#### Abstract

This paper presents a robust, adaptive numerical scheme for simulating high density ratio and high shear multiphase flows on locally refined staggered Cartesian grids that adapt to the evolving interfaces and track regions of high vorticity. The algorithm combines the interface capturing level set method with a variablecoefficient incompressible Navier-Stokes solver that is demonstrated to stably resolve material contrast ratios of up to six orders of magnitude. The discretization approach ensures second-order pointwise accuracy for both velocity and pressure with several physical boundary treatments, including velocity and traction boundary conditions. The paper includes several test cases that demonstrate the order of accuracy and algorithmic scalability of the flow solver. To ensure the stability of the numerical scheme in the presence of high density and viscosity ratios, we employ a consistent treatment of mass and momentum transport in the conservative form of discrete equations. This consistency is achieved by solving an additional mass balance equation, which we approximate via a strong stability preserving Runga-Kutta time integrator and by employing the same mass flux (obtained from the mass equation) in the discrete momentum equation. The scheme uses higher-order total variation diminishing (TVD) and convection-boundedness criterion (CBC) satisfying limiter to avoid numerical fluctuations in the transported density field. The high-order bounded convective transport is done on a dimension-by-dimension basis, which makes the scheme simple to implement. We also demonstrate through several test cases that the lack of consistent mass and momentum transport in non-conservative formulations, which are commonly used in practice, or the use of non-CBC satisfying limiters can yield very large numerical error and very poor accuracy for convection-dominant high density ratio flows. Our numerical scheme also uses well-balanced surface tension and gravity force discretizations. In the hydrostatic limit, we show that the well-balanced formulation mitigates spurious flow currents and achieves discrete force-balance between the pressure gradient and surface tension or gravity.

Keywords: well-balanced force algorithm, adaptive mesh refinement, staggered Cartesian grid, convective flux limiters, continuum surface tension force, matrix-free solver, projection method preconditioner, monolithic Navier-Stokes solver, level set method

# 1. Introduction

Incompressible two-phase flows involving liquid and gas at ambient conditions are prevalent in engineering and natural processes. The high density and high viscosity contrasts in multiphase flows often result in significant shear at the fluid-fluid interface. This poses a significant challenge in the numerical modeling of multicomponent flows because of the stiff system of equations arising from the discretization of the incompressible Navier-Stokes equations. In addition, numerical error accumulation near the highly deforming interface often leads to catastrophic failure of the scheme. Several multiphase flows are driven by interfacial forces like surface tension and volumetric forces like gravity; avoiding spurious currents near such interfaces

requires a consistent and well-balanced discretization of the forces. Despite these difficulties, multiphase flow modeling has been the subject of extensive research for the past two decades owing to its importance in both industrial and natural processes.

Several approaches to track the phases of a multiphase flow simulation exist in the literature, the most prominent being the volume-of-fluid (VOF) method of Hirt and Nichols [1] and the level set method of Osher and Sethian [2]. The VOF method tracks the volume fraction of each phase in each computational cell and reconstructs the phase interface in a piecewise fashion from the volume fraction data. The advection of the VOF-scalar is done though geometric means to ensure strict mass conservation and boundedness of volume fraction. The disadvantages of VOF method include its non-smooth interface representation and tedious geometry implementation requirements. On the other hand, the level set method captures the phase interface by computing a signed distance function. The zero level set of the distance field implicitly defines the position of the interface. The level set method formulates the geometric problem of distance finding as a nonlinear hyperbolic partial differential equation (PDE) for which established numerical techniques can be applied. Higher-order hyperbolic PDE discretization methods can enable smooth interface representation and accurate curvature calculation. The level set method can also lead to spurious mass changes resulting from the transport and reinitialization of the signed distance function [3]. However, this issue can be minimized by penalization techniques [4] or by hybridizing the level set method with VOF-like methods, as done in the mass-conserving level set method (MCLS) [5] and the coupled level set volume-of-fluid methods (CLSVOF [6], and VOSET [7]). In this work, we use the level set method with sign [8] and subcell [9] fixes to mitigate spurious changes in the mass of each phase.

A challenging problem that has not received much attention in the multiphase flow literature is the treatment of large density ratios. The multiphase community has only recently begun to address the fundamental cause and resolution of numerical instabilities associated with flows with density ratios on the order of 100–1000 and greater. Over the past few years, many authors have proposed strategies for mitigating these instabilities within a wide range of numerical contexts; for example, Li et al. [10] for a moment-offluid method, Vaudor et al. [11] for a staggered grid CLSVOF method, Le Chenadec and Pitsch [12] and Owkes and Desjardins [13] for sharp interface VOF methods, and Jemison et al. [14] and Duret et al. [15] for compressible flow solvers, to name a few. Interestingly, some earlier numerical schemes based on the VOF method, particularly that of Rudman [16] and Bussman [17], were not susceptible to flow instabilities with large density ratios because of their use of consistent transport schemes for the convective momentum and VOF-scalar in the discrete set of conservative equations. In the context of the level set framework, in which geometric information about interface transport is absent, it is difficult to maintain a discrete compatibility between mass and momentum transport. Raessi [18] and Raessi and Pitsch [19] introduced the first strategy for dealing with high density ratio flows within the level set framework by introducing geometric mass flux transport. This work has been limited to one- and two-dimensional problems because of the inherent difficulty of interface reconstruction and geometric transport with level sets. A more elegant solution to this problem that is easily extended to three spatial dimensions was proposed by Desjardins and Moureau [20] in the context of structured, staggered-grid Cartesian discretizations, and more recently by Ghods and Herrmann [21] for collocated unstructured grids. Instead of constructing piecewise linear interfaces from the level set field, they suggest solving an additional mass balance equation along with momentum and incompressibility constraint equations. The advantage of this approach is that the same (algebraic) mass flux can be used in both mass and momentum transport for a given time step, yielding a stable scheme for high density ratio flows. The level set is transported independently and is only used to synchronize the density field with level set field at the beginning of each time step. To prevent numerical oscillations in the density field near the interface, both Desjardins and Moureau [20] and Ghods and Herrmann [21] used first-order upwinding for density and velocity transport. Doing so, however, produces diffusive flow features and smeared vortices. A key contribution of this work is to extend their approach to a second-order accurate, bounded scheme. The resulting method is empirically demonstrated to remain stable even at very high density ratios of 10<sup>6</sup>. This is achieved in this work by employing a modified version of the third-order accurate Koren's limited Cubic Upwind Interpolation (CUI) scheme described by Patel and Natarjan [22]. Koren's limited CUI is a total variation diminishing (TVD) and convection-boundedness criterion (CBC) satisfying convective limiter. The mass equation is integrated using a third-order strong-stability preserving Runge-Kutta time integrator (SSP-RK3) [23], and the mass flux from the penultimate (second) stage of the SSP-RK3 scheme is used in the convective operator to maintain discrete compatibility. We also compare the performance of the scheme using TVD but non-CBC convective limiters, such as a version of the piecewise parabolic method (PPM), to CBC limiters like CUI, the Modified Gamma scheme (M-Gamma) [22], and the Flux Blending Interface Capturing scheme (FCIBS) [24] for convection-dominant high density ratio flows.

More recently Patel and Natarajan [25] used a consistent convective scheme for momentum and algebraic (i.e., geometric reconstruction-free) VOF transport. Their consistent transport scheme implicitly maintains the discrete compatibility of the density flux in the mass and momentum equations. Through several examples, they show that any mismatch between mass and momentum transport results in an inconsistent scheme and can result in extremely poor accuracy in certain flow scenarios. We remark that this is not the only way to achieve stabilization for high density ratio flows. For example, Desjardins and Moureau [20] and Sussman et al. [26] use the ghost fluid method to maintain sharp discontinuities across the interface within a hybridized level set framework. This approach also requires the use of some velocity extension algorithm across the phase interface to advect the level set field. Specifically, Sussman et al. [26] use the higher density fluid's extrapolated velocity to advect the interface. We do not analyze the stability of sharp interface methods for high density ratio multiphase flows in this work.

A major challenge in incompressible flow simulation is the treatment of coupled velocity-pressure saddlepoint system. In this work, we solve this saddle-point system in a monolithic fashion (without any timesplitting approach) using a preconditioned flexible GMRES scheme. We achieve high performance via a novel preconditioning strategy that combines a local-viscosity preconditioner [27] with a projection method-based preconditioner introduced by Griffith in the context of constant coefficient problems [28] and extended by Cai et al. [29] to treat variable coefficient problems. This work extends the uniform grid variable-coefficient solvers of Cai et al. to locally refined grids. Another difference is that Cai et al. [29] considers the nonconservative form of equations, i.e, they compute velocity and pressure fields for a given density field. In this work, because we employ consistent mass and momentum transport with conservative form of equations, we solve an additional mass balance equation for density evolution. We empirically demonstrate that our spatiotemporal discretization achieves pointwise second-order accuracy for the velocity, pressure, and density fields for a variety of boundary conditions. We note that most of the multiphase literature [17, 30, 31, 32, 33, 34, 35] treats the spatially varying viscous operator explicitly, although an implicit treatment has been used by some authors as well [26, 36, 37]. Because we use a solver strategy that allows us to treat the viscous operator implicitly, we are able to use a time step size based only on an advective CFL condition. In the context of a level set framework, the implicit treatment of the viscous terms reduces the frequency of level set reinitialization without degrading accuracy, which reduces numerical perturbations in the interface configuration [38].

The remainder of the paper is organized as follows. We first introduce the continuous and discrete system of equations in Sections 2 and 3, respectively. Next we discuss the projection preconditioner in Section 4. Software implementation is described in Section 5. Accuracy and scalability results for the monolithic flow solver are presented thereafter for both conservative and non-conservative discretizations in Section 6. Finally, two-phase flow examples highlighting the importance of consistent and bounded mass and momentum transport are presented in Section 7. We also contrast the consistent results against the results obtained from an inconsistent and non-conservative flow solver. Wherever possible, simulation results from locally refined grids are presented. Examples demonstrating the well-balanced discretization of the interfacial surface tension and volumetric gravitational force are also presented. Well-balanced force formulations are particularly important in the hydrostatic limit, where it helps to mitigate spurious flow currents. This is achieved through a discrete force-balance between the pressure gradient and interfacial/external forces as shown by our test cases.

#### 2. The continuous equations of motion

We follow the single fluid formulation [39] for multiphase flows and consider a single viscous incompressible fluid with spatially and temporally varying density and viscosity occupying a fixed region of space  $\Omega \subset \mathbb{R}^d$ . The equations of motion for the fluid are the incompressible Navier-Stokes equations, which in *conservative* form are

$$\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot \rho \mathbf{u} \mathbf{u} = -\nabla p + \nabla \cdot \left[ \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) \right] + \mathbf{f} + \mathbf{f}_s, \tag{1}$$

$$\nabla \cdot \mathbf{u} = 0, \tag{2}$$

in which  $\mathbf{x} = (x, y) \in \Omega$  are the fixed physical Eulerian coordinates,  $\mathbf{u}(\mathbf{x}, t) = (u(\mathbf{x}, t), v(\mathbf{x}, t))$  is the fluid velocity,  $p(\mathbf{x}, t)$  is the pressure,  $\mathbf{f}(\mathbf{x}, t) = (f_1(\mathbf{x}, t), f_2(\mathbf{x}, t))$  is the momentum body force,  $\mathbf{f}_s(\mathbf{x}, t)$  is the continuum surface tension force, and  $\rho(\mathbf{x}, t)$  and  $\mu(\mathbf{x}, t)$  are the spatially and temporally varying fluid density and dynamic viscosity, respectively. Note that the continuity constraint Eq. (2) follows directly from the conservation of mass equation over the entire domain,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = \frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho \nabla \cdot \mathbf{u} = 0, \tag{3}$$

and the incompressible nature of the fluid, which in the Langrangian form can be expressed as  $\frac{D\rho}{Dt} = 0$ . The equations of motion can also be cast to *non-conservative* form by combining Eqs. (1), (2) and (3), so that

$$\rho \left( \frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot \mathbf{u} \mathbf{u} \right) = -\nabla p + \nabla \cdot \left[ \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) \right] + \mathbf{f} + \mathbf{f}_s, \tag{4}$$

$$\nabla \cdot \mathbf{u} = 0. \tag{5}$$

Although these forms of the equations are equivalent, direct discretizations of these equations lead to numerical schemes with different properties, as discussed in later sections. Note that the convective term  $\nabla \cdot \mathbf{u}\mathbf{u}$  in Eq. (4) can also be expressed as  $\mathbf{u} \cdot \nabla \mathbf{u}$  using the continuity constraint.

To complete the description of the equations of motion, it is necessary to specify initial conditions for  $\mathbf{u}$ ,  $\rho$ , and  $\mu$  and boundary conditions on  $\partial\Omega$ . As described by Griffith [28] for the constant-coefficient case, in this work we consider three types of boundary conditions: periodic, prescribed velocity, and prescribed traction.

Finally, suppose that two fluids with differing densities and viscosities occupy the regions in the computational domain  $\Omega_0(t) \subset \Omega$  and  $\Omega_1(t) \subset \Omega$ , respectively. The codimension-1 interface between the fluids  $\Gamma(t) = \Omega_0 \cap \Omega_1$  can be tracked as the zero contour of a scalar function  $\phi(\mathbf{x}, t)$ , which is the so-called level set function [2, 40, 30],

$$\Gamma(t) = \{ \mathbf{x} \in \Omega \mid \phi(\mathbf{x}, t) = 0 \}. \tag{6}$$

Level set methods are well-suited for tracking interfaces undergoing complex topological changes and are relatively easy to implement in both two and three spatial dimensions. The density and viscosity in the two phases are determined as a function of this scalar field by

$$\rho(\mathbf{x},t) = \rho(\phi(\mathbf{x},t)),\tag{7}$$

$$\mu(\mathbf{x},t) = \mu(\phi(\mathbf{x},t)). \tag{8}$$

The discretized form of Eqs. (7) and (8) are defined in Section 3.3 using a regularized Heaviside function. The signed distance function is passively advected by the incompressible fluid velocity, which in conservative form reads

$$\frac{\partial \phi}{\partial t} + \nabla \cdot \phi \mathbf{u} = 0. \tag{9}$$

One common choice of  $\phi$  is the signed distance function; however,  $\phi$  generally will not remain a signed distance function under advection by Eq. (9). A reinitialization or redistancing procedure is used to maintain the signed distance property of  $\phi$  at every time step. When the fluid properties are determined from  $\phi$ , we need initial conditions for  $\phi$  but not for  $\rho$  or  $\mu$ .

Figure 1: (a) A staggered-grid discretization of the computational domain  $\Omega$ . (b) A single Cartesian grid cell on which the components of the velocity field  $\mathbf{u}$  are approximated on the cell faces ( $\rightarrow$ , black); the pressure p, and level set  $\phi$  are approximated on the cell center ( $\bullet$ , black); and the interpolated viscosity is approximated on cell nodes ( $\blacksquare$ , green).

#### 3. The discretized equations of motion

This section details the discretizations of the non-conservative and conservative forms of the governing equations. For notational simplicity, we present the discretized equations in two spatial dimensions. An extension to three spatial dimensions is straightforward with the exception of the discretization of the viscous term; the treatment of this term in three dimensions is described in Appendix A. The treatment of physical boundary conditions in this work follows an approach similar to that of Griffith [28] and is detailed in Appendix B.

## 3.1. Basic spatial discretization

This work uses a staggered-grid discretization of the equations of incompressible fluid flow on a rectangular domain  $\Omega$ . A  $N_x \times N_y$  Cartesian grid covers the physical domain  $\Omega$  with mesh spacing  $\Delta x$  and  $\Delta y$  in each direction. Without loss of generality, the bottom left corner of the domain is assumed to be situated at the origin (0,0). The position of each grid cell center is then given by  $\mathbf{x}_{i,j} = \left((i+\frac{1}{2})\Delta x,(j+\frac{1}{2})\Delta y\right)$  for  $i=0,\ldots,N_x-1$  and  $j=0,\ldots,N_y-1$ . For a given cell  $(i,j),\mathbf{x}_{i-\frac{1}{2},j}=(i\Delta x,(j+\frac{1}{2})\Delta y)$  is the physical location of the cell face that is half a grid space away from  $\mathbf{x}_{i,j}$  in the x-direction, and  $\mathbf{x}_{i,j-\frac{1}{2}}=\left((i+\frac{1}{2})\Delta x,j\Delta y\right)$  is the physical location of the cell face that is half a grid cell away from  $\mathbf{x}_{i,j}$  in the y-direction. The pressure is approximated at cell centers and is denoted by  $p_{i,j}^n \approx p\left(\mathbf{x}_{i,j},t^n\right)$ , in which  $t^n$  is the time at time step n. Velocity components are defined at cell faces:  $u_{i-\frac{1}{2},j}^n \approx u\left(\mathbf{x}_{i-\frac{1}{2},j},t^n\right)$  and  $v_{i,j-\frac{1}{2}}^n \approx v\left(\mathbf{x}_{i,j-\frac{1}{2}},t^n\right)$ . The components of the body force  $\mathbf{f}=(f_1,f_2)$  are also approximated at x- and y-faces of the staggered grid cells, respectively. The density and viscosity are approximated at cell centers of the staggered grid and are denoted by  $\rho_{i,j}^n \approx \rho\left(\mathbf{x}_{i,j},t^n\right)$  and  $\mu_{i,j}^n \approx \mu\left(\mathbf{x}_{i,j},t^n\right)$ . In our numerical scheme, these values are interpolated onto the required degrees of freedom, as needed. Similarly, the phase interface is tracked via the level set function, which is also defined at cell centers and denoted by  $\phi_{i,j}^n \approx \phi\left(\mathbf{x}_{i,j},t^n\right)$ . See Fig. 1. Finally, we note that it is sometimes convenient to directly approximate the density field on faces of the staggered grid, i.e.  $\rho_{i-\frac{1}{2},j}^n \approx \rho\left(\mathbf{x}_{i,j}^n\right)$  and  $\rho_{i,j-\frac{1}{2}}^n \approx \rho\left(\mathbf{x}_{i,j-\frac{1}{2}},t^n\right)$ , despite it being a scalar quantity; the reasoning behind this will be made apparent in Sec. 3.5.2.

