(Dated: June 12, 2019)

The structure of ²²C plays a vital role in the new physics at subshell closure of N = 16 in the neutron-rich region. We study the two-neutron correlations in the ground state of the weakly-bound Borromean nucleus ²²C sitting at the edge of the neutron-drip line and its sensitivity to core-*n* potential. For the present study, we employ a three-body (core + n + n) structure model designed for describing the Borromean system by explicit coupling of unbound continuum states of the subsystem (core + n). We use a density-independent contact-delta interaction to describe the neutron-neutron interaction and its strength is varied to fix the binding energy. Along with the ground-state properties of ²²C, we investigate its electric-dipole and monopole responses, discussing the contribution of various configurations. Our results indicate more configuration mixing as compared to the previous studies in the ground state of ²²C. However, they strongly depend upon the choice of the ²⁰C-*n* potential as well as the binding energy of ²²C, which call for new precise measurements for the low-lying continuum structure of the binary system (²⁰C+*n*) and the mass of ²²C. These measurements will be essential to understand the Borromean three-body system ²²C with more accuracy.

I. INTRODUCTION

Nowadays, the structure of the dripline isotopes can be studied, due to the novel advancements in the highly sophisticated spectrometers to separate out the exotic products of the fragmentation reactions between the stable nuclear beams and the production targets. In the exploration of the isotopes across the neutron dripline, one of the most eye-catching observed phenomena is the neutron halo. A peculiar feature of these halo nuclei is the long tail of their matter density distribution. In mid of 1980s, at Lawrence Berkeley Laboratory, the first two-neutron halo nucleus ¹¹Li was observed [1], which has two correlated neutrons in its halo. This experiment leads to the conclusion, that weak binding of two neutrons is critical to the formation of a halo.

Among halo nuclei, the two-neutron halo consists of three pieces, two neutrons and a core that bind the system since either of the binary subsystem is unbound. Such a three-body quantal system where all three parts must be present for the existence of the system is named "Borromean" [2] after the three interlocking rings on the 15th century coat of arms of the Borromeo family in northern Italy.

²²C (²⁰C + n + n) is the heaviest observed Borromean nucleus with twice as many protons and neutrons as ¹¹Li has, where neither of the binary system ²⁰C-n and n-n are bound. This nucleus has gained much attention since the early 2000s and is an interesting candidate for checking the persistence of N = 16 magicity, which was established for ²⁴O [3]. Notably, for the persistence of N = 16 shell closure in ²²C, the two-neutron valence configuration would have to be dominated by *s*-wave components, optimal for halo formation. The experimental evidences for the *s*-wave dominance in the ground state of ²²C which reflects N = 16 magicity has been observed in the two-neutron removal cross section from ²²C and the resulting ²⁰C fragment momentum distribution [4]. In fact, the estimated (according to the mass evaluation in 2003) and the observed (at GANIL by direct time-of-flight method) 2*n*-separation energy (S_{2n}) is very small : 0.42 ± 0.96 MeV [5] and 0.14 ± 0.46 MeV [6] with large uncertainties.

However, there is scarce experimental information available before 2010 for ²²C beyond its half-life and β -delayed neutron multiplicities [7]. In 2010, the first reaction cross section (σ_R) measurement of ²²C was performed at RIKEN with a liquid hydrogen (¹H) target at incident energy of 40 MeV/nucleon [8]. They observed large σ_R for ²²C is

 1338 ± 274 mb, showing large enhancement with respect to the neighboring lighter carbon isotopes. This results in the huge root-mean-square (rms) matter radius of 22 C, i.e., 5.4 ± 0.9 fm with large uncertainties. In the spirit of attaining high precision, recently the interaction cross section (σ_I) for 22 C was measured at RIKEN with a 12 C target at 235 MeV/nucleon [9]. The obtained precise value of σ_I is 1280 ± 23 mb and the resultant rms matter radius is 3.44 ± 0.08 fm, which is much smaller than the previous measurement [8]. Very recently, this radius puzzle in which two recent interaction cross section measurements using ¹H and ¹²C targets shows quite different radii was discussed [24]. On theoretical side, before the first experimental data [8], the limited theoretical studies for the ground-state structure of 22 C and the reaction cross sections for 22 C had been reported by Refs. [10–12]. These recent experimental measurements [8, 9] have triggered off several theoretical investigations [13–25].

The stability of the three-body $({}^{20}C + n + n)$ system is linked to the continuum spectrum of the two-body $({}^{20}C + n)$ subsystem [26]. Thus, the structural spectroscopy of ${}^{21}C$ plays a vital role in the understanding of ${}^{22}C$. Experimentally, ${}^{21}C$ is poorly known beyond that it is unbound [27]. The poor information over the structure of ${}^{21}C$ has been used to constrain the core + n potential which directly leads to uncertainties in the three-body calculations of ${}^{22}C$ because the choice of this potential (core + n) is linked to the configuration mixing in the ground state of the core + n + n system.

Although several three-body calculations have been reported so far [10, 15, 19, 23, 25] with different sets of coren potentials, most of these calculations showed the s-wave dominance in the ground state of ²²C, with negligible contribution of other higher *l*-wave components [10, 15, 19]. But recently the mixing of the ground state with $d_{3/2}$ has been reported in [23, 25]. Most of these theoretical models explain the ground-state structure fairly well to study dynamics of nuclear reactions but the uncertainties over the choice of core + n potentials have not been discussed well so far.

