# Resilient Consensus Through Event-based Communication

Yuan Wang and Hideaki Ishii, Senior Member, IEEE

Abstract-We consider resilient versions of discrete-time multiagent consensus in the presence of faulty or even malicious agents in the network. In particular, we develop event-triggered update rules which can mitigate the influence of the malicious agents and at the same time reduce the communication. Each regular agent updates its state based on a given rule using its neighbors' information. Only when the triggering condition is satisfied, the regular agents send their current states to their neighbors. Otherwise, the neighbors will continue to use the state received the last time. Assuming that a bound on the number of malicious nodes is known, we propose two update rules with event-triggered communication. They follow the socalled mean subsequence reduced (MSR) type algorithms and ignore values received from potentially malicious neighbors. We characterize the necessary connectivity in the network for the algorithms to perform correctly, which are stated in terms of the notion of graph robustness. A numerical example is provided to demonstrate the effectiveness of the proposed approach.

## I. INTRODUCTION

The study of distributed coordination in multi-agent systems has received much attention in a wide range of areas including control, robotics, communications, complex networks, and computer science. More recently, it has been recognized that cyber security for networked control systems is a critical issue since the extensive use of communications for the interactions among agents creates numerous vulnerabilities for potential attacks (e.g., [27]). Control related applications such as those in robotics involve physical aspects, and hence, different from cyber attacks purely in the domain of information technology, attacks may lead to damages in equipments or even accidents.

In large-scale multi-agent systems, consensus problems form one of the fundamental problems (e.g., [22]). There, agents interact locally and exchange their information with each other in order to arrive at the global objective of sharing a common value. In an uncertain environment where faults or even adversarial attacks can be present, it is of great importance to defend consensus algorithms by raising their security levels so as to avoid being influenced by such uncertainties in their decision makings. In this context, adversarial agents are those that do not follow the given algorithms and might even attempt to keep the nonfaulty, regular agents from reaching consensus. It is also remarked that, as a different class of cyber attacks, the effects of jamming and DoS attacks on multi-agent consensus have recently been analyzed in [13], [28].

In this paper, we study resilient versions of consensus algorithms and specifically follow the line of research of faulttolerant distributed algorithms in the area of computer science, where such problems have long been studied (see, e.g., [2], [12], [17]). For each regular agent, a simple but effective approach to mitigate the influence of potentially misleading information due to faults and cyber attacks is to ignore the agents whose states are the most different from its own. It is assumed that the nodes know a priori the maximum number F of adversarial agents in the network. Hence, it is useful to remove the F largest values as well as the F smallest values among those received from the neighbors. This class of algorithms is sometimes called the mean subsequence reduced (MSR) algorithms and has been employed in computer science (e.g., [19], [33]), control theory (e.g., [3], [16], [36]), and robotics (e.g., [6], [24], [26]). An important recent progress lies in the characterization of the necessary requirement on the topology of the agent networks. This was initiated by [16], [33], where the relevant notion of robust graphs was proposed.

In this paper, we develop distributed protocols for resilient consensus with a particular emphasis on the communication loads for node interactions. We reduce the transmissions in MSR algorithms through the so-called event-triggered protocols (e.g., [9]). Event-based protocols have been developed for conventional consensus without malicious agents in, e.g., [5], [7], [11], [18], [20], [21], [29]. Related results can be found in [10], where event-based consensus-type algorithms are developed for the synchronization of clocks possessed by the nodes in wireless sensor networks (WSNs).

Under this method, nodes make transmissions only when necessary in the sense that their values sufficiently changed since their last transmissions. In certain cases, the agents may make only a finite number of transmissions to neighbors. The advantage is that the communication can be greatly reduced in frequency and may be required only a finite number of times, while the tradeoff is that the achievable level of consensus may be limited, leaving some gaps in the agents' values. Time-triggered protocols may be a simpler way to reduce the communication load, but will not be able to determine when to stop the communication. More concretely, we develop two protocols for resilient consensus under event-based communication. Their convergence properties are analyzed, and the requirement for the network topology is fully characterized in terms of robust graphs. We will show through a numerical example how the two protocols differ in the amounts of

The difficulty in applying event-triggered protocols in the context of resilient consensus based on MSR algorithms is due to the handling of the errors between the current values and their last transmitted ones. In our approach, we treat such errors as noise in the system. This approach can be seen as an extension of [14], where a resilient version of the WSN clock synchronization problem in [10] mentioned above is analyzed; the exchange of two clock variables creates decaying noises in the consensus-type algorithms. By contrast, in our problem setting, the errors are due to triggering and do not entirely decay to zero. Moreover, we study a different class of adversarial nodes as we clarify later.