The staggered-grid finite-difference approximations to the spatial differential operators have been described in various prior studies [28, 29, 41, 42]. We briefly summarize them here to complete the description of the spatial discretization. The divergence  $\mathbf{D} \cdot \mathbf{u}$  of the velocity field  $\mathbf{u} = (u, v)$  is approximated at cell

centers by

$$(\mathbf{D} \cdot \mathbf{u})_{i,j} = (D^x u)_{i,j} + (D^y v)_{i,j}, \tag{10}$$

$$(D^x u)_{i,j} = \frac{u_{i+\frac{1}{2},j} - u_{i-\frac{1}{2},j}}{\Delta x},\tag{11}$$

$$(D^{y}v)_{i,j} = \frac{v_{i,j+\frac{1}{2}} - v_{i,j-\frac{1}{2}}}{\Delta u}.$$
 (12)

The components of the gradient  $\mathbf{G}p = (G^x p, G^y p)$  of cell-centered pressure p are approximated at cell faces by

$$(G^{x}p)_{i-\frac{1}{2},j} = \frac{p_{i,j} - p_{i-1,j}}{\Delta x},$$
(13)

$$(G^{y}p)_{i,j-\frac{1}{2}} = \frac{p_{i,j} - p_{i,j-1}}{\Delta y}. (14)$$

The continuous strain rate tensor form of the viscous term is

$$\nabla \cdot \left[ \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) \right] = \begin{bmatrix} 2 \frac{\partial}{\partial x} \left( \mu \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left( \mu \frac{\partial u}{\partial y} + \mu \frac{\partial v}{\partial x} \right) \\ 2 \frac{\partial}{\partial y} \left( \mu \frac{\partial v}{\partial y} \right) + \frac{\partial}{\partial x} \left( \mu \frac{\partial v}{\partial x} + \mu \frac{\partial u}{\partial y} \right) \end{bmatrix}, \tag{15}$$

which leads to velocity coupling in the discretization for variable viscosity flows

$$\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u} = \begin{bmatrix} (\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u})_{i-\frac{1}{2},j}^{x} \\ (\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u})_{i,j-\frac{1}{2}}^{y} \end{bmatrix}. \tag{16}$$

The viscous operator is approximated using standard second-order, centered finite-differences

$$(\mathbf{L}_{\mu}\mathbf{u})_{i-\frac{1}{2},j}^{x} = \frac{2}{\Delta x} \left[ \mu_{i,j} \frac{u_{i+\frac{1}{2},j} - u_{i-\frac{1}{2},j}}{\Delta x} - \mu_{i-1,j} \frac{u_{i-\frac{1}{2},j} - u_{i-\frac{3}{2},j}}{\Delta x} \right]$$

$$+ \frac{1}{\Delta y} \left[ \mu_{i-\frac{1}{2},j+\frac{1}{2}} \frac{u_{i-\frac{1}{2},j+1} - u_{i-\frac{1}{2},j}}{\Delta y} - \mu_{i-\frac{1}{2},j-\frac{1}{2}} \frac{u_{i-\frac{1}{2},j} - u_{i-\frac{1}{2},j-1}}{\Delta y} \right]$$

$$+ \frac{1}{\Delta y} \left[ \mu_{i-\frac{1}{2},j+\frac{1}{2}} \frac{v_{i,j+\frac{1}{2}} - v_{i-1,j+\frac{1}{2}}}{\Delta x} - \mu_{i-\frac{1}{2},j-\frac{1}{2}} \frac{v_{i,j-\frac{1}{2}} - v_{i-1,j-\frac{1}{2}}}{\Delta x} \right]$$

$$(\mathbf{L}_{\mu}\mathbf{u})_{i,j-\frac{1}{2}}^{y} = \frac{2}{\Delta y} \left[ \mu_{i,j} \frac{v_{i,j+\frac{1}{2}} - v_{i,j-\frac{1}{2}}}{\Delta y} - \mu_{i,j-1} \frac{v_{i,j-\frac{1}{2}} - v_{i,j-\frac{3}{2}}}{\Delta y} \right]$$

$$+ \frac{1}{\Delta x} \left[ \mu_{i+\frac{1}{2},j-\frac{1}{2}} \frac{v_{i+1,j-\frac{1}{2}} - v_{i,j-\frac{1}{2}}}{\Delta x} - \mu_{i-\frac{1}{2},j-\frac{1}{2}} \frac{v_{i,j-\frac{1}{2}} - v_{i-1,j-\frac{1}{2}}}{\Delta x} \right]$$

$$+ \frac{1}{\Delta x} \left[ \mu_{i+\frac{1}{2},j-\frac{1}{2}} \frac{u_{i+\frac{1}{2},j} - u_{i+\frac{1}{2},j-1}}{\Delta y} - \mu_{i-\frac{1}{2},j-\frac{1}{2}} \frac{u_{i-\frac{1}{2},j} - u_{i-\frac{1}{2},j-1}}{\Delta y} \right],$$

$$(18)$$

in which we require approximations to the viscosity at both the *centers* and *nodes* of the Cartesian grid cells. Node centered quantities are obtained via interpolation by either arithmetically averaging the neighboring cell centered quantities,

$$\mu_{i-\frac{1}{2},j-\frac{1}{2}}^{A} = \frac{\mu_{i,j} + \mu_{i-1,j} + \mu_{i,j-1} + \mu_{i-1,j-1}}{4},$$
(19)

or harmonically averaging those quantities,

$$\mu_{i-\frac{1}{2},j-\frac{1}{2}}^{\mathrm{H}} = \left(\frac{\frac{1}{\mu_{i,j}} + \frac{1}{\mu_{i-1,j}} + \frac{1}{\mu_{i,j-1}} + \frac{1}{\mu_{i-1,j-1}}}{4}\right)^{-1}.$$
 (20)

We remark that in three spatial dimensions, the viscosity is required at the centers and edges of the Cartesian

grid cells. The full three-dimensional discretization of the viscous term is detailed in Appendix A. An additional approximation to the density-weighted, variable-coefficient Laplacian is required for the projection preconditioner described in Sec. 6,

$$(\mathbf{L}_{\wp}p)_{i,j} = \frac{1}{\Delta x} \left[ \frac{1}{\rho_{i+\frac{1}{2},j}} \frac{p_{i+1,j} - p_{i,j}}{\Delta x} - \frac{1}{\rho_{i-\frac{1}{2},j}} \frac{p_{i,j} - p_{i-1,j}}{\Delta x} \right] + \frac{1}{\Delta y} \left[ \frac{1}{\rho_{i,j+\frac{1}{2}}} \frac{p_{i,j+1} - p_{i,j}}{\Delta y} - \frac{1}{\rho_{i,j-\frac{1}{2}}} \frac{p_{i,j} - p_{i,j-1}}{\Delta y} \right], \tag{21}$$

which requires density on faces of the Cartesian grid cells. These values also can be determined using either the arithmetic or harmonic averages of density from the two adjacent cell centers.

Evaluating finite-difference operators near boundaries of the computational domain and locally refined mesh boundaries requires specification of abutting "ghost" values, which will be described in Section 3.6 and Appendix B.

## 3.2. Discretization of the convective derivative

In the present work, the nonlinear convective term,  $\nabla \cdot \mathbf{uu}$  for non-conservative form and  $\nabla \cdot \rho \mathbf{uu}$  for conservative form, is computed using the third-order accurate Koren's limited cubic upwind interpolation (CUI) scheme, first proposed by Roe and Baines [43] and further investigated by Waterson and Deconinck [44] and by Patel and Natarajan [22] for multiphase flows. CUI satisfies both a convection-boundedness criterion (CBC) as well as the total variation diminishing (TVD) property, both of which are essential to ensure a monotonic and bounded convective scheme. This specific method belongs to a class of nonlinear upwind schemes (generally formulated in terms of flux limiters or normalized variables [44]), which attempt to achieve higher than first-order accuracy while maintaining the monotonicity of the convected variable. The nonlinear monotonic schemes overcome the consequences of Godunov's order barrier theorem [45], which states that no linear convection scheme of second-order accuracy or higher can be monotonic. These schemes are generally described for cell-centered quantities, but can be formulated for face-centered quantities after appropriate shifting and averaging operations [28]. We will describe this next.

For simplicity, we describe the CUI discretization of  $(\nabla \cdot \mathbf{u}\psi)_{i-\frac{1}{2},j}$ , in which  $\psi$  is defined on x-faces and is advected by a staggered grid velocity  $\mathbf{u}$ . Note that  $\psi$  in this case could be the x-component of velocity  $u_{i-\frac{1}{2},j}$  or the density on x-faces  $\rho_{i-\frac{1}{2},j}$ . (The need for density advection will become apparent in Sec. 3.5.) As a first step, we construct control volumes centered about  $\mathbf{x}_{i-\frac{1}{2},j}$  by shifting the computational grid by  $\frac{\Delta x}{2}$  in the x-direction; see Fig. 2. The advection velocity  $\mathbf{u}_{\text{adv}}$  on the faces of the shifted control volume is obtained by averaging the adjacent velocity components. As shown in Fig. 2, these velocity components are

$$u_{w} = \frac{u_{i-\frac{3}{2},j} + u_{i-\frac{1}{2},j}}{2},$$

$$u_{e} = \frac{u_{i-\frac{1}{2},j} + u_{i+\frac{1}{2},j}}{2},$$

$$v_{s} = \frac{v_{i-1,j-\frac{1}{2}} + v_{i,j-\frac{1}{2}}}{2},$$

$$v_{n} = \frac{v_{i-1,j+\frac{1}{2}} + v_{i,j+\frac{1}{2}}}{2}.$$
(22)

Next, we use the CUI scheme to obtain  $\psi_w, \psi_e, \psi_s$ , and  $\psi_n$  on the faces of the shifted control volume. For a given shifted face  $f \in \{e, w, n, s\}$ , the upwind  $\psi_C$ , far upwind  $\psi_U$  and downwind  $\psi_D$  are labeled depending on the direction of the advection velocity as shown in Fig. 3. For instance, Fig. 3(a) depicts the case where  $u_e \geq 0$  in which the face right of e is labeled as downstream  $(\psi_D)$  and the two faces counting leftward from e are labeled upwind  $(\phi_C)$  and far upwind  $(\psi_U)$ . Analogous three-point stencils are used for the other shifted control volume faces. The upwinded (limited) approximation of  $\psi_{f,\text{lim}}$  on a shifted face can be written in "normalized variable" form as

$$\widetilde{\psi}_f = \begin{cases}
3\widetilde{\psi}_C, & 0 < \widetilde{\psi}_C \le \frac{2}{13} \\
\frac{5}{6}\widetilde{\psi}_C + \frac{1}{3}, & \frac{2}{13} < \widetilde{\psi}_C \le \frac{4}{5} \\
1, & \frac{4}{5} < \widetilde{\psi}_C \le 1 \\
\widetilde{\psi}_C, & \text{otherwise,} 
\end{cases}$$
(23)

Figure 2: The shifted control volume (---, green) over which an approximation to  $(\nabla \cdot \mathbf{u}\psi)_{i-\frac{1}{2},j}$  is computed. (a) The staggered grid velocities used to compute the advection velocity  $\mathbf{u}_{\text{adv}}$ . (b) The location of the advection velocity on faces (×, green) of the shifted control volume.

in which the normalized value is defined by

$$\widetilde{\psi} = \frac{\psi - \psi_U}{\psi_D - \psi_U}.\tag{24}$$

Finally, we compute the approximation to  $(\nabla \cdot \mathbf{u} \psi)_{i-\frac{1}{2},j}$  via

$$(\nabla \cdot \mathbf{u}_{\text{adv}} \psi_{\text{lim}})_{i-\frac{1}{2},j} \approx \frac{u_e \psi_e - u_w \psi_w}{\Delta x} + \frac{v_n \psi_n - v_s \psi_s}{\Delta y}.$$
 (25)

A similar procedure can be followed to compute a discretization for advected quantities on the y-faces. It is also straightforward to extend this scheme to three spatial dimensions because all the computations are performed on a dimension-by-dimension basis. We remark that there are other CBC and TVD satisfying limiters that can be used in place of CUI, including M-Gamma [22] and FBICS [24]. We refer readers to Waterson and Deconinck [44] and to Patel and Natarajan [22] for further details. We also employ TVD but non-CBC satisfying high resolution limiters like xsPPM7 [28, 46], which is a version of the piecewise parabolic method (PPM), to advect scalars in this work. This method, however, can produce unphysical oscillations in the values of variables that have numerical bounds, as evidenced by numerical experiments reported in Sec. 7.3. Therefore, we use CUI (unless otherwise stated) for the convective discretization, and we use xsPPM7 to advect scalars such as the signed distance function only where noted. We remark that if density and viscosity are formulated in terms of a volume-fraction variable  $\alpha$ , which has bounds  $0 \le \alpha \le 1$ , a CBC satisfying limiter must be employed to advect and bound  $\alpha$  [22]. We also remark that in the cases for which a cell-centered approximation to an advective derivative is needed (e.g.,  $(\nabla \cdot \mathbf{u}\phi)_{i,j}$  such as for evolving the level set function), the convective scheme remains the same (as described above), and the control volume is the unshifted grid cell. As a result, the advective velocity for the cell-centered case would be the original staggered grid velocity  $\mathbf{u}$  which is discretely divergence-free by construction. Finally, it is a simple exercise to show that if the staggered grid velocity is discretely divergence-free, then its linear interpolation onto the staggered control volumes also satisfies the same discrete divergence-free property on those control volumes away from the boundaries of the computational domain [47]. Further, if a discrete divergence-free condition is also enforced in the ghost cells abutting the physical domain, as done in this work (see Appendix B), the interpolated advective velocity for the face-centered control volume is discretely divergence-free throughout the computational domain.

Figure 3: The shifted control volume (---, green) over which an approximation to  $(\nabla \cdot \mathbf{u}\psi)_{i-\frac{1}{2},j}$  is computed. In each diagram, the control volume is surrounding the same face-centered degree of freedom located at  $\mathbf{x}_{i-\frac{1}{2},j}$  and the upwind  $\psi_C$ , far upwind  $\psi_U$ , and downwind  $\psi_D$  are labeled according to their usage in Eq. (23). (a) The required degrees of freedom to compute the cubic upwind interpolation of  $\psi_e$  when  $u_e \geq 0$ . (b) The required degrees of freedom to compute the cubic upwind interpolation of  $\psi_e$  when  $u_e < 0$ . (c) The required degrees of freedom to compute the cubic upwind interpolation of  $\psi_n$  when  $v_n \geq 0$ . (d) The required degrees of freedom to compute the cubic upwind interpolation of  $\psi_n$  when  $v_n < 0$ .

#### 3.3. Interface tracking: the level set method

The interface between the two phases is represented by the zero level set of the scalar field  $\phi(\mathbf{x}, t)$ . It is convenient to initialize  $\phi$  to be the signed distance from the interface  $\Gamma^0 = \Gamma(0)$  (Eq. (6)), i.e.

$$\phi_{i,j}^{0} = \begin{cases} \min_{\mathbf{y} \in \Gamma^{0}} \|\mathbf{x}_{i,j} - \mathbf{y}\|, & \mathbf{x}_{i,j} \in \Omega_{0}(0) \\ -\min_{\mathbf{y} \in \Gamma^{0}} \|\mathbf{x}_{i,j} - \mathbf{y}\|, & \mathbf{x}_{i,j} \in \Omega_{1}(0), \end{cases}$$
(26)

which can be computed analytically for the simple initial interfaces considered in the present work. Note that  $\phi$  is not guaranteed to retain the signed distance property under linear advection, Eq. (9). Let  $\widetilde{\phi}^{n+1}$  denote the level set function following an advection procedure after time stepping through the interval  $[t^n, t^{n+1}]$ . We aim to reinitialize it to obtain a signed distance function  $\phi^{n+1}$ . This can be achieved by computing a steady-state solution to the Hamilton-Jacobi equation

$$\frac{\partial \phi}{\partial \tau} + \operatorname{sgn}\left(\widetilde{\phi}\right) (\|\nabla \phi\| - 1) = 0, \tag{27}$$

$$\phi(\mathbf{x}, \tau = 0) = \widetilde{\phi}(\mathbf{x}),\tag{28}$$

in which we have dropped the n+1 superscript because this process is agnostic to the particular time step under consideration. At the end of a physical time step, Eq. (27) is evolved in psuedo-time  $\tau$ , which, at steady state, produces a signed distance function satisfying the Eikonal equation  $\|\nabla\phi\|=1$ . Here, sgn denotes the sign of  $\widetilde{\phi}$ , which is either 1, -1, or 0. The discretization of Eq. (27) from the psuedo-time interval  $[\tau^m, \tau^{m+1}]$  yields

$$\frac{\phi^{m+1} - \phi^m}{\Delta \tau} + \text{sgn}\left(\tilde{\phi}_{i,j}\right) \left[ H_G\left(D_x^+ \phi_{i,j}, D_x^- \phi_{i,j}, D_y^+ \phi_{i,j}, D_y^- \phi_{i,j}\right) - 1 \right] = 0, \tag{29}$$

in which  $H_{\rm G}$  denotes a discretization of  $\|\nabla\phi\|$  using the Godunov-Hamiltonian, and  $D_x^{\pm}$  and  $D_y^{\pm}$  denote one-sided discretizations of  $\frac{\partial\phi}{\partial x}$  and  $\frac{\partial\phi}{\partial y}$ , respectively <sup>1</sup>. These are typically discretized using high-order essentially non-oscillatory (ENO) or weighted ENO (WENO) schemes [48].

It is well known that continually applying Eq. (29) will cause the interface to shift as a function of  $\tau$  [49], which will eventually shrink closed interfaces and lead to substantial spurious changes in the volume of each phase. To mitigate this numerical issue, we employ second-order ENO finite differences combined with a subcell-fix method described by Min [9]. Briefly, the subcell-fix method uses  $\tilde{\phi}$  to estimate the interface location (i.e., where  $\tilde{\phi}=0$ ) by fitting a high-order polynomial and computing an improved estimate of the one-sided derivates  $D_x^{\pm}$  and  $D_y^{\pm}$  from the polynomial fit. A dimension-by-dimension approach is followed to fit the high-order polynomial. In addition, if  $\tilde{\phi}$  is already close to the desired distance function, as is typically the case after advecting the level set field for only a single time step, further mitigation of spurious changes in mass is achieved by enforcing an immobile boundary condition near the zero level set. This approach is described by Son [8] and is easily implemented by fixing the nearest points to the interface, i.e. Eq. 29 is not applied to  $\phi_{i,j}$  satisfying  $\phi_{i,j}\phi_{p,q} \leq 0$  and  $|\phi_{i,j}| \leq |\phi_{p,q}|$  for  $(p,q) = (i\pm 1,j)$  or  $(p,q) = (i,j\pm 1)$ . Notice that if Eq. 29 is not applied to  $\phi_{i,j}$ , the subcell-fix is also effectively omitted for  $\phi_{i,j}$ . After iterating Eq. 29 to some desired convergence criteria, the level set function  $\phi^{n+1}$  is updated, and the next physical time step is carried out. In the present work, we always reinitialize the level set every time step and declare convergence when the  $L^2$  norm between subsequent psuedo-time iterations is smaller than some tolerance (taken to be  $10^{-6}$  in the present work) or when a maximum number of iterations have been carried out (taken to be the maximum grid size in one direction) — whichever happens first.

We can use the signed distance property to define the material properties at cell-centers of the staggered grid. For a mesh with uniform grid spacing  $\Delta x = \Delta y$ , we can define a smoothed Heaviside function that has

<sup>&</sup>lt;sup>1</sup>In three spatial dimensions  $H_{\rm G}$  also includes  $D_z^{\pm}$  terms.

been regularized over  $n_{\text{cells}}$  grid cells on either side of the interface,

$$\widetilde{H}_{i,j} = \begin{cases}
0, & \phi_{i,j} < -n_{\text{cells}} \Delta x, \\
\frac{1}{2} \left( 1 + \frac{1}{n_{\text{cells}} \Delta x} \phi_{i,j} + \frac{1}{\pi} \sin \left( \frac{\pi}{n_{\text{cells}} \Delta x} \phi_{i,j} \right) \right), & |\phi_{i,j}| \le n_{\text{cells}} \Delta x, \\
1, & \text{otherwise.} 
\end{cases}$$
(30)

A given material property  $\psi$  (such as  $\rho$  or  $\mu$ ) is then set in the whole domain via

$$\psi_{i,j} = \psi_0 + (\psi_1 - \psi_0)\tilde{H}_{i,j},\tag{31}$$

in which  $\psi_0$  and  $\psi_1$  denote the material property value for phases occupying  $\Omega_0$  and  $\Omega_1$  and we have assumed that  $\Omega_0$  is represented by negative  $\phi$  values (without loss of generality).

In all of the cases in the present work, we use either  $n_{\text{cells}} = 1$  or 2. In general we find that for high inertia flows, 2 grid cells of smearing leads to slightly more distorted interfaces than  $n_{\text{cells}} = 1$ . However,  $n_{\text{cells}} = 2$  leads to slightly better convergence properties for the iterative solver described in Sec. 4. We would not recommend using  $n_{\text{cells}} \geq 3$  because, in our experience, larger smearing leads to diffuse interfaces and generates spurious vortex dynamics in the vicinity of those interfaces.

# 3.4. Surface tension force

We use the continuum surface tension model of Brackbill et al. [34] to define the volumetric surface tension force in terms of the level set field

$$\mathbf{f}_{s} = \sigma \kappa \nabla \widetilde{C} = -\sigma \nabla \cdot \left( \frac{\nabla \phi}{\|\nabla \phi\|} \right) \nabla \widetilde{C}, \tag{32}$$

in which  $\sigma$  is the uniform surface tension coefficient,  $\kappa$  is the curvature of the interface computed directly from the signed distance function as

$$\kappa = -\nabla \cdot \mathbf{n} = -\nabla \cdot \left(\frac{\nabla \phi}{\|\nabla \phi\|}\right),\,$$

 ${f n}$  is the unit normal to the surface, and  $\widetilde{C}$  is a mollified version of the Heaviside function  $\widetilde{H}$  that ensures the surface tension force is applied only near the zero level set. In this work we use Peskin's four-point regularized delta function [50] to mollify the numerical Heaviside function, although other functions may also be used to smooth the transition region as described by Williams et al. [35]. Note that one could use a surface tension force function of the form  ${f f}_{\rm s}=\sigma\kappa{f n}\widetilde{\delta}$ , in which  $\widetilde{\delta}$  is a regularized version of the Dirac delta function<sup>2</sup>. However, this would not yield a discrete balance between the surface tension force and the pressure gradient [51], whereas Eq. (32) is discretely well-balanced with the pressure gradient because both  $\nabla\widetilde{C}$  and  $\nabla p$  are discretized in the same manner and at the same degrees of freedom. We refer readers to the works of Brackbill et al. [34] and Williams et al. [35] for more details on the continuum surface tension model and Francois et al. [51] for its well-balanced implementation.

# 3.5. Temporal discretization

Next, we describe the temporal discretization for both the non-conservative and conservative forms of the equations of motion. Within one time step  $[t^n,t^{n+1}]$ , we employ m cycles of fixed-point iteration to obtain an approximate solution to the fully-coupled mass transport and fluid flow problem. In this approach, the advective or convective terms and the body force are treated explicitly, and all other terms are treated implicitly. To begin time stepping, we set k=0 ( $\mathbf{u}^{n+1,0}=\mathbf{u}^n$ ,  $p^{n+\frac{1}{2},0}=p^{n-\frac{1}{2}}$ , and  $\phi^{n+1,0}=\phi^n$ ) and iterate until k=m-1. At the initial time step n=0, these quantities are obtained using the prescribed initial conditions. As described previously [28], the initial value for pressure at the start of each time step  $p^{n+\frac{1}{2},0}$ 

<sup>&</sup>lt;sup>2</sup>This is because  $\nabla \widetilde{C} \approx \mathbf{n} \widetilde{\delta}$ .

does not affect the flow dynamics nor the pressure solution at the end of the time step  $p^{n+\frac{1}{2}}$ ; rather it serves an initial guess to iterative solution of the linear system.