In this paper, we investigate the sensitivity of choice of a core +n potential with the configuration mixing in the ground state of ²²C, which have not been completely explored. We note that the choice of core +n potentials in our study is different from previous studies [10, 23] with the motivation to discuss the effect of l > 0 resonance on the configuration mixing in the ground state of ²²C and also to explore the role of the l > 0 resonances of the subsystem. For this study, we use a three-body (core +n + n) structure model for the ground and continuum states of the Borromean nuclei [28, 29]. We present the ground-state ($J^{\pi} = 0^{+}$) properties of ²²C and transitions to the continuum ($J^{\pi} = 0^{+}$ and 1^{-}) that might be of help in disentangling the two-neutron correlations in ²²C. We compare our findings with the experimental and the theoretical works that have been done in the recent past on this system.

The paper is organized as follows. Section II briefly describes the formulation of our three-body structure model. In Sec. III we analyze the subsystem ²¹C and fix the four different sets for core + n potential, consistent with available scarce experimental and theoretical predictions. Section IV presents our results for the three-body system, ²⁰C + n + n. In Sec. IV A, we describe our model space for the three-body system. In Sec. IV B, we report our main results of the configuration mixing in the ground state of ²²C with different binding energies along with other ground-state properties. Sections V and VI present the results on electric-dipole and monopole responses of the system, respectively. Finally, conclusions are made in Sec. VII. In Appendix we discuss the issue of convergence of our results with respect to variations in the model parameters.

II. MODEL FORMULATION

Here we employ a three-body (core + n + n) structure model to study the weakly-bound ground and low-lying continuum states of Borromean systems sitting at the edge of neutron dripline [28–31]. We start from the solution of the unbound subsystem (core + n) and the two-particle basis is constructed by explicit coupling of the two singleparticle continuum wave functions. Initially, it was tested for studying the structure of ⁶He and has been successful in explaining the ground-state properties and the electric-dipole and quadrupole responses [28, 29]. To confirm the validity of this approach to a heavier Borromean system is another purpose of this paper.

The three-body wave function for the $core(^{20}C) + n + n$ system is specified by the Hamiltonian

$$H = -\frac{\hbar^2}{2\mu} \sum_{i=1}^2 \nabla_i^2 + \sum_{i=1}^2 V_{\text{core}+n}(\vec{r_i}) + V_{12}(\vec{r_1}, \vec{r_2})$$
(1)

where $\mu = A_c m_N / (A_c + 1)$ is the reduced mass, and m_N and $A_c = 20$ are the nucleon mass and mass number of the core nucleus, respectively. The recoil term is neglected in the present study, as $A_c = 20$ is large enough to ignore it. $V_{\text{core}+n}$ is the core-*n* potential and V_{12} is *n*-*n* potential. The neutron single-particle unbound *s*-, *p*-, *d*- and *f*-wave continuum states of the subsystem (²¹C) are calculated in a simple shell model picture for different continuum energy E_C by using the Dirac delta normalization and are checked with a more refined phase-shift analysis. Each single-particle continuum wave function of ^{21}C is given by

$$\phi_{\ell j m}(\vec{r}, E_C) = R_{\ell j}(r, E_C) [Y_\ell(\Omega) \times \chi_{1/2}]_m^{(j)}.$$
(2)

In the present calculations, we use the mid-point method [33, 34] to discretize the continuum, which consists of taking the scattering state defined as

$$\tilde{\phi}_i(\vec{r}) = \sqrt{\Delta E} \ \phi_{\ell j m}(\vec{r}, \bar{E}_i), \quad E_i > 0 \tag{3}$$

for a discrete set of the scattering energies, where $\bar{E}_i = (E_i + E_{i-1})/2$, with ΔE as a common energy interval or bin width. In the mid-point method, continuum channels are represented by the channel at a midpoint of the bin. The resulting set of wave functions $\phi_{ik}(\vec{r})$ satisfies the following orthogonality condition

$$\int \tilde{\phi}_i(\vec{r}) \tilde{\phi}_k(\vec{r}) d\vec{r} = \Delta E \,\delta_{ik} \delta(\bar{E}_i - \bar{E}_k),\tag{4}$$

that depends on the ΔE . The convergence of the results will be checked with the continuum energy cut E_{cut} and ΔE . These core + n continuum wave functions are used to construct the two-particle ²²C states by proper angular momentum couplings and taking contribution from different configurations. The combined tensor product of these two continuum states is given by

$$\psi_{JM}(\vec{r}_1, \vec{r}_2) = [\phi_{\ell_1 j_1 m_1}(\vec{r}_1, E_{C1}) \times \phi_{\ell_2 j_2 m_2}(\vec{r}_2, E_{C2})]_M^{(J)}.$$
(5)

We use a density-independent (DI) contact-delta pairing interaction for simplicity, and its strength is the parameter which will be fixed to reproduce the ground-state energy. For S = 0 the explicit expression for V_{12} is given by

$$V_{12} = g\delta\left(\vec{r}_1 - \vec{r}_2\right),\tag{6}$$

where g is the actual strength of the pairing interaction, is obtained by scaling the coefficient of the contact-delta pairing, G, with the ΔE [28], i.e.,

$$g = \frac{G}{(\Delta E)^2}.$$
(7)