Another feature of this paper is that we deal with eventtriggered protocols for consensus algorithms in the discretetime domain. This is in contrast to the conventional works that deal with event-based consensus in continuous time (e.g., [5], [11], [18], [29]). In such cases, the agents must continuously monitor their states to detect when their states reach the thresholds for triggering events. This mechanism may require special resources for computation. Furthermore, events with short intervals may occur, which can result in undesirable Zeno behaviors. On the other hand, there are works such as [7], [20], [21], where sampled-data controllers are employed for agents with system dynamics in continuous time.

It is interesting to note that in discrete time, event-based consensus algorithms must be designed differently. This issue has also been discussed in [10], which essentially deals with discrete-time asynchronous update rules without adversaries. It is emphasized that in the presence of attacks, this aspect seems even more crucial. In this paper, we present two resilient consensus algorithms, but also discuss a third potential approach. The differences among them are modest: At the updates, each agent has the option of using its own state or its own last transmitted state. We will however see that analysis methods can differ, leading to various levels of conservatism in the bounds on the parameters for the event triggering functions.

Before we close this introduction, we would like to briefly discuss the recent advances in the research of MSR algorithms. The early works [16], [33] dealt with first-order agents with synchronous updates. In [3], MSR-type algorithms are developed for agents having second-order dynamics, which may hence be applicable to autonomous vehicles, and moreover, delays in communication as well as asynchronous updates are taken into account. The work [15] studied the MSRbased resilient synchronization problem in a more general setting with agents having higher-order dynamics, operating in continuous time. While most studies mentioned so far deal with agents whose states take real values, the work [4] considers agents with quantized (i.e., integer-valued) states. Also, there is a line of graph theoretic studies (e.g., [32], [36], [38]), which discuss methods to identify the robustness of certain classes of graphs with specified levels of robustness, for both undirected and directed graphs.

The MSR-based approach is found useful in addressing distributed problems outside of consensus problems as well. In [31], a resilient version of distributed optimization is studied by employing MSR-like mechanisms to detect outliers in the neighbors' variables. Further, in [23], resilient distributed state estimation problem is studied, where another class of robust graphs relevant to the problem is introduced. In the robotics area, [6] applies MSR algorithms for cooperative robots and develops methods for the robots to find if and how the network for their interactions can be built with robust graph properties.

It should highlight that MSR algorithms do not aim to detect adversarial nodes as they simply leave out the values that are the most different. Efforts have been made to develop distributed algorithms to detect and identify the adversaries while performing the given task. For example, in [25], [30], detection techniques using unknown input observers are proposed, in which case the initial values of all normal nodes can be found though they require the global knowledge of the network topology. Methods based on more local information can be found in, e.g., [1], [8], [37].

This paper is organized as follows. In Section II, we introduce some preliminaries and then formulate the event-based resilient consensus problem. We propose two event-based resilient update rules and study their convergence and necessary network structures in Sections III and IV. A numerical example is given in Section V to demonstrate the effectiveness of the proposed algorithms. We provide concluding remarks in Section VI. This paper is an extended version of [34] with full proofs of the results and further discussions.

#### II. EVENT-BASED RESILIENT CONSENSUS PROBLEM

## A. Preliminaries on graphs

Some basic notations related to graphs are introduced for the analysis in this paper.

Consider the directed graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  consisting of n nodes. Here the set of nodes is denoted by  $\mathcal{V} = \{1, 2, \ldots, n\}$  and the edge set by  $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ . The edge  $(j, i) \in \mathcal{E}$  indicates that node j can send a message to node i and is called an incoming edge of node i. Let  $\mathcal{N}_i = \{j : (j, i) \in \mathcal{E}\}$  be the set of neighbors of node i. The number of neighbors of node i is called its degree and is denoted as  $d_i = |\mathcal{N}_i|$  The path from node  $i_1$  to node  $i_p$  is denoted as the sequence  $(i_1, i_2, \ldots, i_p)$ , where  $(i_j, i_{j+1}) \in \mathcal{E}$  for  $j = 1, 2, \ldots, p - 1$ . The graph  $\mathcal{G}$  is said to have a spanning tree if there exists a node from which there is a path to all other nodes of this graph.