Although both solvers converge for a wide range of density and viscosity contrasts, the non-conservative temporal discretization is only stable for density ratios up to  $\rho_1/\rho_0 \approx 100$ . The fundamental cause for this is the discretely inconsistent transport of mass and momentum. As described by Raessi [18] and, more recently, by Ghods and Herrmann [21], inconsistencies in the the numerical mass and momentum fluxes used in the mass and momentum transport equations, respectively, can lead to numerical instabilities at density ratios greater than 100. This problem is especially prevalent in the level set methods, in which the phase mass is transported via an auxiliary field and no flux reconstruction is used. Numerical examples of instabilities for the non-conservative discretization of two phase flows with high density ratios will be shown in Sec. 7.

To prevent these instabilities for high density ratios, we extend an approach described by Desjardins and Moureau [20], in which consistent transport was achieved by solving an additional mass balance equation, Eq. (3), and by ensuring that the same numerical mass flux is used for both mass and momentum transport. A discretization of the conservative form of Eqs. (1) and (2) is necessary to achieve discrete conservation and flux compatibility. The scheme described by Desjardins and Moureau was first-order accurate and diffusive (see Appendix D). We extend this scheme to achieve at least second-order accuracy in velocity, pressure, and density.

#### 3.5.1. Non-conservative discretization

During the time interval  $[t^n, t^{n+1}]$ , for the non-conservative discretization the time stepping proceeds as follows:

1. Advect the signed distance function  $\phi$ : The level set function is updated by discretizing Eq. (9) via

$$\frac{\phi^{n+1,k+1} - \phi^n}{\Delta t} + Q\left(\mathbf{u}_{\text{adv}}^{n+\frac{1}{2},k}, \phi_{\lim}^{n+\frac{1}{2},k}\right) = 0, \tag{33}$$

in which  $Q\left(\mathbf{u}_{\mathrm{adv}}^{n+\frac{1}{2},k},\phi_{\mathrm{lim}}^{n+\frac{1}{2},k}\right) \approx \left[\nabla\cdot\left(\mathbf{u}_{\mathrm{adv}}^{n+\frac{1}{2},k}\phi_{\mathrm{lim}}^{n+\frac{1}{2},k}\right)\right]_{i,j}$  is an explicit xsPPM7-limited approximation to the linear advection term on cell centers. The midpoint velocity and level set are given by  $\mathbf{u}^{n+\frac{1}{2},k} = \frac{1}{2}\left(\mathbf{u}^{n+1,k} + \mathbf{u}^n\right)$ , and  $\phi^{n+\frac{1}{2},k} = \frac{1}{2}\left(\phi^{n+1,k} + \phi^n\right)$ . Here, the subscript "adv" indicates the staggered grid velocity on faces of cell-centered control volume, and the subscript "lim" indicates the limited value also defined on faces of the cell-centered control volume.

2. Reset the material properties  $\rho$  and  $\mu$ :

The density and viscosity in the computational domain are determined from the signed distance function via

$$\rho^{n+1,k+1} = \rho_0 + (\rho_1 - \rho_0)\widetilde{H}\left(\phi^{n+1,k+1}\right),\tag{34}$$

$$\mu^{n+1,k+1} = \mu_0 + (\mu_1 - \mu_0)\widetilde{H}\left(\phi^{n+1,k+1}\right),\tag{35}$$

in which  $\rho_i$  and  $\mu_i$  denote the density and viscosity for the two fluids, i = 0 or 1. The regularized Heaviside function is given by Eq. (30). Note that although the density and viscosity computed here are *cell-centered*, the notations  $\rho^{n+1,k+1}$  and  $\mu^{n+1,k+1}$  are also used to denote the interpolated material properties (to faces for density; to nodes in 2D, or edges in 3D for viscosity), as needed.

3. Solve the incompressible Navier-Stokes equations for  $\mathbf{u}$  and p:

The velocity and pressure are computed from the discretization of the non-conservative fluid momentum and continuity equations

$$\rho^{n+1,k+1} \left( \frac{\mathbf{u}^{n+1,k+1} - \mathbf{u}^n}{\Delta t} + \mathbf{N} \left( \mathbf{u}_{\text{adv}}^{n+\frac{1}{2},k}, \mathbf{u}_{\text{lim}}^{n+\frac{1}{2},k} \right) \right) = -\mathbf{G} p^{n+\frac{1}{2},k+1} + (\mathbf{L}_{\mu} \mathbf{u})^{n+\frac{1}{2},k+1} + \mathbf{f}^{n+\frac{1}{2}}, \quad (36)$$

$$\mathbf{D} \cdot \mathbf{u}^{n+1,k+1} = 0,\tag{37}$$

in which  $\mathbf{N}\left(\mathbf{u}_{\mathrm{adv}}^{n+\frac{1}{2},k},\mathbf{u}_{\mathrm{lim}}^{n+\frac{1}{2},k}\right) \approx \left[\left(\nabla\cdot\left(\mathbf{u}_{\mathrm{adv}}^{n+\frac{1}{2},k}u_{\mathrm{lim}}^{n+\frac{1}{2},k}\right)\right)_{i-\frac{1}{2},j},\left(\nabla\cdot\left(\mathbf{u}_{\mathrm{adv}}^{n+\frac{1}{2},k}v_{\mathrm{lim}}^{n+\frac{1}{2},k}\right)\right)_{i,j-\frac{1}{2}}\right]$  is an explicit CUI-limited approximation to the nonlinear convection term and

 $(\mathbf{L}_{\mu}\mathbf{u})^{n+\frac{1}{2},k+1}=\frac{1}{2}\left[(\mathbf{L}_{\mu}\mathbf{u})^{n+1,k+1}+(\mathbf{L}_{\mu}\mathbf{u})^{n}\right]$  is a semi-implicit approximation to the viscous strain rate. Here, the subscript "adv" indicates the interpolated advective velocity on the faces of face-centered control volume, and the subscript "lim" indicates the convective-limited value, as defined by Eq. (25). The above time-stepping scheme with m=2 is similar to a combination of Crank-Nicolson for the viscous terms and explicit midpoint rule for the convective term, making it second-order accurate in time. Notice that this scheme is semi-implicit in that explicit approximations are used for  $\rho$  and  $\mu$  as well as the advective term.

After m cycles of fixed-point iteration, the final numerical solutions are given by  $\mathbf{u}^{n+1} = \mathbf{u}^{n+1,m}$ ,  $p^{n+\frac{1}{2}} = p^{n+\frac{1}{2},m}$ , and  $\phi^{n+1} = \phi^{n+1,m}$ . We employ m=2 cycles of fixed-point iteration for all the numerical examples, which yields second-order spatio-temporal accuracy. Numerical experiments indicate that the largest stable advective CFL number for the above scheme with m=2 is 0.5.

## 3.5.2. Conservative discretization

During the time interval  $[t^n, t^{n+1}]$ , the time stepping proceeds as follows for the discretely consistent, conservative discretization:

1. Advect the signed distance function  $\phi$ : The level set function is updated by discretizing Eq. (9) via

$$\frac{\phi^{n+1,k+1} - \phi^n}{\Delta t} + Q\left(\mathbf{u}_{\text{adv}}^{n+\frac{1}{2},k}, \phi_{\lim}^{n+\frac{1}{2},k}\right) = 0, \tag{38}$$

which is the same update used for the non-conservative discretization described earlier.

2. Reset the material property  $\mu$ :

The viscosity, but not the density, in the computational domain is determined from the signed distance function via

$$\mu^{n+1,k+1} = \mu_0 + (\mu_1 - \mu_0)\widetilde{H}\left(\phi^{n+1,k+1}\right). \tag{39}$$

3. Advect the face-centered density and compute convective derivative C:

We next update the density and compute the nonlinear convective term in a way that ensures discrete consistency in the mass and momentum fluxes. First, we solve a discretized density update equation on *faces* of the staggered grid using the third-order accurate strong stability preserving Runge-Kutta (SSP-RK3) time integrator [23]

$$\check{\boldsymbol{\rho}}^{(1)} = \check{\boldsymbol{\rho}}^n - \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^n, \check{\boldsymbol{\rho}}_{\text{lim}}^n \right), \tag{40}$$

$$\check{\boldsymbol{\rho}}^{(2)} = \frac{3}{4} \check{\boldsymbol{\rho}}^n + \frac{1}{4} \check{\boldsymbol{\rho}}^{(1)} - \frac{1}{4} \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^{(1)}, \check{\boldsymbol{\rho}}_{\text{lim}}^{(1)} \right), \tag{41}$$

$$\tilde{\rho}^{n+1,k+1} = \frac{1}{3}\tilde{\rho}^n + \frac{2}{3}\tilde{\rho}^{(2)} - \frac{2}{3}\Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^{(2)}, \tilde{\rho}_{\text{lim}}^{(2)} \right), \tag{42}$$

in which  $\mathbf{R}\left(\mathbf{u}_{\mathrm{adv}}, \check{\boldsymbol{\rho}}_{\mathrm{lim}}\right) \approx \left[\left(\nabla \cdot \left(\mathbf{u}_{\mathrm{adv}} \check{\boldsymbol{\rho}}_{\mathrm{lim}}\right)\right)_{i-\frac{1}{2},j}, \left(\nabla \cdot \left(\mathbf{u}_{\mathrm{adv}} \check{\boldsymbol{\rho}}_{\mathrm{lim}}\right)\right)_{i,j-\frac{1}{2}}\right]$  is an explicit CUI-limited approximation to the linear density advection term. In contrast with the non-conservative form, the scalar density variable is defined and directly evolved on faces of the staggered grid. Hence, we distinguish  $\check{\boldsymbol{\rho}}$ , the face-centered density obtained via the SSP-RK3 integrator, from  $\boldsymbol{\rho}$ , the face-centered density that is reset from the level set fields. Here, the subscript "adv" indicates the interpolated advective velocity on the faces of face-centered control volume, and the subscript "lim" indicates the limited value, as defined by Eq. (25). Note that this time integration procedure is occurring within the overall fixed-point iteration scheme. We have found it to be crucial to use appropriately interpolated and

extrapolated velocities to maintain the accuracy of the scheme. To wit, for the first cycle (k=0), the velocities are

$$\mathbf{u}^{(1)} = 2\mathbf{u}^n - \mathbf{u}^{n-1},\tag{43}$$

$$\mathbf{u}^{(2)} = \frac{3}{2}\mathbf{u}^n - \frac{1}{2}\mathbf{u}^{n-1}.\tag{44}$$

For all remaining cycles (k > 0), the velocities are

$$\mathbf{u}^{(1)} = \mathbf{u}^{n+1,k},\tag{45}$$

$$\mathbf{u}^{(2)} = \frac{3}{8}\mathbf{u}^{n+1,k} + \frac{3}{4}\mathbf{u}^n - \frac{1}{8}\mathbf{u}^{n-1}.$$
 (46)

Notice that  $\mathbf{u}^{(1)}$  is an approximation to  $\mathbf{u}^{n+1}$ , and  $\mathbf{u}^{(2)}$  is an approximation to  $\mathbf{u}^{n+\frac{1}{2}}$ . Similarly,  $\check{\boldsymbol{\rho}}^{(1)}$ is an approximation to  $\tilde{\rho}^{n+1}$ , and  $\tilde{\rho}^{(2)}$  is an approximation to  $\tilde{\rho}^{n+\frac{1}{2}}$ .

4. Solve the incompressible Navier-Stokes equations for  $\mathbf{u}$  and p: Using the previously computed density and convective term, the velocity and pressure are computed from the discretization of the conservative fluid momentum and continuity equations

$$\frac{\check{\boldsymbol{\rho}}^{n+1,k+1}\mathbf{u}^{n+1,k+1} - \check{\boldsymbol{\rho}}^{n}\mathbf{u}^{n}}{\Delta t} + \mathbf{C}\left(\mathbf{u}_{\text{adv}}^{(2)}, \check{\boldsymbol{\rho}}_{\text{lim}}^{(2)}\mathbf{u}_{\text{lim}}^{(2)}\right) = -\mathbf{G}p^{n+\frac{1}{2},k+1} + (\mathbf{L}_{\mu}\mathbf{u})^{n+\frac{1}{2},k+1} + \mathbf{f}^{n+\frac{1}{2}}, \tag{47}$$

$$\mathbf{D} \cdot \mathbf{u}^{n+1,k+1} = 0, \tag{48}$$

$$\mathbf{D} \cdot \mathbf{u}^{n+1,k+1} = 0,\tag{48}$$

in which the approximation to the convective derivative is given by

$$\mathbf{C}\left(\mathbf{u}_{\mathrm{adv}}^{(2)}, \check{\boldsymbol{\rho}}_{\mathrm{lim}}^{(2)} \mathbf{u}_{\mathrm{lim}}^{(2)}\right) \approx \left[\left(\nabla \cdot \left(\mathbf{u}_{\mathrm{adv}}^{(2)} \check{\boldsymbol{\rho}}_{\mathrm{lim}}^{(2)} u_{\mathrm{lim}}^{(2)}\right)\right)_{i-\frac{1}{2},j}, \left(\nabla \cdot \left(\mathbf{u}_{\mathrm{adv}}^{(2)} \check{\boldsymbol{\rho}}_{\mathrm{lim}}^{(2)} v_{\mathrm{lim}}^{(2)}\right)\right)_{i,j-\frac{1}{2}}\right],\tag{49}$$

and uses the same velocity  $\mathbf{u}_{\mathrm{adv}}^{(2)}$  and density  $\boldsymbol{\check{\rho}}_{\mathrm{lim}}^{(2)}$  used to update  $\boldsymbol{\check{\rho}}^{n+1,k+1}$  in Eq (42). This is the key requirement for consistent mass and momentum transport.

Results presented in Sec. 7 demonstrate that the consistent discretization is stable for density ratios of at least 10<sup>6</sup> and produce significantly more accurate results than the inconsistent discretization for realistic two phase flow simulations.

For the conservative form as written, the density evolves along with the velocity and pressure at all times, with an initial value of  $\check{\rho}$  directly specified on the cell faces. We note the we can instead synchronize the face-centered density via the signed distance function (averaged to faces) at time step n, i.e.,  $\rho^n =$  $\rho_0 + (\rho_1 - \rho_0)\widetilde{\boldsymbol{H}}(\phi^n)$ , while still maintaining numerical stability. When resetting the mass density in each time step, the new density  $\check{\boldsymbol{\rho}}^{n+1,k+1}$  (used in solving for  $\mathbf{u}$  and p) is still obtained via the SSP-RK3 update; however it is discarded at the end of the time step. When density synchronization is enabled,  $\rho^n$  is used in place of  $\check{\rho}^n$  wherever a density field is needed at time level n in Eqs. (40) – (42) and Eq. (47). Finally, we emphasize that using a level-set synchronized density at time level n is recommended to avoid significant distortions in the interface for high density ratio flows, which are generated by accumulation of errors in advecting  $\check{\rho}$  over the course of the simulation.<sup>3</sup> Sec. 6.3 investigates differences between evolving and resetting the density field, and all of the numerical examples in Sec. 7 use density synchronization.

Note that in both Eqs. (36) and (47) we only considered the volumetric body force term  $\mathbf{f}^{n+\frac{1}{2}}$ . One can approximate the surface tension force  $\mathbf{f}_{s}^{n+\frac{1}{2}}$  as a function of level set field by  $\mathbf{f}_{s}(\phi^{n+\frac{1}{2},k+1})$ , in which  $\phi^{n+\frac{1}{2},k+1} = \frac{1}{2} (\phi^{n+1,k+1} + \phi^n).$ 

Finally, as discussed previously, there is no guarantee that the level set function will remain a signed distance function under advection by an external velocity field. Thus, at the beginning of each time step, the reinitialization procedure described in Section 3.3 is used. Reinitializion is required to accurately evaluate

<sup>&</sup>lt;sup>3</sup>This justifies the additional computational cost incurred by level set and volume-of-fluid methods.

regularized Heaviside functions near the interface, as needed both to determine material properties and to evaluate interfacial forces related to surface tension.

# 3.6. Adaptive mesh refinement

Some cases presented in this work use a structured adaptive mesh refinement (SAMR) framework to discretize the equations of motion. These discretization approaches describe the computational domain as composed of multiple grid levels, which together form a grid hierarchy. Assuming uniform and isotropic mesh refinement, a grid hierarchy with  $\ell$  levels and with a grid spacing  $\Delta x_0$ ,  $\Delta y_0$ , and  $\Delta z_0$  on the coarsest grid level has grid spacings  $\Delta x_{\min} = \Delta x_0/n_{\rm ref}^{\ell-1}$ ,  $\Delta y_{\min} = \Delta y_0/n_{\rm ref}^{\ell-1}$ , and  $\Delta z_{\min} = \Delta z_0/n_{\rm ref}^{\ell-1}$  on the finest grid level, in which  $n_{\rm ref}$  is the integer refinement ratio between levels. (Although not considered here, both the numerical method and software implementation allow for general refinement ratios.)

The locally refined meshes can be static, in that they occupy a fixed region in the domain  $\Omega$ , or adaptive, in that some criteria of interest is used to "tag" coarse cells for refinement. In our current implementation, cells are refined based on two criteria: 1) if the local magnitude of vorticity  $\|\omega\|_{i,j} = \|\nabla \times \mathbf{u}\|_{i,j}$  exceeds a relative threshold and 2) if the signed distance function  $\phi_{i,j}$  is within some threshold of zero. This ensures that the important dynamics (e.g., regions of high velocity gradients or the multiphase interfaces) are always approximated using appropriate mesh spacings.

Each time the grid hierarchy is regenerated, quantities must be transferred from the old grid hierarchy to the new grid hierarchy. In newly refined regions, the fluid velocity  $\mathbf{u}$  is interpolated from the old coarse grid using a conservative, discretely divergence- and curl-preserving interpolation scheme [52]. Similarly, the level set  $\phi$  and material properties  $\rho$  and  $\mu$  are interpolated from the old coarse grid using a conservative linear interpolation scheme, which ensures that positivity is maintained for density and viscosity. The pressure p is interpolated using a simple non-conservative linear interpolation scheme as it is only used as an initial approximation to the updated pressure. In newly coarsened regions, all of the quantities are defined as conservative averages of the old fine-grid data. These interpolations are used to define ghost cell values at the coarse-fine interface, which enables composite-grid approximations to the linear operators  $\mathbf{D} \cdot \mathbf{p}$ ,  $\mathbf{G}$ ,  $\mathbf{L}_{\mu}$ , and  $\mathbf{L}_{\wp}$  described earlier in Sec. 3.1. We refer readers to prior work by Griffith [53] for additional details on the AMR discretization methods.

#### 4. Solution methodology

This section describes the linear solvers required to compute a solution to the fully-coupled, time-dependent incompressible Stokes system

$$\begin{bmatrix} \frac{1}{\Delta t} \wp^{n+1,k+1} - \frac{1}{2} \mathbf{L}_{\mu}^{n+1,k+1} & \mathbf{G} \\ -\mathbf{D} \cdot & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u}^{n+1,k+1} \\ p^{n+\frac{1}{2},k+1} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{\mathbf{u}} \\ \mathbf{0} \end{bmatrix}, \tag{50}$$

in which  $\wp^{n+1,k+1}$  is a diagonal matrix of face-centered densities corresponding to each velocity degree of freedom ( $\wp \equiv \rho$  as defined in Eq. (34) for the non-conservative discretization, and  $\wp \equiv \check{\rho}$  as defined in Eq. (42) for the conservative discretization), and the right-hand side of the momentum equation is lumped into  $\mathbf{f_u}$ , whose value depends on the discretization type. For non-conservative form, it is

$$\mathbf{f}_{\mathbf{u}} = \left(\frac{1}{\Delta t} \boldsymbol{\rho}^{n+1,k+1} + \frac{1}{2} \mathbf{L}_{\boldsymbol{\mu}}^{n}\right) \mathbf{u}^{n} - \boldsymbol{\rho}^{n+1,k+1} \mathbf{N} \left(\mathbf{u}_{\text{adv}}^{n+\frac{1}{2},k} \mathbf{u}_{\text{lim}}^{n+\frac{1}{2},k}\right) + \mathbf{f}^{n+\frac{1}{2}} + \mathbf{f}_{\text{s}}^{n+\frac{1}{2}}, \tag{51}$$

and for conservative form with density synchronization, it is

$$\mathbf{f}_{\mathbf{u}} = \left(\frac{1}{\Delta t} \boldsymbol{\rho}^n + \frac{1}{2} \mathbf{L}_{\boldsymbol{\mu}}^n\right) \mathbf{u}^n - \mathbf{C}\left(\mathbf{u}_{\text{adv}}^{(2)}, \boldsymbol{\check{\rho}}_{\text{lim}}^{(2)} \mathbf{u}_{\text{lim}}^{(2)}\right) + \mathbf{f}^{n+\frac{1}{2}} + \mathbf{f}_{\text{s}}^{n+\frac{1}{2}}.$$
 (52)

The operator on the left-hand side of Eq. (50) is the time-dependent incompressible staggered Stokes operator. To solve this system of equations, we use a flexible GMRES (FGMRES) Krylov solver [54] preconditioned by a variable-coefficient projection method solver that is hybridized with a local-viscosity solver. The efficient preconditioner enables rapid convergence of the variable-coefficient iterative Stokes solver; between 1 and 20 Krylov iterations are observed for all cases considered here. We briefly describe the hybrid preconditioner

here and refer the readers to the work of Griffith [28] and Cai et al. [29] for further details on the constant-coefficient and variable-coefficient preconditioners, respectively.