We ignore the S = 1 pairing for the present study. The full computational procedure of our approach is described in detail in [30, 31]. In order to check the consistency in the configuration mixing of the ground state of ²²C, we have also used a density-dependent (DD) contact-delta pairing interaction [35], given by

$$V_{12} = \delta(\vec{r}_1 - \vec{r}_2) \left(v_0 + \frac{v_\rho}{1 + \exp[(r_1 - R_\rho)/a_\rho]} \right).$$
(8)

The first term in Eq. (8) with v_0 simulates the free *n*-*n* interaction, which is characterized by its strength and the second term in Eq. (8) represents density-dependent part of the interaction. These strengths v_0 and v_{ρ} are also scaled with the ΔE by following Eq. (7).

III. TWO-BODY UNBOUND SUBSYSTEM $(^{20}C + n)$

The scrutiny of the ${}^{20}\text{C} + n$ subsystem (${}^{21}\text{C}$) is imperative in studying ${}^{22}\text{C}$ as a typical nucleus of Borromean family as ${}^{20}\text{C} + n + n$. The interaction of the ${}^{20}\text{C}$ core with the valence neutron (n) plays a crucial role in the binding mechanism of ${}^{22}\text{C}$. The unbound nucleus ${}^{21}\text{C}$ can be described as an inert ${}^{20}\text{C}$ core with an unbound neutron moving in s-, p-, d- or f-wave continuum states in a simple independent-particle shell model picture. The subshell closure of the neutron number 14 is assumed for the core configuration given by $(0s_{1/2})^2(0p_{3/2})^4(0p_{1/2})^2(0d_{5/2})^6$. The seven valence neutron continuum orbits, i.e., $s_{1/2}$, $d_{3/2}$, $f_{7/2}$, $p_{3/2}$, $f_{5/2}$, $p_{1/2}$ and $d_{5/2}$ are considered in the present calculations for ${}^{21}\text{C}$. The primary issue over the choice of a core + n potential is the scarce experimental information about the neutron-core system. The only available experimental study using the single-proton removal reaction from ${}^{22}\text{N}$ at 68 MeV/nucleon reported the limit to the scattering length $|a_0| < 2.8 \text{ fm}$ [27]. In addition, no evidence was found for a low lying state. Due to the low accuracy of the experimental data [27] at low energies, the possibility of resonance states can not be ruled out. The possibility of $d_{3/2}$ resonance has been discussed in [17, 23]. We construct the core + n potential in the view of fixing the available data for the scattering length [27] and the energy of the $d_{3/2}$ resonance in Ref. [23] and references therein. Assuming the ²⁰C core to be inert in the ground state, we take the following core + n potential

$$V_{\text{core}+n} = \left(V_0^l + V_{ls}\vec{l}\cdot\vec{s}\frac{1}{r}\frac{d}{dr}\right)\frac{1}{1+\exp(\frac{r-R_c}{a})},\tag{9}$$

where $R_c = r_0 A_c^{\frac{1}{3}}$ ($A_c = 20$ for ²⁰C) with $r_0 = 1.25$ fm and a = 0.65 fm.

TABLE I: Parameter sets of the core-*n* potential for l = 0, 1, 2, 3 states of a ²⁰C+*n* system. The scattering length a_0 in fm and possible resonances with the resonance energy E_R and the decay width Γ in MeV are also tabulated. The parameters, *a* and r_0 are 0.65 and 1.25 fm for all the four sets. See text for details.

Set	l	V_0^l (MeV)	V_{ls} (MeV)	l_j	a_0	E_R	Γ
1	0	-33.54	0.00	$s_{1/2}$	-2.8		
	1, 2, 3	-43.24	25.63	$d_{3/2}$		1.51	0.38
				$f_{7/2}$		7.42	4.05
2	0	-33.54	0.00	$s_{1/2}$	-2.8		
	1, 2, 3	-45.14	25.63	$d_{3/2}$		0.83	0.09
				$f_{7/2}$		6.67	2.93
3	0	-33.00	0.00	$s_{1/2}$	-47.6		
	2	-47.50	35.00	$d_{3/2}$		0.92	0.09
	1,3	-42.00	35.00	$f_{7/2}$		6.69	3.02
4	0	-33.54	0.00	$s_{1/2}$	-2.8		
	1, 2, 3	-47.80	35.00	$d_{3/2}$		0.80	0.08
				$f_{7/2}$		4.66	1.03

Considering the sensitivity of the core-*n* potential, we examine four different potential sets for the present study listed in Table I. Set 1 of our present work is basically the same as Set B of [10] and the only difference is that, for *s*-wave, V_0 is chosen to keep ²¹C unbound and the corresponding calculated scattering length is -2.8 fm, which is consistent with the available experimental information [27].