To establish resilient consensus results, an important topological notion is that of robustness of graphs [16].

**Definition 1.** The graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  is called (r, s)-robust (r, s < n) if for any two nonempty disjoint subsets  $\mathcal{V}_1, \mathcal{V}_2 \subseteq \mathcal{V}$ , one of the following conditions is satisfied: 1)  $\mathcal{X}_{\mathcal{V}_1}^r = \mathcal{V}_1$ , 2)  $\mathcal{X}_{\mathcal{V}_2}^r = \mathcal{V}_2$ , and 3)  $|\mathcal{X}_{\mathcal{V}_1}^r| + |\mathcal{X}_{\mathcal{V}_2}^r| \ge s$ , where  $\mathcal{X}_{\mathcal{V}_i}^r$  is the set of all nodes in  $\mathcal{V}_i$  which have at least r neighbors outside  $\mathcal{V}_i$  for i = 1, 2. The graph is said to be r-robust if it is (r, 1)-robust.

In Fig. 1, we display an example graph with seven nodes. It can be checked to have just enough connectivity to be (3,3)-robust. This level of robustness is lost if any edge is removed. We summarize some basic properties of robust graphs [16].

**Lemma 1.** An (r, s)-robust graph  $\mathcal{G}$  satisfies the following:

1)  $\mathcal{G}$  is (r', s')-robust, where  $0 \le r' \le r$ ,  $1 \le s' \le s$ , and in particular, it is *r*-robust.

Fig. 1. Network topology with (3,3)-robustness

- 2) G has a directed spanning tree. Moreover, it is 1-robust if and only if it has a directed spanning tree.
- 3)  $r \leq \lceil n/2 \rceil$ , where the ceil function  $\lceil y \rceil$  gives the smallest integer greater than or equal to y. Furthermore, it holds  $r = \lceil n/2 \rceil$  if and only if  $\mathcal{G}$  is a complete graph.
- The degree d<sub>i</sub> for i ∈ V is lower bounded as d<sub>i</sub> ≥ r + s 1 if s < r and d<sub>i</sub> ≥ 2r 2 if s ≥ r.

Moreover, a graph  $\mathcal{G}$  is (r, s)-robust if it is (r + s - 1)-robust.

In consensus problems, the property 2) in the lemma is of interest. Robust graphs may not be strongly connected in general, but this property indicates that the notion of robust graphs is a generalization of graphs containing directed spanning trees, which are of great relevance in the literature of consensus [22]. As we will see, robust graphs play a key role in characterizing the necessary network structure for achieving resilient consensus. It should however be noted that checking the robustness of a given graph involves combinatorial computation and is thus difficult in general [32], [36], [38].

### B. Event-based consensus protocol

We consider the directed graph  $\mathcal{G}$  of n nodes. The nodes in  $\mathcal{V}$  are partitioned into two sets:  $\mathcal{R}$  denotes the set of regular nodes and  $\mathcal{A} = \mathcal{V} \setminus \mathcal{R}$  represents the set of adversarial nodes. The regular nodes will follow the designed algorithm exactly while the adversarial nodes can have different update rules from that of the regular nodes. The attacker is allowed to know the states of the regular nodes and the graph topology, and to choose any node as a member of  $\mathcal{A}$  under some constraints.

We introduce the event-based protocol for the regular nodes to achieve consensus. It can be outlined as follows: At each discrete-time instant  $k \in \mathbb{Z}_+$ , the nodes make updates, but whether they transmit their current values to neighbors depends on the triggering function. More concretely, each node *i* has an auxiliary variable which is its state value communicated the last time and compares it with its own current state. If the current state has changed sufficiently, then it will be sent to its neighbors and the auxiliary variable will be replaced.