## 4.1. Projection preconditioner

The Stokes system can be succinctly written as

$$\mathbf{B} \begin{bmatrix} \mathbf{x_u} \\ \mathbf{x_p} \end{bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{G} \\ -\mathbf{D} \cdot & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{x_u} \\ \mathbf{x_p} \end{bmatrix} = \begin{bmatrix} \mathbf{b_u} \\ \mathbf{b_p} \end{bmatrix}, \tag{53}$$

in which **B** is the Stokes operator,  $\mathbf{A} = \frac{1}{\Delta t} \wp^{n+1,k+1} - \frac{1}{2} \mathbf{L}_{\mu}^{n+1,k+1}$ ,  $\mathbf{x_u}$  and  $\mathbf{x_p}$  denote the velocity and pressure degrees of freedom, and  $\mathbf{b_u}$  and  $\mathbf{b_p} = \mathbf{0}$  denote the right-hand sides of the momentum and continuity equations, respectively.

Saddle-point problems such as Eq. 53 are ill-conditioned, and effective preconditioning strategies are needed to obtain scalable Krylov methods for such equations. The particular preconditioner used in the present work is based on the fractional-step projection method, which is commonly used to solve the incompressible Navier-Stokes equations [55, 56] in an operator-splitting manner. The conversion of the projection method to a projection preconditioner  $\mathbf{P}_{\text{proj}}^{-1}$  was described for constant material properties by Griffith [28], and for variable material properties by Cai et al. [29].

For theoretical completeness and to interpret solver scalability results of section 6.5, we briefly outline the derivation and form of  $\mathbf{P}_{\text{proj}}^{-1}$  and provide some practical considerations for the linear solvers towards the end of the section. To begin, we first note that for the Stokes preconditioner,  $\mathbf{x_u}$  and  $\mathbf{x_p}$  should be interpreted as error in velocity and pressure degrees of freedom, respectively, and  $\mathbf{b_u}$  and  $\mathbf{b_p} \neq \mathbf{0}$  should be interpreted as residuals of the momentum and continuity constraint equations, respectively. As is done in the conventional projection method, we first compute an intermediate approximation to  $\mathbf{x_u}$  by solving

$$\mathbf{A}\widehat{\mathbf{x}}_{\mathbf{u}} = \mathbf{b}_{\mathbf{u}}.\tag{54}$$

Note that this approximation does not in general satisfy the discrete continuity equation i.e.,  $-\mathbf{D} \cdot \hat{\mathbf{x}}_{\mathbf{u}} \neq \mathbf{b}_{\mathbf{p}}$ . This condition can be satisfied by introducing an auxiliary scalar field  $\boldsymbol{\theta}$  and writing out a fractional timestep

$$\wp \frac{\mathbf{x_u} - \widehat{\mathbf{x}_u}}{\Delta t} = -\mathbf{G}\boldsymbol{\theta},\tag{55}$$

$$-\mathbf{D} \cdot \mathbf{x_u} = \mathbf{b_p}. \tag{56}$$

Multiplying Eq. (55) by  $\wp^{-1}$ , taking the discrete divergence  $\mathbf{D}$ , and substituting in Eq. (56) yields the density-weighted Poisson problem

$$-\mathbf{D} \cdot \boldsymbol{\wp}^{-1} \mathbf{G} \boldsymbol{\theta} = -\mathbf{L}_{\boldsymbol{\wp}} \boldsymbol{\theta} = -\frac{1}{\Delta t} \left( \mathbf{b}_{\mathbf{p}} + \mathbf{D} \cdot \hat{\mathbf{x}}_{\mathbf{u}} \right). \tag{57}$$

The updated velocity solution can be computed as

$$\mathbf{x_u} = \widehat{\mathbf{x}_u} - \Delta t \wp^{-1} \mathbf{G} \boldsymbol{\theta}. \tag{58}$$

In the conventional projection method for constant viscosity, the pressure solution can be computed as  $\mathbf{x}_{\mathbf{p}} = \left(\mathbf{I} - \frac{\Delta t}{2} \mu \mathbf{L}_{\wp}\right) \boldsymbol{\theta}$ . For preconditioning purposes, it was shown in [29] that a reasonable approximation to the pressure solution in the presence of a spatially varying viscosity can be written as

$$\mathbf{x_p} \approx \left(\mathbf{I} - \frac{\Delta t}{2} \mathbf{L_{\wp}} 2\boldsymbol{\mu}\right) \boldsymbol{\theta},$$
 (59)

in which  $\mu$  is a diagonal matrix of cell-centered viscosities corresponding to each pressure degree of freedom. The above form of Eq. (59) comes from an approximate Schur complement of the Stokes system Eq. (53) and we refer readers to [29] for more details. Finally, the projection preconditioner can be written in matrix form as

$$\mathbf{P}_{\text{proj}}^{-1} = \begin{bmatrix} \mathbf{I} & -\Delta t \boldsymbol{\wp}^{-1} \mathbf{G} \\ \mathbf{0} & \mathbf{I} - \frac{\Delta t}{2} \mathbf{L}_{\boldsymbol{\wp}} 2\boldsymbol{\mu} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & (-\mathbf{L}_{\boldsymbol{\wp}})^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\frac{1}{\Delta t} \mathbf{D} \cdot & -\frac{1}{\Delta t} \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{A}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \tag{60}$$

in which  $\mu$  is a diagonal matrix of cell-centered viscosities corresponding to each pressure degree of freedom. This preconditioner can be obtained from an approximate block factorization of the Stokes system; see Cai et al. [29] for further details.

There are several advantages to using the projection method as a preconditioner rather than as a solver. We summarize them here:

- The projection method is an operator splitting approach that requires the specification of artificial boundary conditions for the velocity and pressure fields. This split affects the global order of accuracy of the solution [57]. For example, consider the imposition of normal traction on domain boundary points  $\mathbf{x}_b \in \partial \Omega$ , i.e,  $\mathbf{n} \cdot \boldsymbol{\sigma} \cdot \mathbf{n} = -p + 2\mu \frac{\partial u_n}{\partial n} = F(\mathbf{x}_b, t)$  as detailed in Appendix B. Here,  $u_n$  represents the normal velocity and  $F(\mathbf{x}_b, t)$  is the imposed function (possibly of time) defined on the boundary  $\partial \Omega$ . The normal traction boundary condition requires a linear combination of discretized pressure and velocity variables. This combination can be accounted for in the Stokes operator  $\mathbf{B}$  directly. However, it is not possible to split the linear combination a priori into the velocity operator  $\mathbf{A}$  and pressure operator  $\mathbf{L}_{\wp}$  used by the projection solver. In contrast, this artificial split (or artificial boundary conditions) in the projection preconditioner  $^4$  does not affect the final solution of velocity and pressure obtained from the outer Krylov solver. A preconditioner can only affect the convergence rate of the iterative solver, not the accuracy of the converged solution.
- Projection methods are derived by assuming that certain operators commute. Typically, this assumption is only satisfied in the case of constant-coefficient operators defined on periodic computational domains. For variable-coefficient operators, there is an unavoidable commutator error that is associated with using the projection method as a solver.
- Finally, using the projection method as a preconditioner is no less efficient than using it as a solver, as demonstrated by Griffith [28] and Cai et al. [29]. Our tests in Sec. 6.5 also support these previous findings.

We remark that in contrast with the constant coefficient projection preconditioner [28], both the Stokes operator  $\bf B$  and the preconditioner  ${\bf P}_{\rm proj}^{-1}$  will change from time step to time step, and even cycle-to-cycle, because the density and viscosity generally will varying in both space and time. For the Krylov solver, it is vital that  $\bf B$  be updated every time the material properties are updated. It is easy to achieve this in practice by using a matrix-free implementation of the present method. In contrast, we find that there is no need to update  ${\bf P}_{\rm proj}^{-1}$  at the same frequency. Specifically, we find that in many cases, it is computationally efficient to update  ${\bf P}_{\rm proj}^{-1}$  only every 5 to 50 time steps to avoid impairing the convergence of the FGMRES iterations.

## 4.2. Subdomain solvers

Because Krylov methods require only the evaluation of the action of the preconditioning operator, we do not actually form  $\mathbf{P}_{\text{proj}}^{-1}$ , which would be a dense matrix. Notice, however, that evaluating the action of the projection preconditioner  $\mathbf{P}_{\text{proj}}^{-1}$  requires the solution to momentum and pressure-Poisson equations. In practice, these equations are only solved approximately by so-called subdomain solvers: 1) the velocity subdomain system, which requires the (approximate) application of  $\mathbf{A}^{-1}$ , and 2) the pressure subdomain system, which requires the (approximate) application of  $\mathbf{L}_{\wp}^{-1}$ . We again employ iterative methods for these inner subdomain solvers to produce approximate solutions up to a specified relative residual tolerance  $\epsilon_{\text{sub}}$ . It is neither recommended nor required that tight tolerances be used. We find that for the cases considered in this work,  $\epsilon_{\text{sub}} = 10^{-2}$  is sufficient to produce a convergent outer solver that achieves a relative residual tolerance of  $\epsilon_{\text{Stokes}} = 10^{-12}$  for Eq. (53) within 1 to 20 FGMRES iterations, even for highly contrasting material properties, or on highly refined grids.

For both the velocity and pressure subdomain problems, we employ a Richardson solver with a single multigrid V-cycle of an FAC (fast adaptive composite) preconditioner [58], respectively. For each multigrid level, for both the velocity and pressure problems, 3 iterations of Gauss-Seidel smoothing are used. The

<sup>&</sup>lt;sup>4</sup>Since preconditioners employ homogenous versions of the boundary conditions, one can use homogeneous Dirichlet conditions for pressure and homogeneous Neumann conditions for the normal velocity component. This treatment is followed in the current work for the projection preconditioner whenever normal traction boundary conditions are employed in the fluid solver.

solvers chosen here are shown to converge with density and viscosity contrasts up to  $10^6$  in Sec. 6. Homogenous Dirichlet or Neumann boundary conditions, similar to those used in a projection method-based solver, are prescribed for the subdomain problems. We remark that choosing boundary conditions for the inner solvers that are incompatible with the physical boundary conditions imposed in the outer solver can cause the outer FGMRES iterations to fail to converge. More details on the choice of compatible subdomain solver boundary conditions are provided by Griffith [28]. Unlike the case of a projection method-based solver, however, the choice of these boundary conditions do not affect the final solution or the accuracy of the outer solver so long as that outer solver converges.

#### 5. Software implementation

The algorithms and fluid solver described here are implemented in the IBAMR library [59], which is open-source C++ simulation software focused on immersed boundary methods with adaptive mesh refinement. All of the numerical examples presented here are publicly available via https://github.com/IBAMR/IBAMR. IBAMR relies on SAMRAI [60, 61] for Cartesian grid management and the AMR framework. Linear and nonlinear solver support in IBAMR is provided by the PETSc library [62, 63, 64].

#### 6. Solver accuracy and performance

This section investigates the accuracy and convergence rates for the multiphase flow solver, in both non-conservative and conservative form, with various choices of boundary conditions. In all cases, the computed solution from the solver is compared against manufactured solutions on uniform and locally refined grids. We also demonstrate the robustness and scalability of the flow solver for highly contrasting densities and viscosities and also under grid refinement in this section. We employ m=2 cycles of fixed-point iteration for all cases considered in this section. To assess the order of accuracy, errors in the cell centered pressure p are computed using standard formulae for the  $L^1$  and  $L^\infty$  norms

$$||p||_1 = \sum_{i=0}^{N_x - 1} \sum_{j=0}^{N_y - 1} |p_{i,j}| \, \Delta x \Delta y, \tag{61}$$

$$||p||_{\infty} = \max_{\mathbf{x}_{i,j} \in \Omega} |p_{i,j}|. \tag{62}$$

The  $L^1$  error in the face centered velocity  $\mathbf{u}$  is computed using a simple modification for the  $L^1$  norms described in [28], which ensures that  $\|(1,0)\|_1 = \|(0,1)\|_1 = 1$ ; the  $L^1$  norm is computed as  $\|\mathbf{u}\|_1 = \|(u,v)\|_1 = \|u\|_1 + \|v\|_1$ , with

$$||u||_{1} = \frac{1}{2} \sum_{i=0}^{N_{y}-1} \left| u_{-\frac{1}{2},j} \right| \Delta x \Delta y + \sum_{i=1}^{N_{x}-1} \sum_{j=0}^{N_{y}-1} \left| u_{i-\frac{1}{2},j} \right| \Delta x \Delta y + \frac{1}{2} \sum_{j=0}^{N_{y}-1} \left| u_{N_{x}-\frac{1}{2},j} \right| \Delta x \Delta y, \tag{63}$$

$$||v||_1 = \frac{1}{2} \sum_{i=0}^{N_x - 1} \left| v_{i, -\frac{1}{2}} \right| \Delta x \Delta y + \sum_{i=0}^{N_x - 1} \sum_{j=1}^{N_y - 1} \left| v_{i, j - \frac{1}{2}} \right| \Delta x \Delta y + \frac{1}{2} \sum_{i=0}^{N_x - 1} \left| v_{i, N_y - \frac{1}{2}} \right| \Delta x \Delta y.$$
 (64)

Finally, the  $L^{\infty}$  norm of the face centered velocity is computed as  $\|\mathbf{u}\|_{\infty} = \|(u,v)\|_{\infty} = \max(\|u\|_{\infty}, \|v\|_{\infty})$ , with

$$||u||_{\infty} = \max_{\mathbf{x}_{i-\frac{1}{2},j} \in \Omega} |u_{i-\frac{1}{2},j}|,$$
 (65)

$$||v||_{\infty} = \max_{\mathbf{x}_{i,j-\frac{1}{2}} \in \Omega} |v_{i,j-\frac{1}{2}}|.$$
 (66)

The presented convergence rates are essentially the same independent of the time at which these errors are evaluated. Unless otherwise stated, a grid size of  $N \times N$  is used to discretize the computational domain and a relative convergence tolerance of  $\epsilon_{\text{Stokes}} = 10^{-12}$  is specified for the FGMRES solver in all of these cases.

Figure 4: The (a) density and (b) viscosity fields, along with the initial velocity vectors for the manufactured solution described in Sec. 6.1

.

For many of the manufactured solutions considered in this section, a smoothing parameter  $\delta$  is used to ensure that the density and viscosity fields are transitioned from low values to high values over a spatial region of constant width. The specific values of  $\delta$  are chosen to ensure that the coarsest grid in each convergence study is able to resolve this region over at least 1.5 grid cells. Moreover, a constant spatial transition width ensures that the same exact analytical solution is considered on all grids, which makes the order-of-accuracy results consistent.

# 6.1. Non-conservative form: Effect of boundary conditions

We begin by considering the non-conservative set of equations, (4)–(5). A manufactured solution for velocity and pressure is given by

$$u(\mathbf{x},t) = 2\pi\cos(2\pi x)\cos(2\pi t - 2\pi y),\tag{67}$$

$$v(\mathbf{x}, t) = -2\pi \sin(2\pi x) \sin(2\pi t - 2\pi y) - \sin(2\pi t - 2\pi x),\tag{68}$$

$$p(\mathbf{x}, t) = -2\pi \sin(2\pi t - 2\pi x)\cos(2\pi t - 2\pi y),\tag{69}$$

together with time-independent density and viscosity fields of the form

$$\rho(\mathbf{x}) = \rho_0 + \frac{\rho_1}{2} \left( \tanh \left( \frac{0.1 - \sqrt{(x - 0.5)^2 + (y - 0.5)^2}}{\delta} \right) + 1 \right), \tag{70}$$

$$\mu(\mathbf{x}) = \mu_0 + \mu_1 + \mu_1 \sin(2\pi x)\cos(2\pi y),\tag{71}$$

The density, viscosity, and initial velocity fields are shown in Fig. 4. Plugging Eqs. (67)-(71) into the non-conservative momentum equation (4) yields a forcing term  $\mathbf{f}(\mathbf{x},t)$  that produces the specified solution. We set  $\rho_0 = 1$ ,  $\rho_1 = -\rho_0 + 10^3$ ,  $\mu_0 = 10^{-4}$ , and  $\mu_1 = -\mu_0 + 10^{-2}$ , which yields variations in density and viscosity are set to be similar to that of air and water. The computational domain is the unit square,  $\Omega = [0, L]^2 = [0, 1]^2$ . The smoothing parameter is set to  $\delta = 0.05L$ .

We impose periodic boundary conditions in the x-direction and various boundary conditions in the y-direction. The boundary conditions in the y-direction are:

- specified normal and tangential velocities, denoted as "vel-vel";
- specified normal velocity with specified tangential traction, denoted as "vel-tra";
- specified normal traction with specified tangential velocity, denoted as "tra-vel";

Figure 5:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the non-conservative manufactured solution with periodic boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

- specified normal and tangential tractions, denoted as "tra-tra";
- periodic boundary conditions denotes as "periodic".

The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U=1. Errors in the velocity and pressure are computed at time T=tU/L=0.1 with a uniform time step  $\Delta t=1/(15.625N)$ , which yields an approximate CFL number of 0.5. Figs. 5–9 show the discrete  $L^1$  and  $L^\infty$  errors for velocity and pressure as a function of grid size. Second-order convergence rates are observed for both velocity and pressure in both norms. We note that at lower resolutions, the pointwise convergence rates at coarser resolutions are less than two for vel-vel boundary conditions (see Fig. 6(a)), although second-order convergence rates are ultimately obtained on finer grids. We remark that reduction in accuracy at lower resolution is observed for small base viscosity; at higher (base) viscosities, we see second-order convergence rates at all the resolutions considered for the vel-vel boundary conditions (data not shown). This is also consistent with what was observed for the unsplit discretization of the constant coefficient incompressible Navier-Stokes equations in Griffith [28]. These tests show that the present numerical discretization and boundary treatment maintains the pointwise second-order accuracy for a variety of physical boundary conditions.

## 6.2. Non-conservative form: Effect of density and viscosity ratios

Next, we verify the accuracy of the solver/discretization for a wide range of density and viscosity ratios. A manufactured solution for the non-conservative form is taken to be

$$u(\mathbf{x},t) = -\cos(2\pi t - 2\pi x)\sin(2\pi t - 2\pi y),\tag{72}$$

$$v(\mathbf{x},t) = \sin(2\pi t - 2\pi x)\cos(2\pi t - 2\pi y) + \cos(t - 2\pi x),\tag{73}$$

$$p(\mathbf{x},t) = \sin(2\pi t - 2\pi x)\sin(2\pi t - 2\pi y),\tag{74}$$

with time-independent density and viscosity fields,

$$\rho(\mathbf{x}) = \rho_0 \left( \frac{R_\rho - 1}{2} \tanh \left( \frac{0.1 - \sqrt{(x - 0.5)^2 + (y - 0.5)^2}}{\delta} \right) + \frac{R_\rho + 1}{2} \right), \tag{75}$$

$$\mu(\mathbf{x}) = \mu_0 \left( \frac{R_{\mu} - 1}{2} \tanh \left( \frac{0.1 - \sqrt{(x - 0.5)^2 + (y - 0.5)^2}}{\delta} \right) + \frac{R_{\mu} + 1}{2} \right). \tag{76}$$

Figure 6:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the non-conservative manufactured solution with specified normal and tangential velocity (vel-vel) boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

Figure 7:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the non-conservative manufactured solution with specified normal velocity and tangential traction (vel-tra) boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

Figure 8:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the non-conservative manufactured solution with specified normal traction and tangential velocity (tra-vel) boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

Figure 9:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the non-conservative manufactured solution with specified normal and tangential traction (tra-tra) boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

Figure 10: The (a) density and (b) viscosity fields, along with the initial velocity vectors for the manufactured solution described in Sec. 6.2.