In order to include the $d_{3/2}$ resonance at the position predicted in [23], we modify the potential given in [10], i.e., our Set 2, by making the potential deeper for l > 0 waves, we find that the narrow *d*-wave resonance is displaced to lower energy at 0.83 MeV with the decay width of 0.09 MeV. These numbers are consistent with the results presented in [23]. In our strategy, we use the same potential for all other *l*-waves (l > 0). In addition to the $d_{3/2}$ resonance, we find a wider $f_{7/2}$ resonance at relatively lower energy than Set 1, i.e., at 6.67 MeV with the decay width of 2.93 MeV. For Sets 1 and 2, the spin-orbit strength is fixed to $V_{ls} = 25$ MeV, whereas in [23], the spin-orbit strength is fixed to $V_{ls} = 35$ MeV. In order to explore the position and the decay width of the $d_{3/2}$ and $f_{7/2}$ resonances, our analysis includes two more sets with $V_{ls} = 35$ MeV.

Our Set 3 is exactly the same as "set 3" of Ref. [23]. With this potential the scattering length -47.6 fm and the $d_{3/2}$ resonance energy are reproduced. As it can be seen from Set 3 that different depths for different *l*-waves are employed. They used a less deep potential for the *p*- and *f*-waves than for the *d*-wave. Basically, Sets 1 and 3 are introduced to compare the consistency of the configuration mixing in the ground state of ²²C predicted by the other approaches [10, 23] with ours.

With the motivation of using only one-potential depth for l > 0 waves, we modify the potential given in [23], see Set 4 in Table I. With this modified set, we get the $d_{3/2}$ resonance at 0.80 MeV, which is consistent with "set 1" of Ref. [23]. Interestingly, with this set we also find the wider $f_{7/2}$ resonance as with the other Sets of Table I but with this spin-orbit strength it is shifted to the lower energy at 4.66 MeV with the decay width of 1.03 MeV. The very recent work by Shulgina *et al.* [25] deserves a particular mention, as it discussed the sensitivity of the depth of the core-*n* potential and reported the configuration mixing in the ground state of ²²C only with $V_{ls} = 25$ MeV.

IV. THREE-BODY SYSTEM $(^{20}C + n + n)$

A. Model space

As all of these few-body models [10, 19, 23, 25] described the structure of 22 C to a reasonable degree, these approaches normally take as a starting point for calculations with a basis set of bound wave functions which damp at large distances. In our approach, we calculate the full continuum single-particle spectrum of 21 C in a straightforward fashion and use two oscillating continuum wave functions to construct the two-particle states.

The relative motion of the neutron with respect to the core is an unbound $(E_C > 0, k > 0)$, oscillating wave that must approximate a combination of spherical Bessel functions at large distances from the center. In the present study, the continuum single-particle wave functions are calculated, normalized to a Dirac delta in energy, for the *s*-, *p*-, *d*and *f*-wave continuum states of ²¹C on a radial grid that goes from 0.1–100.0 fm with the four different potential sets presented in Table I.

The three-body model with two non-interacting particles in the above single-particle levels of ²¹C produces different parity states, when two neutrons are placed in seven different unbound orbits, i.e., $s_{1/2}$, $d_{3/2}$, $f_{7/2}$, $p_{3/2}$, $f_{5/2}$, $p_{1/2}$ and $d_{5/2}$. Namely seven configurations $(s_{1/2})^2$, $(p_{1/2})^2$, $(p_{3/2})^2$, $(d_{3/2})^2$, $(d_{5/2})^2$ and $(f_{7/2})^2$ couple to $J^{\pi} = 0^+$, eight configurations $(s_{1/2}p_{1/2})$, $(s_{1/2}p_{3/2})$, $(p_{1/2}d_{3/2})$, $(p_{3/2}d_{3/2})$, $(p_{3/2}d_{5/2})$, $(d_{3/2}f_{5/2})$, $(d_{5/2}f_{5/2})$ and $(d_{5/2}f_{7/2})$ couple to $J^{\pi} = 1^-$.

In the three-body calculations, along with the core-*n* potential the other important ingredient is the *n*-*n* interaction. The single-particle states must necessarily have a positive energy for each type of relative motion angular momentum. One must resort to the binding effect of some residual interaction, that brings one of the many unbound energy eigenvalues down into the bound regime following [38, 39] for the ground-state $J^{\pi} = 0^+$ case. An attractive contact-delta pairing interaction is used, $g\delta(\vec{r_1} - \vec{r_2})$ for simplicity, with only one adjustable parameter, *G*, that is related to *g* with Eq. (7).

The task of introduction of the residual n-n interaction between the continuum states, requires careful numerical implementation because one deals with large data sets. The resulting pairing matrix is diagonalized with standard routines and it gives the eigenvalues for the $J = 0^+$ case. The coefficient of the contact-delta pairing, G, is adjusted to reproduce the correct ground-state energy each time. The actual pairing interaction g is obtained by correcting with a factor that depends on the aforementioned spacing between energy states, i.e., ΔE . The biggest adopted basis size gives a fairly dense continuum in the region of interest. All the calculations discussed in this paper are performed with $\Delta E = 0.1$ MeV and $E_{\rm cut} = 5$ MeV. For detailed discussion on convergence of these model parameters one can refer to the Appendix.

B. Ground-state properties of ²²C

The ground-state wave function obtained from the diagonalization in the sufficiently large adopted basis, shows a certain degree of collectivity, taking contributions of comparable magnitude from several basis states, while in contrast the remaining unbound states usually are made up of a few major components. We calculate the wave functions for shallow (-0.140 MeV) and deep (-0.500 MeV) binding cases. The detailed components for each configuration are summarized in Table II, for the shallow case.