The update rule for agent i is described by

$$x_i(k+1) = x_i(k) + u_i(k),$$
 (1)

where  $x_i(k) \in \mathbb{R}$  is the state and  $u_i(k)$  is the control given by

$$u_i(k) = \sum_{j \in \mathcal{N}_i} a_{ij}(k) \left( \hat{x}_j(k) - x_i(k) \right).$$
 (2)

Here,  $\hat{x}_j(k) \in \mathbb{R}$  is an auxiliary state, representing the last communicated state of node j at time k. It is defined as

$$\hat{x}_j(k) = x_j(t_l^j), \quad k \in [t_l^j, t_{l+1}^j),$$

3

where  $t_0^j, t_1^j, \ldots$  denote the transmission times of node j determined by the triggering function to be given below. The initial values  $x_i(0), \hat{x}_j(0)$  are given, and  $a_{ij}(k)$  is the weight for the edge (j, i). Also, let  $a_{ii}(k) = 1 - \sum_{j \in \mathcal{N}_i} a_{ij}(k)$ . Assume that  $\gamma \leq a_{ij}(k) < 1$  if  $a_{ij}(k) \neq 0$  or if i = j for  $i, j \in \mathcal{V}$ , where  $\gamma$  is the lower bound with  $0 < \gamma \leq 1/2$ . In the resilient consensus algorithms to be introduced, the neighbors whose values are used for updates change over time, and hence, the weights  $a_{ij}(k)$  are time varying. The update rule above can be seen as a discrete-time counterpart of the event-based consensus algorithms in, e.g., [7], [18], [29].

We now introduce the triggering function. Denote the error at time k between the updated state  $x_i(k+1)$  and the auxiliary state  $\hat{x}_i(k)$  by  $e_i(k) = \hat{x}_i(k) - x_i(k+1)$  for  $k \ge 0$ . Then, let

$$f_i(k) = |e_i(k)| - (c_0 + c_1 e^{-\alpha k}), \qquad (3)$$

where  $c_0$ ,  $c_1$ , and  $\alpha > 0$  are positive constants. If  $f_i(k) > 0$ , agent *i* transmits its new state  $x_i(k+1)$  to the neighbors at time *k*. This mechanism will be discussed further later.

## C. Adversary model and resilient consensus

For each adversarial node i in the set  $\mathcal{A}$ , its state  $x_i(k)$  is updated as in (1), but its control  $u_i(k)$  can take arbitrary values at any k. Such nodes may have knowledge on the entire network including its topology, the values of all normal nodes, and their update rules. In this respect, we take account of their worst-case behaviors. Specifically, we employ the malicious model introduced in [16] as follows:

**Definition 2.** (*Malicious nodes*): An adversarial node i is said to be malicious if it updates its state  $x_i(k)$  in (1) by arbitrarily choosing  $u_i(k)$  and sends the state  $x_i(k)$  to all of its neighbors at each transmission.

Adversarial nodes more difficult to deal with are those that can transmit different values to different neighbors. Such nodes are referred to as being Byzantine [33]. The motivation for considering malicious nodes as defined above comes, for example, from the applications of WSNs, where sensor nodes communicate to their neighbors by broadcasting their data.

We also set a bound on the number of malicious nodes in the network. In this paper, we will deal with networks of the so-called F-total model as defined below.

**Definition 3.** (*F*-total model): For  $F \in \mathbb{N}$ , we say that the adversarial set  $\mathcal{A}$  follows an *F*-total model if  $|\mathcal{A}| \leq F$ .

Let the number of malicious agents be denoted by  $N_m = |\mathcal{A}|$ . Then, let  $N = |\mathcal{V}| - N_m$  be the number of regular agents.

Now, we introduce the notion of resilient consensus for multi-agent systems.

**Definition 4.** (*Resilient consensus*): Given  $c \ge 0$ , if for any possible sets and behaviors of the malicious agents and any initial state values of the regular nodes, the following conditions are satisfied, then the multi-agent system is said to reach resilient consensus at the error level c:

Safety condition: There exists an interval S ⊂ R such that x<sub>i</sub>(k) ∈ S for all i ∈ R, k ∈ Z<sub>+</sub>.

 Consensus condition: For all i, j ∈ R, it holds that lim sup<sub>k→∞</sub> |x<sub>i</sub>(k) - x<sub>j</sub>(k)| ≤ c.

In this paper, we would like to design event-based update rules for the regular agents to reach resilient consensus at a prespecified error level c under the F-total model by using only local information obtained from their neighbors

## III. ROBUST PROTOCOLS FOR EVENT-BASED CONSENSUS

## A. E-MSR algorithm

In this section, we outline a distributed protocol to solve the resilient consensus problem. As discussed above, every node makes an update at every time step in a synchronous manner, but only when an event happens, the auxiliary values will be updated and then sent to neighbors. The basis of the algorithm follows those in the works of, e.g., [3], [16]. The algorithm in this paper is called the event-based mean subsequence reduced (E-MSR) algorithm.