Physically, this describes a "bubble" centered in the computational domain  $\Omega = [0, L]^2 = [0, 1]^2$ . The density (viscosity) in the domain varies smoothly between  $\rho_0$  ( $\mu_0$ ) outside of the domain to  $R_\rho \cdot \rho_0$  ( $R_\mu \cdot \mu_0$ ), indicating a density (viscosity) ratio of  $R_\rho$  ( $R_\mu$ ). The smoothing parameter is set to  $\delta = 0.03L$ . The density, viscosity, and initial velocity fields are shown in Fig. 10.

The effect of varying density ratio  $R_{\rho}$  is considered first. The outer viscosity is set to  $\mu_0 = 10^{-4}$  with viscosity ratio  $R_{\mu} = 10^{1}$ , while the outer density is set to  $\rho_0 = 10^{0}$ . Density ratios of  $R_{\rho} = 10^{1}, 10^{2}, 10^{3}, 10^{4}, 10^{5}, 10^{6}$  are considered. For all physical boundaries, specified normal velocity and tangential traction boundary conditions are used. The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U=1. Errors in the velocity and pressure are computed at time T=tU/L=0.1 using a uniform time step  $\Delta t=1/(6.25N)$ , which yields an approximate CFL number of 0.3.

Fig. 11 shows the  $L^1$  and  $L^{\infty}$  errors for velocity and pressure as a function of grid size. Second-order convergence rates are achieved for velocity and pressure in both norms. It is clear that for a given grid size, the error increases as a function of density ratio. Additionally, this increase in error is more pronounced in the pressure than in the velocity. This is unsurprising: high density ratio simulations need to be adequately refined in order to accurately resolve the pressure jump across a dense region. We remark that for many air-water interface impact problems that are prevalent in ocean and marine engineering, pressure forces dominate viscous traction. Therefore, high accuracy in the pressure is desirable for this class of applications.

Next, we consider the effect of varying viscosity ratio. The outer density is set to  $\rho_0 = 10^0$  with density ratio  $R_{\rho} = 10^1$ , while the outer viscosity is set to  $\mu_0 = 10^{-4}$ . Viscosity ratios of  $R_{\mu} = 10^1, 10^2, 10^3, 10^4, 10^5, 10^6$  are considered. The same grid sizes and time step from the varying density case are used.

Fig. 12 shows the  $L^1$  and  $L^{\infty}$  errors for velocity and pressure as a function of grid size. We again observe second-order convergence rates for both velocity and pressure. At a given grid size, the errors increase as a function of viscosity ratio, although the growth is not as significant as in the varying density case. These tests show that the present numerical discretization maintains the desired order of accuracy for a wide range of fluid properties.

# 6.3. Conservative form: Effect of density evolution and synchronization

In this next case, we verify the effect of consistent mass density update and conservative discretization on the order of accuracy of the computed solution. For this test case we take the velocity and pressure solutions

Figure 11: Errors as a function of grid size N for varying density ratios  $\rho_R=10^1-10^6$  with  $\rho_0=10^0$  and constant viscosity ratio  $\mu_R=10^1$  with  $\mu_0=10^{-4}$  for a non-conservative manufactured solution. Normal velocity and tangential traction boundary conditions are specified at all physical boundaries in every case. (a)  $L^1$  convergence rate for  $\mathbf{u}$ ; (b)  $L^\infty$  convergence rate for  $\mathbf{p}$ ; (c)  $L^1$  convergence rate for p; (d)  $L^\infty$  convergence rate for p.

Figure 12: Errors as a function of grid size N for varying viscosity ratios  $\mu_R = 10^1 - 10^6$  with  $\mu_0 = 10^{-4}$  and constant density ratio  $\rho_R = 10^1$  with  $\rho_0 = 10^0$  for a non-conservative manufactured solution. Normal velocity and tangential traction boundary conditions are specified at all physical boundaries in every case. (a)  $L^1$  convergence rate for  $\mathbf{u}$ ; (b)  $L^{\infty}$  convergence rate for p; (d)  $L^{\infty}$  convergence rate for p.

Figure 13: The (a) initial density and (b) viscosity fields, along with the initial velocity vectors for the manufactured solution described in Sec. 6.3.

to be

$$u(\mathbf{x},t) = -y\cos(t),\tag{77}$$

$$v(\mathbf{x},t) = x\cos(t),\tag{78}$$

$$p(\mathbf{x},t) = \sin(t)\sin(x)\sin(y),\tag{79}$$

and we prescribe

$$\rho(\mathbf{x},t) = \rho_0 + \frac{\rho_1}{2} \left( \tanh\left(\frac{0.1 - \sqrt{x^2 + y^2}}{\delta}\right) + 1 \right) + x \cos(\sin(t)) + y \sin(\sin(t)) + 2, \tag{80}$$

$$\mu(\mathbf{x}) = \mu_0 + \mu_1 + \mu_1 \sin(2\pi x) \cos(2\pi y). \tag{81}$$

Plugging Eqs. (67)–(81) into the conservative momentum equation (1) yields a forcing term  $\mathbf{f}(\mathbf{x},t)$  that produces the desired conservative manufactured solution. Moreover, it can be verified that the time-dependent density function in Eq. (80) satisfies the conservative mass balance equation (3). Also notice that density function in Eq. (80) is only  $C^0$  continuous, and, in particular, that it has singular spatial derivatives at the origin. We remark that unlike the non-conservative form of equations, in which an arbitrary density function can be selected for the manufactured solution, constructing manufactured solutions for the conservative form is non-trivial because the velocity and density fields must satisfy both the mass balance and divergence-free condition. The viscosity and initial velocity and density fields are shown in Fig. 13.

For this case, the variations in density are set to  $\rho_0 = 1$  and  $\rho_1 = 10^3 - \rho_0$ , and the variations in viscosity are set to  $\mu_0 = 10^{-2}$  and  $\mu_1 = 1 - \mu_0$ . The computational domain is  $\Omega = [-L, L]^2 = [-1, 1]^2$ . The smoothing parameter is set to  $\delta = 0.05L$ . Normal velocity and tangential traction boundary conditions are used at all physical boundaries. The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U = 1. Errors in the velocity and pressure are computed at time T = tU/L = 0.6 with a uniform time step size  $\Delta t = 1/(1.042N)$ , which yields an approximate CFL number of 0.5

As a first test, we consider the evolution of density along with velocity and pressure. The time-independent viscosity is set at the initial time and is not evolved during the simulation. Fig. 14 shows the  $L^1$  and  $L^{\infty}$  errors for velocity, pressure, and density as a function of grid size. Second-order convergence rates are achieved for velocity and pressure in both norms. The convergence rate for the  $L^1$  density error is at least second order. Local reductions in pointwise convergence rates (less than second-order) are seen for density. This can be attributed to the  $\mathcal{C}^0$  spatial continuity of  $\rho(\mathbf{x},t)$ . We do indeed obtain full second-order convergence rates for all norms when considering a smooth density manufactured solution (see Appendix C).

Figure 14:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the conservative manufactured solution with specified normal velocity and tangential traction boundary conditions on all boundaries. In these cases, the density  $\rho$  is not reset between time steps. (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p; (c) convergence rate for  $\rho$ .

In our next test, we consider the same conservative manufactured solution as above, but we instead reset the density field at the beginning of each time step by computing the face-centered  $\rho^n$  directly from Eq. (80) at time  $t^n$ . Hence, within each time step,  $\rho^n$  is numerically evolved to  $\check{\rho}^{n+1,k+1}$  using the SSP-RK3 update described in Sec. 3.5.2. To wit, the density evolution reads as

$$\check{\boldsymbol{\rho}}^{(1)} = \boldsymbol{\rho}^n - \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^n, \boldsymbol{\rho}_{\text{lim}}^n \right), \tag{82}$$

$$\tilde{\boldsymbol{\rho}}^{(2)} = \frac{3}{4} \boldsymbol{\rho}^n + \frac{1}{4} \tilde{\boldsymbol{\rho}}^{(1)} - \frac{1}{4} \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^{(1)}, \tilde{\boldsymbol{\rho}}_{\text{lim}}^{(1)} \right), \tag{83}$$

$$\check{\boldsymbol{\rho}}^{(2)} = \frac{3}{4} \boldsymbol{\rho}^{n} + \frac{1}{4} \check{\boldsymbol{\rho}}^{(1)} - \frac{1}{4} \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^{(1)}, \check{\boldsymbol{\rho}}_{\text{lim}}^{(1)} \right), \tag{83}$$

$$\check{\boldsymbol{\rho}}^{n+1,k+1} = \frac{1}{3} \boldsymbol{\rho}^{n} + \frac{2}{3} \check{\boldsymbol{\rho}}^{(2)} - \frac{2}{3} \Delta t \mathbf{R} \left( \mathbf{u}_{\text{adv}}^{(2)}, \check{\boldsymbol{\rho}}_{\text{lim}}^{(2)} \right). \tag{84}$$

This evolved quantity is only used in the conservative discretization of the momentum equation (47). Upon numerically solving for the velocity and pressure, this density approximation is discarded and we begin the next time step with  $\rho^{n+1}$  computed from Eq. (80) at time  $t^{n+1}$ . On the final time step, the density error norms are computed with respect to the evolved  $\check{\rho}$  in order to determine the order of accuracy of a single time step of SSP-RK3 integration. This density resetting procedure emulates the level set synchronization approach described in Sec. 3.5.2, which is used in all of the numerical examples presented in Sec. 7. This methodology is commonly used in other interface capturing models as well, such as volume of fluid [1] and phase field [65] approaches, in which the material properties are set via an auxiliary indicator function.

Fig. 15 shows the  $L^1$  and  $L^{\infty}$  errors for velocity, pressure, and density as a function of grid size. We again observe full second-order convergence rates for velocity and pressure. We also no longer see a reduction in the order of accuracy for density, even for the  $C^0$  density field; this is because the error is essentially computed after a single time step of density evolution. These tests therefore show that the present numerical discretization maintains the desired order of accuracy for a conservative formulation with consistent mass update.

# 6.4. Non-conservative/Conservative form: Effect of local mesh refinement

We now consider the non-conservative and conservative manufactured solutions of the previous sections, 6.1 and 6.3, on locally refined grids and analyze the error convergence rate. In all of the cases considered here, we use  $\ell=2$  mesh levels with a refinement ratio of  $n_{\rm ref}=4$ . The refined region is always assigned to the center of the domain, which contains the dense region, as shown in Fig. 16. It should be noted that for practical multiphase simulations, we always restrict the fluid-gas interface to the finest mesh level in the grid hierarchy.

In our first test, we consider the non-conservative manufactured solution detailed in Sec. 6.1. We consider vel-tra boundary conditions, i.e., periodic boundary conditions in the x-direction and specified normal velocity and tangential traction in the y-direction. Fig. 17 shows the  $L^1$  and  $L^{\infty}$  errors for velocity and pressure as a function of coarsest grid spacing. We again obtain second-order convergence rates for velocity and pressure on the locally refined grid.

Next, we consider the conservative manufactured solution described in Sec. 6.3. In this case, we do not reset the density at the beginning of time steps. Fig. 18 shows the  $L^1$  and  $L^{\infty}$  errors for velocity, pressure. and density as a function of coarsest grid spacing. The observed convergence rates observed on this locally refined mesh are nearly identical to those shown for the uniform mesh case.

#### 6.5. Conservative form: Solver scalability

Finally, we investigate the scalability of the preconditioned FGMRES solver for the staggered Stokes system given by Eq. (53) and also show the linear solver iteration results for the velocity and pressure subdomain problems. A bubble is placed in a computational domain  $\Omega = [0, L]^2$  with L = 1, which is discretized by an  $N \times N$  grid. The radius of the bubble is R = 0.2L with initial center position  $(X_0, Y_0) =$ (L/2, L/2). The bubble has density  $\rho_i$  and viscosity  $\mu_i$  and is placed within ambient fluid of density  $\rho_0$  and  $\mu_{\rm o}$ . The density and viscosity jump is smeared over  $n_{\rm cells}=2.5$  grid cells on each side of the interface and harmonic averaging is used to average viscosity from cell-centers to nodes of the staggered grid. The initial

Figure 15:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the conservative manufactured solution with specified normal velocity and tangential traction boundary conditions on all boundaries. In these cases, the density  $\rho$  is reset between time steps. (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p; (c) convergence rate for  $\rho$ .

Figure 16: Velocity vectors and pressure field plotted on the grid hierarchy used for the locally refined mesh convergence study. In both figures, the purple box indicates a locally refined grid with grid spacing  $\Delta x_{\min} = \Delta x_0/4$ .

Figure 17:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of coarsest grid spacing  $\Delta x_0$  for the non-conservative manufactured solution described in Sec. 6.1 on a locally refined mesh. The specified boundary conditions are normal velocity and tangential traction (vel-tra). (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

Figure 18:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of coarsest grid spacing  $\Delta x_0$  for the conservative manufactured solution with specified normal velocity and tangential traction boundary conditions on all boundaries. In these cases, the density  $\rho$  is *not* reset between time steps. (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p; (c) convergence rate for  $\rho$ .

Figure 19: The initial location of the air-suspended water droplet, and the initial velocity vectors for the problem set up described in Sec. 6.5.

velocity and pressure are set to

$$u(\mathbf{x},0) = \cos(2\pi x)\sin(2\pi y),\tag{85}$$

$$v(\mathbf{x},0) = -\sin(2\pi x)\cos(2\pi y),\tag{86}$$

$$p(\mathbf{x},0) = 0. \tag{87}$$

Homogenous normal velocity and homogeneous tangential traction boundary conditions are used at all sides of the domain, and homogenous Neumann boundary conditions for  $\phi$ ,  $\rho$ , and  $\mu$  are specified on  $\partial\Omega$ . No additional body forces are applied to the momentum equations (i.e.,  $\mathbf{f}(\mathbf{x},t)=0$ ). The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U=1. Each case is run until T=tU/L=0.1 with a uniform time step  $\Delta t=1/(3.125N)$ , which yields an approximate CFL number of 0.3. Residual values are presented at the final time from the second fixed-point cycle.

In the first case, the bubble is set to have  $\rho_i = 10^3$  and  $\mu_i = 8.9 \times 10^{-4}$ , and the exterior fluid is set to have  $\rho_0 = 1.225$  and  $\mu_0 = 1.81 \times 10^{-5}$ . This corresponds to the material properties of water and air, respectively, in meter-kilogram-second (MKS) units. The initial problem set up is shown in Fig. 19. The Reynolds number based on the properties of the exterior fluid, the diameter of the bubble, and the maximum initial velocity in the domain is  $Re = 2.71 \times 10^4$ . The subdomain solvers with loose relative convergence tolerance of  $\epsilon_{\rm sub} = 10^{-2}$  are used for this problem. For the outer FGMRES solver, a tight relative convergence tolerance of  $\epsilon_{\text{Stokes}} = 10^{-16}$  is employed. Fig. 20 summarizes iteration results for the three linear solvers considered. We only show residual data for the velocity and pressure solves from the final FGMRES iteration of each simulation, although we note that each outer iteration requires essentially the same number of inner solver iterations. Hence, the number of inner solver V-cycles per Stokes cycle can be approximated as the number of subdomain solver iterations multiplied by the number of FGMRES iterations shown in Fig. 20(c). For the velocity subdomain solver at all grid sizes, we see that it only takes a single iteration to reduce the residual by several orders of magnitude, well below the desired tolerance. This is expected for this particular case because the system is strongly diagonally dominant. For the pressure subdomain solver, we see that it takes between three and six iterations to reduce the relative residual below  $\epsilon_{\rm sub}$ . Although the required number of iterations increases as a function of grid size, it does so at only a modest rate. For the full staggered Stokes system, the FGMRES solver converges to machine precision within five iterations for all the grid sizes N. To converge the Stokes system for the wide range of grid sizes shown here to a relative residual tolerance of  $\epsilon_{\rm Stokes} = 10^{-12}$ , we would expect to carry out around 3–4 velocity V-cycles and 12–18 pressure V-cycles. To obtain accurate results for practical multiphase fluid flow problems, it is reasonable to converge the Stokes system to a relative residual of around  $10^{-6}$ , requiring only a single FGMRES iteration, a single V-cycle for the velocity and around 3–6 V-cycles for the pressure.

In the second case, the bubble is set to have  $\rho_i = 1$  and  $\mu_i = 8.9 \times 10^{-3}$ , whereas the outside fluid is set to have  $\rho_o = 1.225 \times 10^{-3}$  and  $\mu_o = 1.81 \times 10^{-4}$ . This corresponds to the material properties of water and air, respectively, in centimeter-gram-second (CGS) units. The Reynolds number based on the properties of

Figure 20: Relative residual as a function of iteration count for the final solves of the water bubble problem described in Sec. 6.5, for varying grid sizes N=32-1024. MKS units are used to specify the material properties of both water and air, yielding a Reynolds number of Re =  $2.71 \times 10^4$ . (a) Velocity subdomain solver relative residual  $\|\mathbf{A}\hat{\mathbf{x}}_{\mathbf{u}} - \mathbf{b}_{\mathbf{u}}\|_2 / \|\mathbf{b}_{\mathbf{u}}\|_2$  vs. number of iterations. (b) Pressure subdomain solver relative residual  $\|-\mathbf{L}_{\wp}\boldsymbol{\theta} + \frac{1}{\Delta t} \left(\mathbf{b}_{\mathbf{p}} + \mathbf{D} \cdot \hat{\mathbf{x}}_{\mathbf{u}}\right)\|_2 / \|-\frac{1}{\Delta t} \left(\mathbf{b}_{\mathbf{p}} + \mathbf{D} \cdot \hat{\mathbf{x}}_{\mathbf{u}}\right)\|_2$  vs. number of iterations. (c) Staggered Stokes solver relative residual  $\|\mathbf{B}\mathbf{x} - \mathbf{b}\|_2 / \|\mathbf{b}\|_2$  vs. number of iterations.

Figure 21: Relative residual as a function of iteration count for the final solves of the water bubble problem described in Sec. 6.5, for varying grid sizes N=32-1024. CGS units are used to specify the material properties of both water and air, yielding a Reynolds number of Re =  $2.71 \times 10^{0}$ . (a) Velocity subdomain solver relative residual  $\|\mathbf{A}\widehat{\mathbf{x}}_{\mathbf{u}} - \mathbf{b}_{\mathbf{u}}\|_{2} / \|\mathbf{b}_{\mathbf{u}}\|_{2}$  vs. number of iterations. (b) Pressure subdomain solver relative residual  $\|\mathbf{-L}_{\wp}\theta + \frac{1}{\Delta t}(\mathbf{b}_{\mathbf{p}} + \mathbf{D} \cdot \widehat{\mathbf{x}}_{\mathbf{u}})\|_{2} / \|\mathbf{-L}_{\wp}\theta + \mathbf{D} \cdot \widehat{\mathbf{x}}_{\wp}\|_{2} / \|\mathbf{b}_{\wp}\|_{2}$  vs. number of iterations. (c) Staggered Stokes solver relative residual  $\|\mathbf{B}\mathbf{x} - \mathbf{b}\|_{2} / \|\mathbf{b}\|_{2}$  vs. number of iterations.

the exterior fluid, the diameter of the bubble, and the maximum initial velocity in the domain is Re = 2.71. Fig. 21 summarizes iteration results for the three linear solvers considered. In contrast with the higher Reynolds number case, it generally takes between two and three iterations for the velocity subdomain solver to converge below the desired tolerance. Again, this is expected, because at this Reynolds number, **A** is not as diagonally dominant. Similarly, the pressure subdomain solver requires between two and three iterations for all grid sizes. The full staggered Stokes system requires between 14 and 19 iterations to converge to machine precision. Hence, to converge the Stokes system to a relative residual tolerance of  $\epsilon_{\text{Stokes}} = 10^{-12}$ , we would expect to carry out around 20–39 velocity V-cycles and a comparable number of pressure V-cycles. To achieve a relative residual tolerance of  $10^{-6}$ , we would expect to carry out around 6–9 V-cycles for both the velocity and pressure.

The results here suggest that the preconditioned iterative solver is scalable for high density and high viscosity ratio flows, including practical air-water interfacial flows at both low and high Reynolds numbers. The number of iterations required to converge the outer and inner solvers are relatively insensitive to grid size. Similar convergence behaviors are observed for other combinations of physical boundary conditions (results not shown). In the following sections, we mainly focus on multiphase flows involving air-water interaction, for which the solver parameters discussed here are reasonably efficient.

#### 7. Numerical examples

This section investigates several multiphase flow problems to verify the accuracy, consistency, and stability of the present numerical method. Both conservative and non-conservative formulations are used, and differences between the formulations are examined. We also compare our results to benchmark problems drawn from the multiphase flow literature. We employ m=2 cycles of fixed-point iteration for all the examples in this section. We note that errors lower than machine precision may be truncated during computation, and we only report errors lower than  $10^{-16}$  as  $\leq 10^{-16}$ .