As it can be clearly seen from the Table II, on moving from Set 1 to Set 4, the mixing in the ground state with higher l-wave components increases in magnitude. Our results for smaller binding energy (-0.140 MeV) shows the *s*-wave dominance for all sets, which is consistent with experimental observation [4]. In order to explore the dependence of the configuration mixing with the binding energy, we also fix the ground-state energy deeper, i.e., -0.500 MeV. As summarized in Table III, we find that for Sets 1–3, the *s*-wave dominance is present, whereas for Set 4 an inversion of *s*- and *f*-wave components takes place. The present calculations of the configuration mixing percentage is consistent with the previous calculations of [10] for Set 1 and of [23] for Set 3, although these [10, 23] and all the other three-body calculations used more sophisticated two-neutron interactions. Here we want to stress that, the comparison of our Set 4 results cannot be made with the results of [23], where the authors use different potential strengths for different *l*-waves, whereas in our case the potential strengths for all l > 0 waves are the same. That's why we have *f*-wave dominance in contrast to their findings [23]. We also use the DD contact-delta pairing interaction [35] to check the consistency with the DI contact-delta pairing interaction. In the DD contact-delta pairing interaction of Eq. (8), the strength of the DI part is given as [35]

$$v_0 = 2\pi^2 \frac{\hbar^2}{m_N} \frac{2a_{nn}}{\pi - 2k_c a_{nn}},\tag{10}$$

TABLE II: Components of the ground state (0^+) of ²²C in full model space, i.e., s, p, d and f-waves for the shallow case with the ground-state energy -0.140 MeV.

where a_{nn} is the scattering length for the free neutron-neutron scattering and k_c is related to the cutoff energy, e_c , as $k_c = \sqrt{\frac{m_N e_c}{\hbar^2}}$. We use $a_{nn} = 15 \text{ fm}$ and $e_c = 30 \text{ MeV}$ [35], which leads to $v_0 = 857.2 \text{ MeV} \text{ fm}^3$. For the parameters of the DI part in Eq. (8), we determine them so as to fix the ground-state energy of ${}^{22}\text{C}$, E = -0.140 MeV [6]. The values of the parameters that we employ are $R_{\rho} = 1.25 \times A_c^{\frac{1}{3}}$ ($A_c = 20$), a = 0.65 fm. and $v_{\rho} = 581.55 \text{ MeV} \text{ fm}^3$. We found that configuration mixing in the ground state of ${}^{22}\text{C}$ does not change much with the choice of interaction. We present the numbers for our potential Set 3 in Table IV, and the same behavior is observed for the other sets, too.

TABLE IV: Comparison of the components of the ground state (0^+) of ²²C for the DI and DD pairing interactions. Calculations are done in the full model space for the shallow case with the ground-state energy -0.140 MeV.

We find that the percentage of different configuration mixing in the ground state of 22 C, are consistent with [10]

for Set 1 and with [23] for Set 3. The calculated ground-state properties are summarized for all the Sets in Tables V and VI in comparison with the experimental [9] and theoretical values [24].

TABLE V: Radial extension of the ground state of 22 C in units of fm, in the full model space, for the shallow case with the ground-state energy -0.140 MeV.

	Set 1	Set 2	Set 3	Set 4	Expt. [9]	Ref. [24]
$R_{ m m}$	3.35	3.32	3.31	3.51	3.44 ± 0.08	3.38 ± 0.10
$\sqrt{\langle r_{NN}^2 \rangle}$	8.42	8.18	8.06	9.87		
$\sqrt{\langle r_{c-2N}^2 \rangle}$	4.21	4.10	4.03	4.93		

FIG. 1: (Color online) Two-particle density for the ground state of ²²C as a function of $r_1 = r_2 = r$ and the opening angle between the valence neutrons θ_{12} for the shallow case with the ground-state energy, -0.140 MeV. Set 2 and 4 are employed.

The matter radius is calculated by

$$\langle R_m^2 \rangle = \frac{A_{\rm core}}{A_{\rm core} + 2} \langle r_{\rm core}^2 \rangle + \frac{1}{A_{\rm core} + 2} \\ \left(\frac{1}{2} \langle r_{NN}^2 \rangle + \frac{2A_{\rm core}}{A_{\rm core} + 2} \langle r_{c-NN}^2 \rangle \right),$$
(11)

where $\sqrt{\langle r_{\text{core}}^2 \rangle} = 2.99 \text{ fm} [10]$ and this value is consistent with the evaluated value, i.e., $2.98 \pm 0.05 \text{ fm} [32]$. The mean-square distance between the valence neutrons and that of their center of mass with respect to the core are respectively given by

$$\langle r_{NN}^2 \rangle = \langle \Psi_{00}(\vec{r_1}, \vec{r_2}) | (\vec{r_1} - \vec{r_2})^2 | \Psi_{00}(\vec{r_1}, \vec{r_2}) \rangle, \langle r_{c-NN}^2 \rangle = \langle \Psi_{00}(\vec{r_1}, \vec{r_2}) | (\vec{r_1} + \vec{r_2})^2 / 4 | \Psi_{00}(\vec{r_1}, \vec{r_2}) \rangle,$$

$$(12)$$

where $\Psi_{00}(\vec{r_1}, \vec{r_2})$ is the ground-state wave function.