The E-MSR algorithm has four steps as follows:

- (Collecting neighbors' information) At each time step k, every regular node i ∈ R uses the values x̂<sub>j</sub>(k), j ∈ N<sub>i</sub>, most recently communicated from the neighbors as well as its own value x<sub>i</sub>(k) and sorts them from the largest to the smallest.
- 2) (Deleting suspicious values) Comparing with  $x_i(k)$ , node *i* removes the *F* largest and *F* smallest values from its neighbors. If the number of values larger or smaller than  $x_i(k)$  is less than *F*, then all of them are removed. The removed data is considered as suspicious and will not be used in the update. The set of the node indices of the remaining values is written as  $\mathcal{M}_i(k) \subset \mathcal{N}_i$ .
- 3) (Local update) Node i updates its state by

$$x_i(k+1) = x_i(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k) \left( \hat{x}_j(k) - x_i(k) \right).$$
(4)

4) (Communication update) Node i checks if its own triggering function f<sub>i</sub>(k) in (3) is positive or not. Then, it sets x̂<sub>i</sub>(k + 1) as

$$\hat{x}_i(k+1) = \begin{cases} x_i(k+1) & \text{if } f_i(k) > 0, \\ \hat{x}_i(k) & \text{otherwise.} \end{cases}$$
(5)

The communication rule in this algorithm shows that only when the current value has varied enough to exceed a threshold, then the auxiliary variable will be updated, and only at this time the node sends its value to its neighbors. This event triggering scheme can significantly reduce the communication burden as we will see in the numerical example in Section V.

## B. Protocol 1

The first protocol of this paper is the E-MSR algorithm as stated above, which will be referred to as Protocol 1. We are now ready to present our main result for this protocol.

We introduce two kinds of minima and maxima of the states of the regular agents: The first involves only the states as  $\overline{x}(k) = \max_{i \in \mathcal{R}} x_i(k)$  and  $\underline{x}(k) = \min_{i \in \mathcal{R}} x_i(k)$  while the second uses also the auxiliary variables as  $\underline{\hat{x}}(k) = \min_{i \in \mathcal{R}} \{x_i(k), \hat{x}_i(k)\}$  and  $\overline{\hat{x}}(k) = \max_{i \in \mathcal{R}} \{x_i(k), \hat{x}_i(k)\}$ .

The safety interval S is chosen as  $S = [\hat{x}(0), \hat{x}(0)]$ . It is noted that at initial time,  $\hat{x}_i(0)$  need not be the same as  $x_i(0)$ .

**Theorem 1.** Under the *F*-total model, the regular agents with E-MSR using (4) and (5) reach resilient consensus at an error level *c* if and only if the underlying graph is (F + 1, F + 1)-robust. The safety interval is given by  $S = [\hat{x}(0), \hat{x}(0)]$ , and the consensus error level *c* is achieved if the parameter  $c_0$  in the triggering function (3) satisfies

$$c_0 \le \frac{\gamma^N c}{4N}.\tag{6}$$

*Proof.* (Necessity) This essentially follows from [16], which considers the special case without the triggering function, that is,  $c_0 = c_1 = 0$ .

(Sufficiency) We first show that the interval  $S = [\underline{\hat{x}}(0), \overline{\hat{x}}(0)]$  satisfies the safety condition by induction. Note that the update rule (4) can be rewritten as

$$x_i(k+1) = a_{ii}(k)x_i(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k)\hat{x}_j(k), \quad (7)$$

where  $a_{ii}(k) = 1 - \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k)$ . At time k = 0, it is clear by definition that  $x_i(0), \hat{x}_i(0) \in S$ ,  $i \in \mathcal{R}$ . Suppose that for each regular agent  $i, x_i(k), \hat{x}_i(k) \in S$ . Then, for agent i, its neighbors in  $\mathcal{M}_i(k)$  take values only in S, since there are agents with values outside S at most F, and they are ignored in step 2 of the E-MSR. From (7), we have  $x_i(k+1) \in S$ . Moreover, by (5), it follows that  $\hat{x}_i(k+1) \in S$ . Thus, S is the safety interval.