## 7.1. Static bubble with surface tension

We first demonstrate that our treatment of surface tension is well-balanced with respect to the treatment of the pressure gradient in the hydrostatic limit. A bubble is placed in a computational domain  $\Omega = [0, L]^2$  with L = 1, which is discretized by a uniform  $N \times N$  grid. The radius of the bubble is R = 0.25L with initial center position  $(X_0, Y_0) = (L/2, L/2)$ . Both the fluids inside and outside the bubble are initially at rest. Zero normal and tangential velocity boundary conditions are imposed on the boundaries of the computational domain. The only momentum body force considered for this case is the surface tension force; other body forces such as gravity are neglected. The conservative discretization is used for all cases considered here, but the non-conservative discretization yields similar results because these flows are not dominated by convection (data not shown). A relative convergence tolerance of  $\epsilon_{\text{Stokes}} = 10^{-15}$  is specified for the FGMRES solver, which can corresponds to absolute tolerances in the range of  $10^{-10} - 10^{-15}$ . Two grid cells  $(n_{\text{cells}} = 2)$  of smearing are used on either side of the interface.

As a first test case, we consider an inviscid flow with inner and outer viscosities  $\mu_i = \mu_o = 0$ . The grid size is taken to be N = 80, and a constant time step size  $\Delta t = 1/(12.5N)$  is used. Density ratios of  $\rho_i/\rho_o = 1, 10^3$ , and  $10^6$  are considered, and each case is run for 50 time steps. For this particular case, the surface tension should exactly balance the pressure difference across the interface, resulting in a stationary bubble with zero velocity everywhere in the domain. The exact pressure difference is analytically given by the Young-Laplace equation

$$\Delta p_{\text{exact}} = \sigma \kappa = \frac{\sigma}{R},\tag{88}$$

in which the surface tension coefficient is set to  $\sigma=73$ , and the exact curvature of the bubble is  $\kappa=1/R$ . This case has been extensively investigated by a number of previous studies, including Williams et al. [35], Francois et al. [51], and Patel and Natarajan [25]. If an unbalanced treatment of surface tension and pressure gradient is used, significant parasitic currents will be generated during the first time step, and the exact pressure jump will not be captured. As in previous studies, we use the exact curvature for the surface tension force calculation. Because the fluid should remain at rest, any nonzero velocities are the result of solver error. We assess the accuracy of the solver in terms of the  $L^1$  and  $L^\infty$  norms of the velocity along with the relative error in the pressure jump

$$E(\Delta p) = \frac{|\Delta p - \Delta p_{\text{exact}}|}{|\Delta p_{\text{exact}}|},$$
(89)

in which  $\Delta p = p_{\rm i} - p_{\rm o}$  is the numerically computed pressure difference across the interface and  $\Delta p_{\rm exact} = 73/0.25 = 292$ . Tables 1 and 2 show the errors in velocity and pressure at  $t = \Delta t$  and  $t = 50\Delta t$ , respectively. For all density ratios, we see that the errors are close to machine precision, indicating negligible spurious currents and a numerical balance between pressure and surface tension forces.

Next, we consider the temporal evolution of velocity and pressure errors for a viscous droplet suspended in fluid. We consider the same geometric parameters as the previous example for the bubble and the domain size. The density ratio is held fixed at  $\rho_{\rm i}/\rho_{\rm o}=10^3$ , and we consider grids with N=40,80,160, and 320. A constant time step size of  $\Delta t=1/(50N)$  is used, and the surface tension coefficient is again set to  $\sigma=73$ . The viscosity in each fluid is determined using the dimensionless Laplace number La =  $\rho D \sigma/\mu^2=12000$ , in which D=2R is the diameter of the bubble. Using the parameters described here yields a viscosity ratio of  $\mu_{\rm i}/\mu_{\rm o}=31.62$ , and both fluids are initially at rest. In contrast with the previous example, here the curvature is computed directly from the level set function. Time is nondimensionalized using the capillary time scale  $t_{\sigma}=\sqrt{\rho_{\rm o}D^3/\sigma}$ . Similar cases have been numerically investigated by Popinet [66] and by Abadie et al. [67].

Table 1: Errors in velocity and pressure after a single time step for the two-dimensional static and inviscid bubble. The exact curvature  $\kappa = 1/R$  is used for the surface tension force calculation.

	Errors at $t = \Delta t$		
$ ho_{ m i}/ ho_{ m o}$	$\ \mathbf{u}\ _1$	$\ \mathbf{u}\ _{\infty}$	$E(\Delta p)$
1	$3.76 \times 10^{-14}$	$1.11 \times 10^{-13}$	$9.95 \times 10^{-14}$
$10^{3}$	$2.03 \times 10^{-15}$	$1.20 \times 10^{-13}$	$\leq 10^{-16}$
$10^{6}$	$8.44 \times 10^{-13}$	$4.73 \times 10^{-11}$	$5.84 \times 10^{-16}$

Table 2: Errors in velocity and pressure after a 50 time steps for the two-dimensional static and inviscid bubble. Exact curvature  $\kappa = 1/R$  is used for the surface tension force calculation.

	Errors at $t = 50\Delta t$		
$ ho_{ m i}/ ho_{ m o}$	$\ \mathbf{u}\ _1$	$\ \mathbf{u}\ _{\infty}$	$E(\Delta p)$
1	$4.17 \times 10^{-16}$	$9.36 \times 10^{-15}$	$5.84 \times 10^{-16}$
$10^{3}$	$1.95 \times 10^{-14}$	$5.16 \times 10^{-13}$	$\leq 10^{-16}$
$10^{6}$	$3.61 \times 10^{-12}$	$1.81 \times 10^{-10}$	$\leq 10^{-16}$

Figure 22: Temporal evolution of errors for a viscous bubble with  $\rho_{\rm i}/\rho_{\rm o}=10^3$  and La = 12000, for grid sizes N=40-320. Here, curvature is computed numerically from the level set function. (a) Pressure difference relative error  $E(\Delta p)$  vs. nondimensional time. (b)  $L^1$  norm of velocity vs. nondimensional time. (c)  $L^\infty$  norm of velocity vs. nondimensional time.

Figure 23: Velocity vectors and pressure of the static bubble with  $\rho_i/\rho_o = 10^3$  and La = 12000, for grid size N = 320 at time  $t/t_\sigma = 60.41$ . Curvature is computed numerically from the level set function.

Fig. 22 shows the time evolution of  $E(\Delta p)$ ,  $\|\mathbf{u}\|_1$ , and  $\|\mathbf{u}\|_{\infty}$ . We observe that the errors do not grow substantially as a function of time, and that each computation maintains stability. These results are consistent with the results of other level set based multiphase flow solvers. In particular, it is known that the reinitialization procedure will slightly shift the interface every time step, which can prevent the spurious velocities from decaying to machine precision [67]. In contrast, certain geometric VOF methods exhibit exponential decay of the spurious velocities because of the absence of any redistancing process [66]. Nonetheless, the errors shown in shown in Fig. 22 decrease as the resolution increases, yielding convergence rates of 1.98 for  $E(\Delta p)$ , 1.94 for  $\|\mathbf{u}\|_1$ , and 1.75 for  $\|\mathbf{u}\|_{\infty}$  between the two finest cases N=160 and N=320. Fig. 23 shows the velocity vectors and pressure for the finest case N=320 at  $t/t_{\sigma}=60.41$ . Although we do see some spurious velocities across the computational domain, the large internal pressure required to maintain the bubble's shape is accurately resolved. These results indicate that the surface tension treatment described here is well-balanced and does not significantly reduce the expected order of accuracy of the fluid solver.

#### 7.2. Gas/liquid tank

This section demonstrates that our treatment of the gravitational body force is well-balanced with respect to the treatment of the pressure gradient. The computational domain  $\Omega = [0, L]^2$  with L = 1 is filled halfway from y = 0 to y = L/2 with a heavy fluid of density  $\rho_h$ . The remainder of the tank, from y = L/2 to y = L, is occupied by a lighter fluid with density  $\rho_l = 1$ , and the density ratio  $\rho_h/\rho_l$  is varied. The viscosity is set to zero for both fluids,  $\mu_l = \mu_h = 0$ . The domain is discretized by a uniform  $N \times N$  grid, and both the fluids are initially at rest. A gravitational acceleration  $\mathbf{g} = (0, -g_y) = (0, -9.81)$  is specified, and surface tension is neglected. The conservative discretization is used for all cases considered here, but we found that the non-conservative discretization yields similar results because these flows are not dominated by convection (data not shown). A relative convergence tolerance of  $\epsilon_{\text{Stokes}} = 10^{-15}$  is specified for the FGMRES solver, and two grid cells of smearing  $(n_{\text{cells}} = 2)$  are used on either side of the interface.

As a first test case, we prescribe homogenous normal velocity conditions on the left, bottom, and right boundaries and homogenous normal traction conditions on the top boundary along with homogenous tangential velocity conditions on all boundaries of the computational domain. The grid is held fixed with size N = 100 and a constant time step size  $\Delta t = 1/(10N)$  is used. Density ratios of  $\rho_h/\rho_l = 10^1, 10^3$ , and  $10^6$  are considered and each case is run for 50 time steps. For this particular case, the gravitational force should exactly balance the pressure difference across the interface, resulting in a stationary tank of fluid with zero velocity everywhere in the domain. Similar cases has been computationally investigated by Montazeri et al. [68] and by Patel and Natarajan [25]. Because the pressure is defined on cell-centers of the staggered grid, the analytical pressure jump for this problem can be computed by integrating the momentum equation

Table 3: Errors in velocity and pressure after a single time step for the two-dimensional static and inviscid fluid column.

	Errors at $t = \Delta t$	
$ ho_{ m h}/ ho_{ m l}$	$\ \mathbf{u}\ _{\infty}$	$E(\Delta p)$
$10^{1}$	$2.53 \times 10^{-16}$	$5.45 \times 10^{-15}$
$10^{3}$	$7.21 \times 10^{-15}$	$9.32 \times 10^{-14}$
$10^{6}$	$4.40 \times 10^{-12}$	$5.42 \times 10^{-12}$

Table 4: Errors in velocity and pressure after a 50 time steps for the two-dimensional static and inviscid fluid column.

	Errors at $t = 50\Delta t$		
$ ho_{ m h}/ ho_{ m l}$	$\ \mathbf{u}\ _{\infty}$	$E(\Delta p)$	
$10^{1}$	$\leq 10^{-16}$	$1.33 \times 10^{-16}$	
$10^{3}$	$\leq 10^{-16}$	$\leq 10^{-16}$	
$10^{6}$	$1.62 \times 10^{-16}$	$1.92 \times 10^{-16}$	

(ignoring velocity terms):

$$\int_{\Delta y/2}^{L-\Delta y/2} \nabla p(y) \, dy = \int_{\Delta y/2}^{L-\Delta y/2} \rho(y) \mathbf{g} \, dy = -g_y \left( \int_{L/2}^{L-\Delta y/2} \rho_{\mathbf{l}} \, dy + \int_{\Delta y/2}^{L/2} \rho_{\mathbf{h}} \, dy \right)$$

$$\Rightarrow \Delta p_{\text{exact}} = p \Big|_{\Delta y/2}^{L-\Delta y/2} = -\frac{1}{2} g_y \left( \rho_{\mathbf{h}} + \rho_{\mathbf{l}} \right) \left( L - \Delta y \right), \tag{90}$$

in which the pressure is evaluated at the cell centers adjacent to the top and bottom computational boundaries and  $\Delta y = L/N$  is the vertical grid spacing for this particular problem. If an unbalanced treatment of gravity and pressure gradient is used, significant parasitic currents will be generated, and the exact pressure jump will not be captured. Similar to the static bubble case in the previous section, two quantitative measurements are used to assess the accuracy of the simulation: the  $L^{\infty}$  norm in velocity, and the relative error in pressure jump  $E(\Delta p)$  using the numerically computed pressure difference between  $y = \Delta y/2$  and  $y = L - \Delta y/2$ , and the exact pressure difference  $\Delta p_{\rm exact} = -9.81/2 \times (\rho_{\rm h} + \rho_{\rm l}) \times (1 - 0.01)$ .

Tables 3 and 4 show the errors in velocity and pressure at  $t = \Delta t$  and  $t = 50\Delta t$ , respectively. For all density ratios considered, we see that the errors are close to machine precision, indicating negligible spurious currents and a numerical balance between pressure and gravitational body force.

Next, we consider the dynamic case of a tank being filled with fluid. The same numerical parameters from the previous case are used, except that the normal velocity at the bottom boundary is set to be unity. Over time, the fluid will displace the gas out of the domain until the tank consists only of the fluid phase. Only the case for density ratio of  $\rho_h/\rho_l = 10^3$  is presented here, although the results are similar for a wide range of density ratios. Montazeri et al. demonstrated that the use of an unbalanced formulation will produce significant interface deformation resulting from the spurious currents, which eventually destabilizes the computation [68].

Fig. 24 shows three snapshots in time for the evolution of the filling water tank. We see the fluid-gas interface evolve upward with no deformation because negligible spurious horizontal velocities generated. These cases demonstrate that even though we are treating gravity as a momentum body force acting throughout the entire domain (and *not* as an interfacial force as done in by Montazeri et al. [68]), the staggered-grid discretization provides a well-balanced pressure gradient and gravity forcing. The reason is attributed to the fact that the pressure gradient and the gravity forces are defined at the same spatial location, namely, the Cartesian grid faces. It was also recently recognized by Patel and Natarajan [25] that it is *not* necessary to express gravity force in terms of a gradient operator to obtain a well-balanced formulation.

Figure 24: Temporal evolution of a tank being filled with heavy liquid for  $\rho_h/\rho_l = 10^3$  and N = 100. Velocity vectors are denoted by arrows  $(\rightarrow, \text{black})$ .

#### 7.3. Convection of high density droplet

In this section, we demonstrate the importance of consistent mass and momentum transport to achieve stability in high density ratio flows. A dense bubble is placed in a fully periodic computational domain  $\Omega = [0, L]^2$  with L = 1, which is discretized by an  $N \times N$  grid. The radius of the bubble is R = 0.2L with initial center position  $(X_0, Y_0) = (L/4, L/2)$ . The density ratio between the bubble and the outer fluid is  $\rho_i/\rho_o = 10^6$ , and the viscosity is set to  $\mu = 0$  in the entire domain. The initial velocity is set via a smoothed Heaviside function defined on faces

$$\widetilde{H}_{i-\frac{1}{2},j}^{f} = \begin{cases}
0, & \phi_{i-\frac{1}{2},j} < -\Delta x \\
\frac{1}{2} \left( 1 + \frac{1}{\Delta x} \phi_{i-\frac{1}{2},j} + \frac{1}{\pi} \sin \left( \frac{\pi}{\Delta x} \phi_{i-\frac{1}{2},j} \right) \right), & |\phi_{i-\frac{1}{2},j}| \leq \Delta x \\
1, & \text{otherwise}
\end{cases}$$
(91)

in which  $\phi(\mathbf{x},0) = \sqrt{(x-X_0)^2 + (y-Y_0)^2} - R$  is the initial signed distance function away from the circular interface and the face centered level set is obtained by averaging  $\phi$  in the two adjacent cell centers  $\phi_{i-\frac{1}{2},j} = \frac{1}{2} \left( \phi_{i-1,j} + \phi_{i,j} \right)$ . The initial horizontal velocity  $u(\mathbf{x},0)$  is set to be unity inside the bubble and zero outside the bubble, i.e.  $u_{i-\frac{1}{2},j} = 1 - \widetilde{H}_{i-\frac{1}{2},j}^f$ . The vertical velocity v is initialized to be identically zero.

Notice that this initial velocity profile is not discretely divergence-free. Because this is an inviscid case, numerical instabilities and errors that are generated during the first time step can persist for the duration of the simulation. Hence, we apply a density-weighted projection to construct a discretely mass-conserving initial velocity  $\mathbf{u}_{p}(\mathbf{x},0)$ . This can be achieved by numerically solving the Poisson problem

$$-\mathbf{D} \cdot \left(\frac{1}{\rho(\mathbf{x},0)}\mathbf{G}\psi(\mathbf{x})\right) = -\mathbf{D} \cdot \mathbf{u}(\mathbf{x},0), \tag{92}$$

for  $\psi(\mathbf{x})$  and then adding its gradient to the initial velocity field,

$$\mathbf{u}_{p}(\mathbf{x},0) = \mathbf{u}(\mathbf{x},0) - \frac{1}{\rho(\mathbf{x},0)} \mathbf{G} \psi(\mathbf{x}). \tag{93}$$

This problem has been studied numerically by Bussman et al. [17], Desjardins and Moureau [20], Ghods and Herrmann [21], and Patel and Natarajan [25]. For all of the following cases, the density is set via the level set function at the beginning of each time step with one grid cell of smearing ( $n_{\text{cells}} = 1$ ) on either side of the interface. We find that smearing over two or more cells leads to a more distorted interface for this particular problem. This is expected because analytically the dense bubble mimics a thick solid blob, but numerically, as the interface of the blob thickens, it acts more like a fluidic blob whose interface tends to "flow" under the pressure drag. Each case is run until t = 1 with a constant time step size of  $\Delta t = 1/(31.25N)$ . Under the prescribed conditions, the dense rigid blob should maintain its circular shape and return exactly to its initial position, analytically.

Figure 25: Initial condition/exact solution (---, red) and numerical solution (—, black) for convection of a high density droplet with density ratio  $\rho_i/\rho_o = 10^6$  and initial velocity  $\mathbf{u}_{\mathbf{p}}(\mathbf{x},0)$ . Inconsistent transport of mass and momentum occurs while employing a non-conservative momentum integrator. PPM is used for advection of the level set and CUI limiter is used for the convective operator. (a) Grid size N = 32 at time t = 1 (b) Grid size N = 64 at time t = 1 (c) Grid size N = 128 at time t = 0.5; the simulation becomes unstable shortly after the shown time (d) Grid size N = 256 at time t = 0.5; the simulation becomes unstable shortly after the shown time

As a first test, we demonstrate the importance of consistent mass and momentum transport for the stability of high density ratio flows. Fig. 25 shows the shape of the bubble for four different grid spacings, N=32,64,128,256, when simulated with inconsistent mass and momentum transport, i.e., by using a non-conservative momentum integrator. There is clear distortion in the bubble at time t=1 at the lower resolutions (Figs. 25(a) and 25(b)), whereas the simulations quickly become unstable at higher grid resolutions (Figs. 25(c) and 25(d)). Lowering the time step even further did not resolve these stability problems. However the simulations are stable when using consistent mass and momentum transport (Fig. 26), and the bubble's shape converges towards the analytical solution as the resolution increases. The bubble's distortion at lower resolutions can be attributed to discretization errors from advection and interface tracking. For these cases, xsPPM7 is used to advect the level set, and CUI limiters are used for mass and convective fluxes. Therefore, these cases also demonstrate that the level set and mass updates can have dissimilar limiters and still maintain numerical stability for the consistent and conservative momentum integrator. This is in contrast to the numerical scheme of Patel and Natarajan [25], which remains consistent only when same limiter is employed for the advection of algebraic VOF-scalar and momentum flux.

We next demonstrate the importance of using a CBC satisfying limiter for the mass density update. We consider the same simulation parameters above (for the consistent transport case) at a grid resolution of N=256 and compare the shape of the bubble at t=1 for four different limiters: xsPPM7 [46] along with high resolution versions of CUI [22], M-Gamma [22], and FBICS [24]. Figs. 27(a)–27(c) show the shape of the bubble for the CUI, M-Gamma, and FBICS limiters. All of these limiters maintain numerical stability and produce reasonable results when compared to the analytical solution. Results for the PPM limiter are not shown here because the simulation quickly becomes unstable within ten time steps. Note that of these four limiters, PPM is the only one that can produce undershoots and overshoots for advected

Figure 26: Initial condition/exact solution (---, red) and numerical solution (---, black) for convection of a high density droplet with density ratio  $\rho_{\rm i}/\rho_{\rm o}=10^6$  and initial velocity  ${\bf u}_{\rm p}({\bf x},0)$ . Consistent transport of mass and momentum is used for these cases. PPM is used for advection of the level set and CUI limiters are used for mass and convective fluxes. (a) Grid size N=32 at time t=1. (b) Grid size N=64 at time t=1. (c) Grid size N=128 at time t=1. (d) Grid size N=256 at time t=1.

Figure 27: Initial condition/exact solution (---, red) and numerical solution (---, black) for convection of a high density droplet with density ratio  $\rho_{\rm i}/\rho_{\rm o}=10^6$  and initial velocity  ${\bf u}_{\rm p}({\bf x},0)$ . Consistent transport of mass and momentum is used for these cases. PPM is used for advection of the level set and various limiters are used for mass and convective fluxes. The grid size is N=256 for all cases. (a) CUI limiter at time t=1. (b) M-Gamma limiter at time t=1. (c) FBICS limiter at time t=1. (d) Minimum density in the domain during the first eight simulation time steps.

quantities [69]. It is required that the density remain positive throughout the computation to obtain a physically accurate solution. Fig. 27(d) shows the minimum updated density  $\rho^{n+1}$  within each time step in the domain over the first eight time steps. It is clear that the CBC satisfying limiters maintain physically realistic minimum (maximum) densities whereas PPM generates undershoots (overshoots) that eventually corrupt the simulation. Throughout the remainder of the simulation, the CBC satisfying limiters do not undershoot the minimum or overshoot the maximum initial density (data not shown for overshoots).