TABLE VI: Same as Table V but for the deep case with the ground-state energy -0.500 MeV.

		Set 1	Set 2	Set 3	Set 4	Expt. [9]	Ref. [24]
	$R_{ m m}$	3.18	3.14	3.17	3.32	3.44 ± 0.08	3.38 ± 0.10
	$\sqrt{\langle r_{NN}^2 \rangle}$	6.78	6.30	6.61	8.13		
۱	$\left< r_{c-2N}^2 \right>$	3.39	3.15	3.30	4.06		

FIG. 2: (Color online) Same as Fig. (1) but for the deep case with the ground-state energy, -0.500 MeV. Set 2 and 4 are employed.

In Tables V and VI, while the matter radius is fairly consistent with the experimental value [9] and recent theoretical evaluation [24] for the shallow case, for the deep case it is slightly underestimated for all sets, but our values for deep case are consistent with the mean field calculations [18, 36]. There are slight differences for $\sqrt{\langle r_{NN}^2 \rangle}$ and $\sqrt{\langle r_{c-2N}^2 \rangle}$ in comparison to previous studies [10, 25] that can be ascribed to the choice of different pairing interactions. However, these properties are not sensitive to the configuration mixing as reported in Tables II and III, due to difference in magnitude of the pairing strength. In the shallow case, the calculated matter radii are closer to the recent theoretical evaluation [24] and the the experimental observation [9] than those of the deep case. So, our results favor the shallow binding energy and they call for the accurate experimental data for ²²C binding energy as there are large uncertainties reported in the previous measurement [6].

The two particle angle between them utrons, and the

FIG. 3: (Color online) Angular density for S = 0 weighted with a factor $2\pi \sin \theta_{12}$ for the ground state of the ²²C as a function of the opening angle between the valence neutrons θ_{12} for the shallow and deep case with the ground-state energy -0.140 MeV and -0.500 MeV respectively. Sets 2 and 4 are employed.

The two particle density of 22 C as a function of two radial coordinates, r_1 and r_2 , for valence neutrons, and their

opening angle, θ_{12} in the LS-coupling scheme is given by

$$\rho(r_1, r_2, \theta_{12}) = \rho^{S=0}(r_1, r_2, \theta_{12}) + \rho^{S=1}(r_1, r_2, \theta_{12})$$
(13)

The explicit expression for S = 0 component is given by [40]

$$\rho^{S=0}(r_1, r_2, \theta_{12} = \frac{1}{8\pi} \sum_L \sum_{\ell,j} \sum_{\ell',j'} \frac{\hat{\ell}\hat{\ell}'\hat{L}}{\sqrt{4\pi}} \begin{pmatrix} \ell & \ell' & L \\ 0 & 0 & 0 \end{pmatrix}^2 \\ \times (-1)^{\ell+\ell'} \sqrt{\frac{2j+1}{2\ell+1}} \sqrt{\frac{2j'+1}{2\ell'+1}} \\ \times \psi_{\ell j}(r_1, r_2) \psi_{\ell' j'}(r_1, r_2) Y_{L0}(\theta_{12})$$
(14)

where $\hat{\ell} = \sqrt{2l+1}$ and $\psi_{\ell j}(r_1, r_2)$ is the radial part of the two-particle wave function which is determined from Eq. (5) by making use of Eqs. (5) and (6) of [29]. The angular density for S = 0 is defined by [37]

$$A(\theta_{12}) = 4\pi \int_0^\infty r_1^2 dr_1 \int_0^\infty r_2^2 dr_2 \,\rho^{S=0}(r_1, r_2, \theta_{12}).$$
(15)

Figures 1 and 2 shows the two-particle density plotted as a function of the radius $r_1 = r_2 = r$ and their opening angle θ_{12} , with a weight factor of $4\pi r^2 \cdot 2\pi r^2 \sin \theta_{12}$ for Sets 2 and 4 for the shallow and deep case, respectively. We also calculate the two-particle densities for Sets 1 and 3, and find them to be consistent with the previous study [10]. One can see in Figs. 1 and 2 that the two-particle density is well concentrated in the smaller θ_{12} , which is the clear indication of the di-neutron correlation. The distribution at smaller and larger θ_{12} are referred to as "di-neutron" and "cigar-like" configurations, respectively. The di-neutron structure component for both Sets 2 and 4 has a relatively higher density, in comparison to the small cigar-like component. Figure 3 shows the three peak decomposition of the angular density of Eq. (15) as a function of θ_{12} . The origin of the central peak around $\theta_{12} = 90^{\circ}$ ("boomerang" configuration [41]) is from the configuration mixing with d- and f-waves coupled to even- $L \geq 2$ for the Sets 2 and 4. One can see the magnitude of the boomerang component is larger for the shallow and deep binding energy cases for Set 4 in comparison to Set 2, this effect can also be seen from Figs. 1 and 2. The extension of the di-neutron structure is different for both sets and is attributed to the large degree of mixing of different *l*-components for the Set 4 (see from Tables II and III). We will explore this difference in the nuclear responses in the following sections.

