricted to the circumstances where only quadratic features are relevant.

In Appendix A, another method is used to show that the quadratic network is a universal approximator. According to Algebraic Fundamental Theorem, every univariate function can be facterized into a product of elementary factors of first order or second-order in the real number field. Quadratic networks are ideal for such factorization, which helps optimize the efficiency of the network representation.

In conclusion, we have analyzed the approximatation ability of the quadratic networks and proved three theorems, suggesting a great potential of squadratic networks in terms of expressibility and efficiency. Future research will be focused on evaluating the performance of deep quadratic networks in typical applications.

## Appendix A <br> Another Proof of Theorem 3

There is another path to prove that the quadratic network is a universal approximator, which reveals the uniqueness of quadratic networks. First, we show any univariate polynomial of degree N can be ecactly expresssed by a quadratic netwok with a complexity of $O\left(\log _{2}(N)\right)$ in depth. Next we refer

Fig. 7. Quadratic network approximating a univariate polynomial according to the Algebraic Fundamental Theorem.
the result [39] regarding Hilbert's thirteen problem that multivariate functions can be represented with a group of separable functions, and then finalize the proof.

Lemma 8: Any univariate polynomial of degree $N$ can be perfectly computed by a quadratic network with depth of $O\left(\log _{2}(N)\right)$ and width of no more than $N$.

Proof: According to Algeraic Fundamental Theorem [40], a general univariate polynomial of degree $N$ can be expressed as $P_{N}(x)=C \prod_{i}^{l_{1}}\left(x-x_{i}\right) \prod_{j}^{l_{2}}\left(x^{2}+a_{j} x+b_{j}\right)$, where $l_{1}+2 l_{2}=N$. Similarly, we set $O_{i, j}$ as the output of the $j$-th unit in the $i$-th layer. The network we construct is shown in Fig. 7. Every neuron in the first layer computes $\left(x-x_{i}\right),\left(x-x_{i}\right)\left(x-x_{i+1}\right)$ or $x^{2}+a_{i} x+b_{i}$, then the second layer merely use as half the number of neurons as that of the first layer to combine the outputs of the first layer. By repeating such a process, with the depth of $O\left(\log _{2}(N)\right)$ the quadratic network can exactly represent $P_{N}(x)$.

Lemma 9: Every continuous n-variable function on $[0,1]^{2}$ can be represented in the form:

$$
f\left(x_{1}, \ldots, x_{n}\right)=\sum_{i=1}^{2 n+1} g_{i}\left(\sum_{j=1}^{n} h_{i j}\left(x_{j}\right)\right)
$$

Proof: This is a classical theorem made by Kolmogorov and his student Arnold. Please refer to [39].

Corollary 3: The quadratic network is a universal approximator.

Proof: Refering to Lemmas 7, 8 and 9, it can be shown that the quadratic network is a universal approximator. Specifically, assuming that $h_{i, j}$ is a polynomial of degree $N_{i j}^{h}$, and $g_{i}$ is a polynomial of degree $N_{i}^{g}$, the size of a quadratic network can be estimated to approximate $f\left(x_{1}, \ldots, x_{n}\right)$ well. The representation of $\sum_{j=1}^{n} h_{i j}$ requires a network with a width of $\sum_{j}^{n} N_{i j}^{h}$ and a depth of $\max _{j}\left\{\log _{2} N_{i j}^{h}\right\}$. Then, the representation of $g_{i}$ demands an additional configuration with a width of $N_{i}^{g}$ and a depth of $\log _{2} N_{i}^{g}$. Therefore, the structure used for $g_{i}\left(\sum_{j=1}^{n} h_{i j}\left(x_{j}\right)\right)$ is of width $\max \left\{\sum_{j}^{n} N_{i j}^{h}, N_{i}^{g}\right\}$ and depth
$\max _{j}\left\{\log _{2} N_{i j}^{h}\right\}+\log _{2} N_{i}^{g}$. Integrating all $g_{i}\left(\sum_{j=1}^{n} h_{i j}\left(x_{j}\right)\right)$ terms in parallel, the final quadratic network architecture will be of at most width $\sum_{i=1}^{2 n+1} \max \left\{\sum_{j}^{n} N_{i j}^{h}, N_{i}^{g}\right\}$ and depth $\max _{i}\left\{\max _{j}\left\{\log _{2} N_{i j}^{h}\right\}+\log _{2} N_{i}^{g}\right\}$.

Also, aided by the concept of partially separable functions, the complexity of the quadratic network can be further reduced, such as in the case of computing an $L^{t h}$ separable function. By the $L^{t h}$ separable function, we mean that $f\left(x_{1}, \ldots, x_{n}\right)$ is $L^{t h}$ separable defined as follows:

$$
f\left(x_{1}, \ldots, x_{n}\right)=\sum_{l=1}^{L} \prod_{i}^{n} \phi_{l i}\left(x_{i}\right)
$$

In practice, almost all continuous functions can be represented as $L^{t h}$ separable functions, which are of low ranks at the same time.