Finally, we demonstrate that the consistent transport scheme produces stable results in three spatial dimensions and with adaptive mesh refinement. Similar to the previous case, a dense bubble is placed in a fully periodic computational domain  $\Omega = [0, L]^3$  with L = 1, which is discretized by a two-level  $(\ell = 2)$  locally refined grid with coarsest grid spacing  $\Delta x_0 = \Delta y_0 = \Delta y_0 = 1/64$  and refinement ratio  $n_{\text{ref}} = 2$ . At the finest level, the grid spacing is  $\Delta x_{\min} = \Delta y_{\min} = \Delta z_{\min} = 1/128$ . The radius of the bubble is R = 0.2L with initial center position  $(X_0, Y_0, Z_0) = (L/4, L/2, L/2)$ . The density ratio between the bubble and the outer fluid is again  $\rho_i/\rho_0 = 10^6$ , and the viscosity is set to  $\mu = 0$  in the entire domain. The initial velocity  $\mathbf{u}_p(\mathbf{x}, 0)$  is again set via density weighted projection, which is zero for the non-horizontal velocity components. Each case is run until t = 1 with a constant time step size  $\Delta t = 2\Delta x_0/125$ . Coarse grid cells are tagged for refinement where the local vorticity magnitude exceeds a relative threshold of 0.25, or where  $\phi \leq 2\Delta x_0$ , which ensures that the surface and interior of the bubble are always placed on the finest grid level. Fig. 28 shows evolution of the bubble at three snapshots in time. The top row shows the case for inconsistent transport using the non-conservative integrator, which quickly becomes unstable, as in the two-dimensional case. The bottom row shows the case for consistent transport, which remains stable and exhibits similar distortion because of numerical errors as the two dimensional case with a comparable spatial resolution.

#### 7.4. Collapsing water column

This section demonstrates the importance of consistent mass and momentum transport to achieve stability for air-water density ratios. A water column of initial height and width of  $a = 5.715 \times 10^{-2}$  m is placed in a two-dimensional computational domain  $\Omega = [7a, 1.75a]$  that is discretized using a  $4N \times N$  grid. No-slip boundary conditions are imposed along  $\partial\Omega$ . At the initial time, the bottom left corner of the water column

Figure 28: Three-dimensional convection of a high density ratio droplet (blue) with density ratio  $\rho_{\rm i}/\rho_{\rm o}=10^6$  and initial velocity  ${\bf u}_{\rm p}({\bf x},0)$ . The coarse grid has grid spacing  $\Delta x_0=\Delta y_0=\Delta y_0=1/64$ , with each simulation using  $\ell=2$  grid levels and refinement ratio  $n_{\rm ref}=2$ . The coarse grid level is bounded by the red boxes, while the fine grid level is bounded by green boxes. (a)-(c) Three snapshots in time for inconsistent transport of mass and momentum, which becomes unstable shortly after t=0.6. (d)-(f) Three snapshots in time for inconsistent transport of mass and momentum, which remains stable throughout the simulation time.

coincides with the bottom left corner of the computational domain. The density of water is  $\rho_{\rm l}=1000~{\rm kg/m^3}$ , the density of air is  $\rho_{\rm g}=1.226~{\rm kg/m^3}$ , the viscosity of water is  $\mu_{\rm l}=1.137\times 10^{-3}~{\rm kg\cdot m/s}$ , the viscosity of air is  $\mu_{\rm g}=1.78\times 10^{-5}~{\rm kg\cdot m/s}$ , the surface tension coefficient is  $\sigma=0.0728~{\rm N/m}$ , and the gravitational acceleration is  $g=9.81~{\rm m/s^2}$  (directed in the negative y-direction). Both fluids are initially at rest. This problem has been studied numerically by Rezende et al. [70] and by Patel and Natarajan [25]. We also consider the analogous case in three spatial dimensions, in which a cubic water block with side length  $a=5.715\times 10^{-2}~{\rm m}$  is placed in a computational domain of size  $\Omega=[7a,a,1.75a]$  discretized by a  $4N\times 9N/16\times N$  grid. In this case, gravity is directed in the negative z-direction. This problem has been studied numerically by Gu et al. [71] and experimentally by Martin and Moyce [72]. For all of the following cases, the density is set via the level set function at the beginning of each time step with one grid cell of smearing  $(n_{\rm cells}=1)$  on either side of the interface.

Using N=128 and uniform time step  $\Delta t=1/(62.5N)$ , we carry out the two-dimensional simulation using both inconsistent and consistent mass and momentum transport. Fig. 29 shows the evolution of the water column over time. Unphysical deformations and numerical instabilities plague the inconsistent approach whereas the consistent transport remains stable and produces a physically accurate solution that compares favorably to the experimental study [72]. To demonstrate the qualitative accuracy of the present method in three dimensions, we carry out the three-dimensional simulation using consistent transport with N=64 (Fig. 30). The 3D case differs from the 2D case because that the water column makes contact with an additional pair of walls. It is seen that the numerical solution is again physically reasonable and stable, and that the three-dimensional results qualitatively agree with the two-dimensional simulation.

Finally, we quantitatively compare our results to those of other numerical and experimental studies. The front position and height (nondimensionalized by a) of the water column is plotted against time (nondimensionalized by  $\sqrt{a/g}$ ) in Fig. 31. Excellent agreement is demonstrated between the present study and previous works. We again emphasize that this test case demonstrates how vitally important consistent mass and momentum transport is for stable simulation of practical multiphase flows, for which air-water density ratios are ubiquitous.

# 7.5. Droplet splashing on thin liquid film

## 7.5.1. Two spatial dimensions

This section investigates the problem of a droplet splashing on a thin liquid film, which is representative of real-world applications such as spray cooling [73] and inkjet printing [74]. A circular droplet of initial diameter D=1 is placed just above a liquid film in a two-dimensional computational domain of size  $\Omega = [0, 8D] \times [0, 2D]$ , which is discretized by an  $4N \times N$  uniform grid with N = 400. The droplet has initial downward velocity  $\mathbf{u}(\mathbf{x},0) = (0,-U)$ , with U=1, which is projected to produce a discretely divergencefree initial condition. The droplet has initial center  $(X_0, Y_0) = (4D, 0.75D)$  and the liquid film has initial height 0.2D. The boundary normal and tangential velocities are set to zero, imposing no-slip boundary conditions on  $\partial\Omega$ . The density ratio between the liquid droplet (or the film phase) and the surrounding gas phase is  $\rho_l/\rho_g = 815$ , with  $\rho_g = 1$ . The Reynolds number based on the gas phase, Re =  $\rho_g U D/\mu_g$ , is used to determine the gas phase viscosity, and the viscosity ratio between liquid and gas is  $\mu_l/\mu_g = 55$ . The Weber number based on the gas phase, We =  $\rho_{\rm g}U^2D/\sigma = 0.126$ , is used to determine the surface tension coefficient  $\sigma$ . Gravity is neglected for this particular problem, which, because of the high impact velocity, is a convection and surface tension driven flow. Time is nondimensionalized as T = tU/D, and each case is run until T=1.5 with a constant time step size of  $\Delta t=1/(10N)$ . The conservative discretization is used for all cases considered here, but we found that the non-conservative discretization yields similar results (data not shown). For all of the cases, the density is synchronized via the level set function at the beginning of each time step with one grid cell of smearing  $(n_{\text{cells}} = 1)$  on either side of the interface. Similar problems have been studied numerically using the VOF methods by Coppola et al. [75] and by Patel and Natarajan [25], and using a lattice Boltzmann method by Li et al. [76].

As a first test we consider Re = 6.6 (left panels in Fig. 32), which can be directly compared to the results of Patel and Natarajan [25]. It is seen that the droplet merges into the liquid film and produces a thick, symmetric liquid sheet upon impact. Because of the relatively low Reynolds number, no satellite droplets are formed. The results are in excellent qualitative agreement with prior work [25], including resolution of the gas entrapment by the droplet into the liquid film. A second test case is carried out at Re = 66 (right panels in Fig. 32), which not only produces a splash with higher vertical reach than the lower Reynolds number

Figure 29: Two dimensional evolution of the spreading water column with density ratio  $\rho_l/\rho_g = 815.66$  and  $\mu_l/\mu_g = 63.88$  at four different time instances: (left) Inconsistent and (right) consistent transport of mass and momentum is used with grid size  $512 \times 128$ .

Figure 30: Three dimensional evolution of the spreading water column with density ratio  $\rho_1/\rho_g=815.66$  and  $\mu_1/\mu_g=63.88$  at four different time instances. Consistent transport of mass and momentum is used for this case with grid size  $256\times36\times64$ .

Figure 31: Temporal evolution of (a) dimensionless front position and (b) dimensionless height for the present 2D (—, black) and 3D ( $\times$ , red) consistent transport simulations, along with experimental data ( $\bullet$ , blue) from Martin and Moyce [72], 3D simulation data ( $\blacksquare$ , green) from Gu et al. [71], 2D simulation data ( $\bullet$ , grey) from Rezende et al. [70], and 2D simulation data ( $\blacktriangledown$ , yellow) from Patel and Natarajan [25].

case but also exhibits satellite droplets that break away from film. The results compare favorably to those of Patel and Natarajan [25]. As described by Coppola et al. [75], the jet base location  $x_{\rm J}$  can be computed by averaging the x-position of the two neck points of the liquid sheet (see Fig. 33(a)). According to the theoretical studies of Josserand and Zaleski [77] and Howison et al. [78], the normalized jet base location  $(x_{\rm J} - X_0)/D$  should scale with the square root of dimensionless time  $(Ut/D)^{1/2}$ . As shown in Fig.33(b), our simulation shows excellent quantitative agreement with this power law. These cases demonstrate that surface tension flows with complex merging dynamics are adequately simulated by the present numerical scheme.

Figure 33: (a) Location of the jet base  $x_J$  ( $\bullet$ , red), which is the midpoint of the two neck points (\*, red) for the liquid sheet (T = 0.2, Re = 66); (b) Temporal evolution of the dimensionless jet based location.

# 7.5.2. Three spatial dimensions

For our final case, we consider the problem of a three-dimensional droplet splashing on a thin liquid film. Experimental and theoretical consideration [79, 80] of this particular problem has inspired numerous numerical studies of this phenomena, including those of Nikolopoulos et al. [81, 82] and Manik et al. [83]. In particular, we follow a similar setup as described in [82]. A spherical droplet of initial diameter  $D_0 = 1$  is placed in a computational domain of size  $\Omega = [0, L]^3 = [0, 8D_0]^3$ , which is discretized by a base uniform grid of size  $N^3$  (with N=20) and four grid levels  $\ell=4$  with refinement ratio  $n_{\rm ref}=2$ . Hence at the

Figure 32: Temporal evolution of the droplet splashing on a thin liquid film with density ratio  $\rho_{\rm l}/\rho_{\rm g}=815$  and  $\mu_{\rm l}/\mu_{\rm g}=55$  at five different time instances with grid size  $1600\times400$ : (left) Re = 6.6 and (right) Re = 66.

finest level, the grid spacing is  $\Delta x_{\rm min} = \Delta y_{\rm min} = \Delta z_{\rm min} = 8/160$ . The domain is filled with a liquid film of height a, with the dimensionless height set as  $\overline{a} = a/D_0 = 0.116$  and the droplet has initial center  $(X_0, Y_0, Z_0) = (0.5L, 0.5L, 2.8D_0)$ . The density ratio between the liquid droplet (or the film phase) and the surrounding gas phase is  $\rho_{\rm l}/\rho_{\rm g} = 1000$ , with  $\rho_{\rm l} = 1000$ . The viscosity ratio between liquid and gas is  $\mu_{\rm l}/\mu_{\rm g} = 40$ , with  $\mu_{\rm l} = 8.9 \times 10^{-4}$ . The droplet has initial downward velocity  ${\bf u}({\bf x},0) = (0,-U_0)$ , which is projected to produce a discretely divergence-free initial condition  ${\bf u}_{\rm p}({\bf x},0)$ . The Reynolds number based on the liquid phase, Re  $= \rho_{\rm l} U_0 D_0/\mu_{\rm l} = 11294$ , is used to specify the initial downward velocity. The Weber number based on the liquid phase, We  $= \rho_{\rm l} U_0^2 D_0/\sigma = 250$ , is used to specify the surface tension coefficient  $\sigma$ . The Froude number, Fr  $= U_0^2/(ga) = 363$ , is used to specify the gravitational constant g. No-slip boundary conditions are applied on all computational boundaries. A constant time step size of  $\Delta t = 12.5\Delta x_{\rm min}$  is used, yielding an approximate initial CFL number of 0.125. The CFL number throughout the simulation remains less than 0.5 for all time steps. The conservative discretization is used for this case. The density is synchronized using the level set function at the beginning of each time step with one grid cell of smearing  $(n_{\rm cells} = 1)$  on either side of the interface.

Time is made dimensionless via  $T = (t - t_i)U_0/D_0$ . We again begin by demonstrating the importance of using consistent transport of mass and momentum by attempting to run this case with the non-conservative discretization. As seen in Fig. 34, the droplet undergoes significant (unphysical) deformation as it travels towards the liquid film. As a result, a coherent lamella does not form, and we see unphysical impact dynamics. In contrast, Fig. 35 shows the post-impact splashing dynamics of the liquid interface when this case is simulated with the conservative and consistent integrator. As the droplet travels downwards, it deforms because of the resistance from the gas phase. Upon impacting the liquid sheet at around  $t_i = 218.75$  (T = 0), the droplet is no longer a sphere. A lamella begins to emanate from the film and forms a secondary ring thereafter. The ring eventually splits from the top of the lamella at around T = 3.5, which then further disintegrates into smaller satellite droplets. The results are in very good qualitative agreement with [82], with small dissimilarities in the formation of satellite droplets at later times. This can be attributed to the differences in interface tracking methodology and computational set up of the problem.

We plot the dimensionless radial distance at the bottom of the rim  $(R_b/D_0)$  and dimensionless height of the lamella  $(a_l/D_0)$  as a function of time in Fig. 36. The results for the present work compare favorably to previous computational studies [81, 82, 83] that use the VOF method for interface tracking. This case demonstrates that the complex surface tension and gravity driven splashing dynamics are accurately simulated by the present (consistent) numerical scheme, even when significant adaptive mesh refinement is used.

Figure 34: (a)-(c) Temporal evolution of the 3D droplet splashing on a thin liquid film with density ratio  $\rho_{\rm l}/\rho_{\rm g}=1000$  and  $\mu_{\rm l}/\mu_{\rm g}=40$  at three different time instances. Inconsistent transport of mass and momentum occurs while employing a non-conservative momentum integrator. Contrast these results to those shown in Fig. 35, in which consistent transport is used.

Figure 35: (a)-(e) Temporal evolution of the 3D droplet splashing on a thin liquid film with density ratio  $\rho_l/\rho_g=1000$  and  $\mu_l/\mu_g=40$  at five different time instances. (f) Locations of the different refined mesh levels from coarsest to finest: red, green, pink, orange. Consistent transport of mass and momentum is used for these cases. Unlike the results shown in Fig. 34, here we observe a physical solution.

Figure 36: Temporal evolution of (a) dimensionless bottom radius and (b) dimensionless lamella height for the present 3D ( $\bullet$ , red) simulations, along with 3D simulation data ( $\blacksquare$ , blue) from Nikolopoulos et al. 2005 [81], 3D simulation data ( $\blacktriangle$ , green) from Nikolopoulos et al. 2007 [81], and 3D simulation data ( $\blacklozenge$ , grey) from Manik et al. [83].

#### 8. Conclusions

This study extended the monolithic variable-coefficient incompressible Navier-Stokes solver of Cai et al. [29] and used it for practical high density ratio and high shear multiphase flow applications. We demonstrated that our solver yields second-order convergence in a variety of conditions where analytic solutions are available, including with nontrivial physical boundary conditions, both on uniform and on locally refined computational grids. Further, we demonstrated the importance of consistent mass and momentum transport to maintain numerical stability for convection-dominated high density ratio flows. Achieving consistency between mass and momentum transport also necessitates the use of the conservative form of the momentum equation.

The projection preconditioner described here, and by Griffith [28] and Cai et al. [29], has several distinct advantages over the projection method solver. For variable-coefficient operators, there is an unavoidable commutator error that is associated with using the projection method as a solver. By considering the coupled velocity-pressure Stokes system, we avoid this source of error. Moreover, operator splitting approaches require the specification of artificial boundary conditions for the velocity and pressure fields. These affect the overall solution accuracy of the projection method solver, but only affect the convergence rate of the projection method preconditioner. Finally, we again emphasize that the using the projection method as a preconditioner to the coupled Stokes system is no less efficient than using it as a solver.

We also demonstrated that the solver has scalable convergence properties at both low and high Reynolds numbers and for high density and viscosity ratios. In our numerical experiments, we have seen that a number of factors can affect the convergence of the FGMRES solver. Generally speaking, smoother problems (i.e., that use more grid cells of interface smearing) allow for more rapid linear solver convergence than problems with sharp interfaces. Additionally, harmonic averaging of material properties leads to fewer iterations than simple arithmetic averaging. We also see that larger Reynolds numbers requires fewer iterations whereas smaller Reynolds numbers requires more iterations. Finally, the subdomain solvers can be further optimized for higher or lower (than air-water combination) density and viscosity ratios by tweaking  $\epsilon_{\text{sub}}$ , or by using stronger Krylov subdomain solvers or multigrid preconditioners.

A key contribution of this paper is that it extends the first-order conservative discretization algorithm of Desjardins and Moureau [20] and Ghods and Hermann [21] to a second-order accurate scheme. This is achieved here by using a SSP-RK3 time integrator for integrating the mass balance equation and employing higher-order CBC and TVD satisfying limiters. Our implementation also allows for the use of a forward Euler or SSP-RK2 integrator for the mass balance equation, although we have found that these can become numerically unstable for high density ratio and convection dominated flows. In fact, Appendix D demonstrates that we revert to a first-order accurate solution by switching to the forward Euler mass integrator and upwind limiter as done originally in [20] and [21]. Compatibility between mass and momentum transport is achieved at a discrete level by using the same mass flux in both the density evolution equation and

the momentum equation. The consistent discretization is also shown to be well-balanced with respect to the pressure gradient force and the gravitational and surface tension forces. By coupling this robust fluid solver with a level-set approach to interface tracking, we enable the simulation of complex multiphase flows such as spreading, merging, and splashing dynamics. We also demonstrated that level set function can be advected independently of the fluid solver, and can use a different (and possibly a non-CBC satisfying) convective limiter without affecting the overall stability of the scheme. Furthermore, we note that the present consistent mass and momentum update scheme remains stable even when conventional projection method solvers [55, 56] are used [84].

The present numerical method can be easily extended to allow for fluid-structure interaction in presence of multiple phases. In particular, future work involving the coupling between this solver and a constraint-based immersed boundary method (CIB) [85, 86] is already underway. In addition to this, the treatment of the viscous term described here allows for an implicit treatment of eddy viscosity, which is a key ingredient to turbulence modeling using both RANS and LES formulations [87, 88, 89]. Integrating this solver with CIB and turbulence modeling will enable simulation of many important industrial and engineering applications, including high inertia vehicles, wave-energy converter devices, and windmills. Finally, efforts are also underway to compute initial distance functions from CAD and STL files directly. This will allow complex geometries to be represented on Cartesian grids and further enhance our level set based solvers for realistic applications.