V. ELECTRIC-DIPOLE STRENGTH DISTRIBUTION

The detailed mathematical set up for calculations of the electric-multipole transitions to continuum is explained in Sec. 6 of [29]. There is only a number of limited theoretical studies, that have been focused on calculations of the electric-dipole (E1) strength function [23, 25]. In order to compare our results with these predictions, we also perform a set of calculations for the E1 response from the ground state to all components of $J^{\pi} = 1^{-}$ state. The E1 excitations describes the transitions from the ground state to the continuum states by E1 operator [29]. After constructing a basis for sufficiently dense continuum, made up of eight components, namely $[s_{1/2} \times p_{1/2}]^{(1)}$, $[s_{1/2} \times p_{3/2}]^{(1)}$, $[p_{1/2} \times d_{3/2}]^{(1)}$, $[p_{3/2} \times d_{3/2}]^{(1)}$, $[d_{3/2} \times f_{5/2}]^{(1)}$, $[d_{5/2} \times f_{5/2}]^{(1)}$ and $[d_{5/2} \times f_{7/2}]^{(1)}$, we diagonalize the Hamiltonian and obtain eigenvalues. We calculate the E1 response for Sets 2 and 4 and use the same value of the pairing strength that is used for the ground state. There is total of 16 possible different transitions from the initial 0^+ ground state to the final 1^- state of ²²C. We investigate the detailed structure of the E1 strength distribution to study the role of different configurations. However, our model does not include the recoil correction at the moment. This was discussed in Ref. [35], where it was concluded that the no-recoil approximation works quite well for several observables. Figure 4 shows the total E1 transition strength of 22 C and its contribution of dominant transitions for the two different core-*n* potential Sets 2 and 4, for the shallow and deep binding energies. Our calculations satisfy the cluster sum rule [42]. The total integrated strengths with the range of $0 < E_C < 4 \text{ MeV}$ accounts for 89.2% (93.9%) and 88.8% (95.5%) of the sum rule value for Set 2 and Set 4 for the shallow (deep) binding energy respectively. Our calculations give strength distributions at discrete values of energy to which we apply a Gaussian smoothing procedure that does not alter the total integrated strength. As a result of the smoothing procedure, the curves in Fig. 4 show a few minor wiggles, that are not to be attributed to resonances, but must be considered as an artifact. The shape and strength of our E1 response function are consistent with the previous calculations [15, 23, 25]. It is clear, though, that there is a concentration of strength at low energies and possible maximum close to ~ 0.4 and ~ 0.6 MeV for the shallow

FIG. 4: (Color online) Total E1 transition strength distribution from the ground state 0^+ to the final state 1^- for ²²C along with the dominant transitions for Sets 2 and 4 for the shallow and deep cases with the ground-state energies of -0.140 MeV and -0.500 MeV, respectively.

and deeper case respectively. We find in these calculations that the transitions $[s_{1/2} \times s_{1/2}]^{(0)} \rightarrow [s_{1/2} \times p_{3/2}]^{(1)}$ and $[s_{1/2} \times s_{1/2}]^{(0)} \rightarrow [s_{1/2} \times p_{1/2}]^{(1)}$ play the dominant role in the total *E*1 transition strength and are shown in the Fig. 4 for both sets, whereas all the remaining 14 transitions are less significant. The role of the core excitation has been discussed [18] in context to the momentum distribution of ²⁰C fragment of ²²C breakup, which is beyond the scope of the present study. Our findings show the negligible difference in *E*1 response for two different core + *n* potentials, for the same binding energy. The negligible difference for the peak position with different core + *n* potentials is due to the fact that the two sets give the same binding energies. The shifting of the peak of the *E*1 strength distribution with different binding energies was discussed in [23, 25]. We also find the slight shift of the peak position to the higher energy side for the deep case. Also, for the deep case due to more mixing of *d*- and *f*-waves, the *E*1 strength distribution is wider than that corresponding to the shallow case. In order to reach final conclusion for the *E*1 response, precise measurement of ²²C binding energy is highly needed of the moment.

VI. MONOPOLE STRENGTH DISTRIBUTION

Among the excited states in weakly-bound nuclei, the excitation modes which correspond to the collective motion between halo neutrons and core are particularly intriguing. This section is devoted to study the low-energy monopole excitations in ²²C. The monopole excitations describe the transitions from the $J^{\pi} = 0^+$ ground state to the $J^{\pi} = 0^+$ continuum states with monopole operator defined by $\sum_{k=1}^{2} r_k^2$. These calculations have also led us to study the role of various configurations in the total monopole strength. After constructing a basis made up of seven components, namely $(s_{1/2})^2$, $(p_{1/2})^2$, $(p_{3/2})^2$, $(d_{3/2})^2$ $(d_{5/2})^2$, $(f_{5/2})^2$ and $(f_{7/2})^2$, we diagonalize the Hamiltonian for $J^{\pi} = 0^+$. Only one state is bound and all the remaining ones are unbound. There are seven possible transitions from the ground-state components to continuum 0^+ states ones. Figure 5 shows the total monopole transition strength of ²²C and the contribution of the dominant transitions for Sets 2 and 4, for the shallow and deep binding energy. Out of the possible seven transitions, $[(s_{1/2})^2]^{(0)}$ (ground state) $\rightarrow [(s_{1/2})^2]^{(0)}$ (continuum) transition is the dominant one, whereas the transition $[(f_{5/2})^2]^{(0)}$ (ground state) $\rightarrow [(f_{5/2})^2]^{(0)}$ (continuum) is the least significant in the total monopole