### A. Discretization of the viscous term in three spatial dimensions

The numerical treatment of the strain rate tensor  $\nabla \cdot \left[ \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) \right]$  in three spatial dimensions warrants additional discussion. For the velocity field  $\mathbf{u}(\mathbf{x},t) = (u(\mathbf{x},t),v(\mathbf{x},t),w(\mathbf{x},t))$ , the continuous strain rate tensor form of the viscous term is

$$\nabla \cdot \left[ \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^{T} \right) \right] = \begin{bmatrix} 2 \frac{\partial}{\partial x} \left( \mu \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left( \mu \frac{\partial u}{\partial y} + \mu \frac{\partial v}{\partial x} \right) + \frac{\partial}{\partial z} \left( \mu \frac{\partial u}{\partial z} + \mu \frac{\partial w}{\partial x} \right) \\ 2 \frac{\partial}{\partial y} \left( \mu \frac{\partial v}{\partial y} \right) + \frac{\partial}{\partial x} \left( \mu \frac{\partial v}{\partial x} + \mu \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left( \mu \frac{\partial v}{\partial z} + \mu \frac{\partial w}{\partial y} \right) \\ 2 \frac{\partial}{\partial z} \left( \mu \frac{\partial w}{\partial z} \right) + \frac{\partial}{\partial x} \left( \mu \frac{\partial w}{\partial x} + \mu \frac{\partial u}{\partial z} \right) + \frac{\partial}{\partial y} \left( \mu \frac{\partial w}{\partial y} + \mu \frac{\partial v}{\partial z} \right) \end{bmatrix}, \tag{A.1}$$

which leads to a discretization of the form

$$\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u} = \begin{bmatrix} (\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u})_{i-\frac{1}{2},j,k}^{x} \\ (\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u})_{i,j-\frac{1}{2},k}^{y} \\ (\mathbf{L}_{\boldsymbol{\mu}}\mathbf{u})_{i,j,k-\frac{1}{2}}^{z} \end{bmatrix}. \tag{A.2}$$

The two-dimensional discretization scheme required viscosity on both Cartesian cell centers, where  $\frac{\partial u}{\partial x}$  and  $\frac{\partial v}{\partial y}$  are naturally approximated, and nodes, where  $\frac{\partial u}{\partial y}$  and  $\frac{\partial v}{\partial x}$  are naturally approximated. In three spatial

Figure A.37: Two adjacent 3D staggered grid cells on which the viscous component  $(\mathbf{L}_{\mu}\mathbf{u})_{i-\frac{1}{2},j,k}^x$  is computed on a particular face  $(\times, \text{ red})$  using velocity derivatives and viscosity on cell centers  $(\bullet, \text{ black}), xy$ -edges  $(\blacktriangledown, \text{ orange}), \text{ and } xz$ -edges  $(\blacktriangle, \text{ green})$ . The yz-edges  $(\blacklozenge, \text{ blue})$  are not used in the computation of  $(\mathbf{L}_{\mu}\mathbf{u})_{i-\frac{1}{2},j,k}^x$ , but would be required to compute  $(\mathbf{L}_{\mu}\mathbf{u})_{i,j-\frac{1}{2},k}^y$  and  $(\mathbf{L}_{\mu}\mathbf{u})_{i,j,k-\frac{1}{2}}^z$ 

dimensions, the off-diagonal components of  $\left[\mu\left(\nabla\mathbf{u}+\nabla\mathbf{u}^{T}\right)\right]$  are naturally defined on the *edges* of the grid cells,

$$\left(\mu \frac{\partial u}{\partial y} + \mu \frac{\partial v}{\partial x}\right)_{i = \frac{1}{3}, j = \frac{1}{3}, k} = \mu_{i = \frac{1}{2}, j = \frac{1}{2}, k} \left(\frac{u_{i = \frac{1}{2}, j, k} - u_{i = \frac{1}{2}, j = 1, k}}{\Delta y} + \frac{v_{i, j = \frac{1}{2}, k} - v_{i = 1, j = \frac{1}{2}, k}}{\Delta x}\right), \tag{A.3}$$

$$\left(\mu \frac{\partial u}{\partial z} + \mu \frac{\partial w}{\partial x}\right)_{i - \frac{1}{2}, j, k - \frac{1}{2}} = \mu_{i - \frac{1}{2}, j, k - \frac{1}{2}} \left(\frac{u_{i - \frac{1}{2}, j, k} - u_{i - \frac{1}{2}, j, k - 1}}{\Delta z} + \frac{w_{i, j, k - \frac{1}{2}} - w_{i - 1, j, k - \frac{1}{2}}}{\Delta x}\right), \tag{A.4}$$

$$\left(\mu \frac{\partial v}{\partial z} + \mu \frac{\partial w}{\partial y}\right)_{i,j-\frac{1}{3},k-\frac{1}{3}} = \mu_{i,j-\frac{1}{2},k-\frac{1}{2}} \left(\frac{v_{i,j-\frac{1}{2},k} - v_{i,j-\frac{1}{2},k-1}}{\Delta z} + \frac{w_{i,j,k-\frac{1}{2}} - w_{i,j-1,k-\frac{1}{2}}}{\Delta y}\right). \tag{A.5}$$

Fig. A.37 shows the location of these xy-, xz-, and yz-edges. The full discretization of the x-component of the strain rate tensor reads,

$$(\mathbf{L}_{\mu}\mathbf{u})_{i-\frac{1}{2},j,k}^{x} = \frac{2}{\Delta x} \left[ \mu_{i,j,k} \frac{u_{i+\frac{1}{2},j,k} - u_{i-\frac{1}{2},j,k}}{\Delta x} - \mu_{i-1,j,k} \frac{u_{i-\frac{1}{2},j,k} - u_{i-\frac{3}{2},j,k}}{\Delta x} \right]$$

$$+ \frac{1}{\Delta y} \left[ \mu_{i-\frac{1}{2},j+\frac{1}{2},k} \frac{u_{i-\frac{1}{2},j+1,k} - u_{i-\frac{1}{2},j,k}}{\Delta y} - \mu_{i-\frac{1}{2},j-\frac{1}{2},k} \frac{u_{i-\frac{1}{2},j,k} - u_{i-\frac{1}{2},j-1,k}}{\Delta y} \right]$$

$$+ \frac{1}{\Delta y} \left[ \mu_{i-\frac{1}{2},j+\frac{1}{2},k} \frac{v_{i,j+\frac{1}{2},k} - v_{i-1,j+\frac{1}{2},k}}{\Delta x} - \mu_{i-\frac{1}{2},j-\frac{1}{2},k} \frac{v_{i,j-\frac{1}{2},k} - v_{i-1,j-\frac{1}{2},k}}{\Delta x} \right]$$

$$+ \frac{1}{\Delta z} \left[ \mu_{i-\frac{1}{2},j,k+\frac{1}{2}} \frac{u_{i-\frac{1}{2},j,k+1} - u_{i-\frac{1}{2},j,k}}{\Delta z} - \mu_{i-\frac{1}{2},j,k-\frac{1}{2}} \frac{u_{i-\frac{1}{2},j,k-1}}{\Delta z} \right]$$

$$+ \frac{1}{\Delta z} \left[ \mu_{i-\frac{1}{2},j,k+\frac{1}{2}} \frac{w_{i,j,k+\frac{1}{2}} - w_{i-1,j,k+\frac{1}{2}}}{\Delta x} - \mu_{i-\frac{1}{2},j,k-\frac{1}{2}} \frac{w_{i,j,k-\frac{1}{2}} - w_{i-1,j,k-\frac{1}{2}}}{\Delta x} \right],$$
(A.6)

which again uses cell centered viscosities and requires approximations to the viscosity on edges. The edge viscosities can be computed using arithmetic or harmonic averages of cell centered values, i.e.,  $\mu_{i-\frac{1}{2},j-\frac{1}{2},k}$  would be computed from  $\mu_{i-1,j-1,k}$ ,  $\mu_{i,j-1,k}$ ,  $\mu_{i-1,j,k}$ , and  $\mu_{i,j,k}$ . Approximations to the remaining components in Eq. (A.2) can be determined analogously. The other spatial discretizations described in Section 3 can be straightforwardly extended to three dimensions.

To complete our discussion, we consider the following manufactured solution in three spatial dimensions

Figure A.38:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the 3D non-conservative manufactured solution with specified normal velocity and tangential traction (vel-tra) boundary conditions: (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p.

for the non-conservative set of equations,

$$u(\mathbf{x},t) = 2\pi\cos(2\pi x)\sin(2\pi z)\cos(2\pi t - 2\pi y),\tag{A.7}$$

$$v(\mathbf{x},t) = -2\pi \sin(2\pi x)\cos(2\pi z)\sin(2\pi t - 2\pi y),\tag{A.8}$$

$$w(\mathbf{x},t) = \pi \sin(2\pi x)\cos(2\pi t - 2\pi y)(-2\sin(2\pi z) - 2\cos(2\pi z)),\tag{A.9}$$

$$p(\mathbf{x},t) = 2\pi \sin(2\pi t - 2\pi x)\cos(2\pi t - 2\pi y)\sin(2\pi t - 2\pi z),\tag{A.10}$$

together with time-independent density and viscosity fields of the form

$$\rho(\mathbf{x}) = \rho_0 + \frac{\rho_1}{2} \left( \tanh \left( \frac{0.1 - \sqrt{(x - 0.5)^2 + (y - 0.5)^2 + (z - 0.5)^2}}{\delta} \right) + 1 \right), \tag{A.11}$$

$$\mu(\mathbf{x}) = \mu_0 + \mu_1 + \mu_1 \sin(2\pi x)\cos(2\pi y)\sin(2\pi z). \tag{A.12}$$

The variations in density and viscosity are set to be similar to that of air and water:  $\rho_0 = 1$ ,  $\rho_1 = -\rho_0 + 10^3$ ,  $\mu_0 = 10^{-4}$ , and  $\mu_1 = -\mu_0 + 10^{-2}$ . The computational domain is the unit square  $\Omega = [0, L]^2 = [0, 1]^2$ , which is discretized by N grid cells in each direction. The smoothing parameter is set to  $\delta = 0.05L$ . The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U = 1. Errors in the velocity and pressure are computed at time T = tU/L = 0.1 with a uniform time step  $\Delta t = 1/(31.25N)$ , which yields an approximate CFL number of 0.3. A relative convergence tolerance of  $\epsilon_{\text{Stokes}} = 10^{-12}$  is specified for the FGMRES solver. We impose periodic boundary conditions in the x-and x-direction and consider normal velocity and tangential traction boundary conditions in the x-direction (vel-tra). Fig. A.38 shows the x-and x-direction and pressure as a function of grid size. Second-order convergence rates are achieved for both velocity and pressure in both norms, which demonstrates that the solver is maintaining the expected order of accuracy in three spatial dimensions.

## B. Physical boundary conditions

This section details the physical boundary condition treatment used in this work. The treatment of physical boundary conditions has been described in detail by Griffith for the constant-coefficient case [28], although we note that the imposition of normal traction boundary conditions used in this work differs slightly. We follow the same strategy as in Griffith [28] and restrict our attention to the vicinity of a single grid cell  $(N-1,j), 0 \le j < N$  on the right side of the physical domain (Fig. B.39). The treatment along other physical domain boundaries and in three dimensions is analogous.

Figure B.39: The velocity, pressure, and viscosity degrees of freedom in the vicinity of cell (N-1,j) required to enforce physical boundary conditions. Interior and boundary values are colored in black, and ghost values are colored in grey.

## B.1. Scalar boundary conditions

For the scalar fields, namely density  $\rho$ , viscosity  $\mu$ , and the signed distance function  $\phi$ , we restrict our attention to homogenous Neumann boundary conditions. For a given scalar field  $\psi$ , the boundary condition is

$$\frac{\partial \psi}{\partial x} \left( \mathbf{x}_{N - \frac{1}{2}}, t \right) = 0, \tag{B.1}$$

which is imposed using the standard ghost value treatment [41],

$$\psi_{N,j}^n = \psi_{N-1,j}^n. (B.2)$$

In cases where  $n_{\rm G} > 1$  ghost cell values are required for  $\psi$ , the condition is imposed by setting the  $k^{\rm th}$  ghost cell with the  $k^{\rm th}$  interior value, i.e.,  $\psi_{N+k-1} = \psi_{N-k}$  for  $k = 1, \ldots, n_{\rm G}$ .

# B.2. Fluid boundary conditions

Considering the right domain boundary once again, the outward unit normal is  $\mathbf{n} = (1,0)$ , and the unit tangent vector is  $\boldsymbol{\tau} = (0,1)$ . The viscous stress tensor for an incompressible fluid is

$$\boldsymbol{\sigma} = -p\mathbf{I} + \mu \left[ \nabla \mathbf{u} + \nabla \mathbf{u}^T \right]. \tag{B.3}$$

Following Griffith [28], four types of physical boundary conditions for **u** and  $\sigma$  are considered in this work:

1. The normal velocity is prescribed at face  $\mathbf{x}_{N-\frac{1}{2},j}$ : Suppose that the normal velocity at position  $\mathbf{x}_{N-\frac{1}{2},j}$  is given by  $u_{N-\frac{1}{2},j}^{\mathrm{norm}}(t)$ . The treatment of this boundary condition is straightforward because we can simply set

$$u_{N-\frac{1}{2},j}^{n} = u_{N-\frac{1}{2},j}^{\text{norm}}(t^{n}).$$
 (B.4)

As in Griffith [28], no ghost values are required for  $p_{N,j}$  or  $u_{N+\frac{1}{2},j}$ , nor may any pressure condition be prescribed at this boundary.

2. The tangential velocity is prescribed at node  $\mathbf{x}_{N-\frac{1}{2},j-\frac{1}{2}}$ : Suppose that the tangential velocity at position  $\mathbf{x}_{N-\frac{1}{2},j-\frac{1}{2}}$  is given by  $v_{N-\frac{1}{2},j-\frac{1}{2}}^{\tan}(t)$ . This boundary condition is imposed via a linear fit of the prescribed velocity and the closest internal value,

$$v_{N,j-\frac{1}{2}}^{n} = 2v_{N-\frac{1}{2},j-\frac{1}{2}}^{\tan}(t^{n}) - v_{N-1,j-\frac{1}{2}}^{n}.$$
(B.5)

3. The tangential traction is prescribed at node  $\mathbf{x}_{N-\frac{1}{2},j-\frac{1}{2}}$ : Suppose that the tangential traction,  $(\boldsymbol{\tau} \cdot \boldsymbol{\sigma} \cdot \mathbf{n}) = \mu \left( \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right)$ , is given by  $F_{N-\frac{1}{2},j-\frac{1}{2}}^{\mathrm{tan}}(t)$ . In contrast with prior work [28], the spatially varying viscosity must be treated when imposing this boundary condition. Writing out a second-order finite difference approximation to this boundary condition at time  $t^n$  yields

$$\mu_{N-\frac{1}{2},j-\frac{1}{2}}^{n} \left( \frac{v_{N,j-\frac{1}{2}}^{n} - v_{N-1,j-\frac{1}{2}}^{n}}{\Delta x} + \frac{u_{N-\frac{1}{2},j}^{n} - u_{N-\frac{1}{2},j-1}^{n}}{\Delta y} \right) = F_{N-\frac{1}{2},j-\frac{1}{2}}^{\tan}(t^{n}), \tag{B.6}$$

which is an expression for the ghost velocity  $v_{N,j-\frac{1}{2}}^n$  in terms of the interior values. Note that in the above expression the node-centered viscosity value is needed, which is already being computed and used for the discretization of the viscous operator (Eqs. (17) and (18)).

4. The normal traction is prescribed at face  $\mathbf{x}_{N-\frac{1}{n},i}$ :

Suppose that the normal traction,  $(\mathbf{n} \cdot \boldsymbol{\sigma} \cdot \mathbf{n}) = -p + 2\mu \frac{\partial u}{\partial x}$ , is given by  $F_{N-\frac{1}{2},j}^{\text{norm}}(t)$ . Again, the spatially varying viscosity must be handled when imposing this boundary condition. This boundary condition requires ghost values  $u_{N+\frac{1}{2},j}$  and  $p_{N,j}$  to be set, which implies a second condition must be enforced in order to uniquely specify these values. As in prior work [28], we enforce the divergence-free condition  $\nabla \cdot \mathbf{u}(x_{N,j},t) = 0$  in the ghost cell surrounding  $x_{N,j}$ . A second-order finite difference approximation to this condition at time  $t^n$  is

$$\frac{u_{N+\frac{1}{2},j}^{n} - u_{N-\frac{1}{2},j}^{n}}{\Delta x} + \frac{v_{N,j+\frac{1}{2}}^{n} - v_{N,j-\frac{1}{2}}^{n}}{\Delta u} = 0,$$
(B.7)

which yields

$$u_{N+\frac{1}{2},j}^{n} = u_{N-\frac{1}{2},j}^{n} - \frac{\Delta x}{\Delta y} \left( v_{N,j+\frac{1}{2}}^{n} - v_{N,j-\frac{1}{2}}^{n} \right).$$
 (B.8)

Now that we have obtained the ghost value  $u_{N+\frac{1}{2},j}$ , we can write out the finite difference approximation to the traction boundary condition,

$$-\frac{p_{N,j}^{n+\frac{1}{2}}+p_{N-1,j}^{n+\frac{1}{2}}}{2}+\mu_{N-\frac{1}{2},j}^{n+\frac{1}{2}}\left(\frac{3u_{N-\frac{1}{2},j}^{n}-4u_{N-\frac{3}{2},j}^{n}+u_{N-\frac{5}{2},j}^{n}}{2\Delta x}+\frac{3u_{N-\frac{1}{2},j}^{n+1}-4u_{N-\frac{3}{2},j}^{n+1}+u_{N-\frac{5}{2},j}^{n+1}}{2\Delta x}\right)=F_{N-\frac{1}{2},j}^{\text{norm}}(t^{n+\frac{1}{2}}),$$

$$(B.9)$$

in which we have used a one-sided second-order finite difference approximation to  $\frac{\partial u}{\partial x}$  at  $\mathbf{x}_{N-\frac{1}{2},j}$ . The viscosity on the face  $\mu_{N-\frac{1}{2},j}^{n+\frac{1}{2}}$  is computed using an arithmetic or harmonic average of the viscosity in the neighboring cells  $\mu_{N-1,j}^{n+\frac{1}{2}}$  and  $\mu_{N,j}^{n+\frac{1}{2}}$ . Rearranging Eq. (B.9) yields an expression for the desired ghost value for pressure  $p_{N,j}^{n+\frac{1}{2}}$  based on interior values.

We note that the numerical imposition of the normal traction boundary condition using (one-sided) second-order derivative here differs from the one-sided first-order approximation to  $\frac{\partial u}{\partial x}$  at  $\mathbf{x}_{N-\frac{1}{2},j}$  previously used by Griffith [28].

# C. Conservative form: Smooth density profile evolution

Figure C.40:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the conservative manufactured solution with specified normal velocity and normal velocity boundary conditions on all boundaries, and smooth density profile given by Eq. (C.1). In these cases, the density  $\rho$  is *not* reset between time steps. (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for  $\rho$ ; (c) convergence rate for  $\rho$ .

In Sec. 6.3, we note that the  $C^0$  spatial continuity of the manufactured solution density field can lead to reductions in the pointwise convergence rate. This section demonstrates that using the smooth density field,

$$\rho(\mathbf{x},t) = 2 + x\cos(\sin(t)) + y\sin(\sin(t)),\tag{C.1}$$

yields second-order pointwise convergence rates for  $\mathbf{u}$ , p, and  $\rho$ . The same velocity (Eqs. (77)–(78)), pressure (Eq. (79)), and viscosity (Eq. (81)) fields are used to produce the desired forcing term. Note that this density field also satisfies the conservative mass balance equation (3). For all physical boundaries, specified normal velocity and tangential velocity boundary conditions are used. The domain  $\Omega = [-L, L] = [-1, 1]^2$  is discretized by an  $N \times N$  grid. The maximum velocities in the domain for this manufactured solution are  $\mathcal{O}(1)$ , hence a relevant time scale is L/U with U=1. Errors in the velocity and pressure are computed at time T=tU/L=0.6 with a uniform time step size  $\Delta t=1/(1.042N)$ , which yields an approximate CFL number of 0.5. A relative convergence tolerance of  $\epsilon_{\text{Stokes}}=10^{-12}$  is specified for the FGMRES solver. For these cases, density is evolved and not reset between time steps. Fig. C.40 shows the  $L^1$  and  $L^\infty$  errors for velocity, pressure, and density as a function of grid size. Second-order convergence rates are achieved for velocity, pressure, and density in both norms.

## D. First-order density update scheme

Figure D.41:  $L^1$  ( $\blacksquare$ , blue) and  $L^{\infty}$  ( $\bullet$ , red) errors as a function of grid size N for the conservative manufactured solution with specified normal velocity and normal velocity boundary conditions on all boundaries, and smooth density profile given by Eq. (C.1). In these cases, the density  $\rho$  is *not* reset between time steps. Forward Euler timestepping is used to update  $\rho$ , while an upwind scheme is used to approximate  $\rho^{\lim}$  on the faces of the shifted control volumes. (a) convergence rate for  $\mathbf{u}$ ; (b) convergence rate for p; (c) convergence rate for  $\rho$ .

Here, we demonstrate the importance of the SSP-RK3 and CUI limited density update for maintaining second-order convergence rates. Using the same manufactured solution of Appendix C, we instead use forward Euler timestepping for the density update and an first-order upwind scheme to approximate the shifted control volume density  $\rho_{\text{lim}}$ . We still use CUI to approximate the shifted control volume velocity  $\mathbf{u}_{\text{lim}}$  for the convective derivative. A similar scheme was considered in [20]. Fig. D.41 shows that first order convergence rates are obtained not only for the density field, but also for pressure and velocity. Therefore, the additional complexity of the primary discretization scheme is justified.