FIG. 5: (Color online) Total monopole transition strength distribution and the dominant transition from 0^+ (ground state) to the 0^+ (continuum) for 22 C for Sets 2 and 4 for the shallow and deep cases with the ground-state energies of -0.140 MeV and -0.500 MeV, respectively.

transition strength. From Fig. 5, one can see there is slightly larger difference between the total monopole strength and the dominant transition strength for Set 4 than Set 2. This is due to the fact that for Set 4, we have slightly larger contribution from the two other less significant transitions, i.e., $[(d_{3/2})^2]^{(0)}(\text{ground state}) \rightarrow [(d_{3/2})^2]^{(0)}(\text{continuum})$ and $[(f_{7/2})^2]^{(0)}(\text{ground state}) \rightarrow [(f_{7/2})^2]^{(0)}(\text{continuum})$. This fact can also be seen from large percentage of the $d_{3/2}$ -wave $f_{7/2}$ -wave for potential Set 4 (see Table II), for the shallow case. The peak position for the total monopole strength, for these two different sets is almost same as they correspond to the same binding energy. We find the slight shift in the peak position to higher energy for the deep case. Also, the magnitude of the peak strength is larger for Set 4 as compared to Set 2, this can be due to the fact that Set 4 gives larger matter radius than that of Set 2. Again, one needs accurate binding energy to reach the final conclusion for the low-lying continuum spectrum of ²²C.

VII. SUMMARY AND CONCLUSIONS

In summary, the sensitivity of the core-neutron potential has been explored with the mixing of different *l*-wave components in the ground state of 22 C by using a three-body structure model [28–31]. The ground-state properties have been calculated and found to be consistent with other theoretical predictions. Also, the electric-dipole and monopole responses of 22 C have been investigated and the role of the various possible transitions has been studied in each case.

Our results strongly depend on the choice of the $\operatorname{core} + n$ potential and the binding energy of the $\operatorname{core} + n + n$ system. Four different potential sets have been examined and the emergence of the *f*-wave resonance has been discussed. Sets 1 and 3 are examined to check the consistency of our calculations with the previous studies, whereas Sets 2 and 4 predict the different position of the *f*-wave resonance state. In order to explore configuration mixing we have studied the electric-dipole and monopole responses. We find that there is negligible difference in the response functions for the same binding energy.

In addition, our results for Set 4 predict the s-wave dominance for the lower binding energy (-0.140 MeV) and the f-wave dominance for the deeper binding energy (-0.500 MeV). However, we found that it is difficult to propose the

best core + n potential unless we have more precise experimental data for the low-lying spectrum of ²¹C as well as for the binding energy of ²²C. Thus, our results encourage the precise experimental measurements for these observables. In the present calculations we assumed the inert ²⁰C core, it would be interesting to extend our model by considering the core excitations as a future direction. We expect that our efforts might be of help to unravel the structure of low-lying continuum spectrum of ²²C.

Appendix - Convergence with model parameters

FIG. 6: (Color online) (a)Convergence with continuum energy cut E_{cut} of the model space and (b)Convergence with energy spacing ΔE of the model space.

We calculate the continuum single-particle wave functions for different $E_{\rm cut}$'s. After fixing the convergence with $E_{\rm cut}$, the continuum single-particle wave functions, using the mid-point method for $E_{\rm cut} = 5$ MeV, with $\Delta E = 1.0$, 0.5, 0.2, 0.1, 0.08, 0.06 and 0.05 MeV, the two-particle states are formed and the matrix elements of the pairing interaction are calculated. The convergence of the results is discussed on two different levels:

1. Convergence with the continuum energy cut $(E_{\rm cut})$ of the model space

We check the convergence of our results (dominant contribution in the ground state of ²²C) with different E_{cut} 's. In the Fig. 6(a), we show the variation of three dominant contributions $(s_{1/2}, d_{3/2} \text{ and } f_{7/2})$ in the ground state of ²²C with different E_{cut} 's for different values of the energy spacing (ΔE). One can clearly see that we achieve the convergence with different E_{cut} 's but still there is significant variation in the percentage contribution with different ΔE s. In the fourth quadrant of the Fig. 6(a), due to huge computational costs, we restrict ourselves to only 10 MeV. It is convincing that one can choose fairly well the $E_{\text{cut}} = 5$ MeV for this study and we will do all the calculations with $E_{\text{cut}} = 5$ MeV.

2. Convergence with the energy spacing (ΔE) of the model space As seen from the Fig. 6(b), we study the convergence of our results (dominant contribution in the ground state of ²²C) with inverse of ΔE for $E_{\text{cut}} = 5 \text{ MeV}$. It is clear from the Fig. 6(b), the curves start getting flat from $\Delta E = 0.1 \text{ MeV}$. Therefore, we adopt $\Delta E = 0.1 \text{ MeV}$ ($1/\Delta E = 10 \text{ MeV}$) for the present calculations.