We next establish the consensus condition. Note that for time  $k \in (t_l^i, t_{l+1}^i)$  between two triggering instants, we have  $f_i(k) \leq 0$ . Moreover, for the neighbor node  $j \in \mathcal{N}_i$ , if  $f_j(k) > 0$ , then we have  $\hat{x}_j(k+1) = x_j(k+1)$ . If  $f_j(k) \leq 0$ , then  $\hat{x}_j(k+1) = \hat{x}_j(k) = x_j(k+1) + e_j(k)$ . As a result, it holds  $\hat{x}_j(k) = x_j(k) + \hat{e}_j(k-1)$  for  $k \geq 1$ , where

$$\hat{e}_j(k) = \begin{cases} e_j(k) & \text{if } f_j(k) \le 0, \\ 0 & \text{otherwise.} \end{cases}$$

Note that

$$|\hat{e}_j(k)| \le c_0 + c_1 \mathbf{e}^{-\alpha k}, \quad \forall k \ge 0.$$
(8)

Then, we can write (7) as

$$x_i(k+1) = a_{ii}(k)x_i(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k) \left(x_j(k) + \hat{e}_j(k-1)\right)$$
(9)

This can be bounded by using the maximum state  $\overline{x}(k)$  as

$$x_{i}(k+1) \leq a_{ii}(k)\overline{x}(k) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k) \left(\overline{x}(k) + \hat{e}_{j}(k-1)\right)$$
$$= \overline{x}(k) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k)\hat{e}_{j}(k-1)$$
$$\leq \overline{x}(k) + \max_{j \in \mathcal{M}_{i}(k)} \left|\hat{e}_{j}(k-1)\right|.$$
(10)

Thus, by (8) it follows

$$x_i(k+1) \le \overline{x}(k) + c_0 + c_1 \mathbf{e}^{-\alpha(k-1)}.$$

Let  $V(k) = \overline{x}(k) - \underline{x}(k)$ . Then, introduce two sequences by

$$\overline{x}_0(k+1) = \overline{x}_0(k) + c_0 + c_1 \mathbf{e}^{-\alpha(k-1)}, \qquad (11)$$

$$\underline{x}_0(k+1) = \underline{x}_0(k) - c_0 - c_1 e^{-\alpha(k-1)}, \quad (12)$$

where  $\overline{x}_0(0) = \overline{x}(0) - \sigma_0$ , and  $\underline{x}_0(0) = \underline{x}(0) + \sigma_0$  with  $\sigma_0 = \sigma V(0)$ . We next introduce another sequence  $\varepsilon_0(k)$  defined by

$$\varepsilon_0(k+1) = \gamma \varepsilon_0(k) - (1-\gamma)\sigma_0, \qquad (13)$$

where  $\varepsilon_0(0) = \varepsilon V(0)$ . Take the parameters  $\varepsilon$  and  $\sigma$  so that

$$\varepsilon + \sigma = \frac{1}{2}, \quad 0 < \sigma < \frac{\gamma^N}{1 - \gamma^N} \varepsilon.$$
 (14)

For the sequence  $\varepsilon_0(k)$ , let

$$\begin{aligned} \mathcal{X}_0(k,\varepsilon_0(k)) &= \left\{ j \in \mathcal{V} : \ x_j(k) > \overline{x}_0(k) - \varepsilon_0(k) \right\}, \\ \mathcal{X}_0(k,\varepsilon_0(k)) &= \left\{ j \in \mathcal{V} : \ x_j(k) < \underline{x}_0(k) + \varepsilon_0(k) \right\}. \end{aligned}$$

These two sets are both nonempty at time k = 0 and, in particular, each contains at least one regular node; this is because by definition,  $\overline{x}(0) > \overline{x}_0(0) - \varepsilon_0(0)$  and  $\underline{x}(0) < \underline{x}_0(0) + \varepsilon_0(0)$ .

In the following, we show that  $\overline{\mathcal{X}_0}(k, \varepsilon_0(k))$  and  $\underline{\mathcal{X}_0}(k, \varepsilon_0(k))$  are disjoint sets. To this end, we must show

$$\overline{x}_0(k) - \varepsilon_0(k) \ge \underline{x}_0(k) + \varepsilon_0(k).$$

By (11) and (12) for  $\overline{x}_0(k)$  and  $\underline{x}_0(k)$ , we have

$$\begin{aligned} (\overline{x}_{0}(k) - \varepsilon_{0}(k)) &- (\underline{x}_{0}(k) + \varepsilon_{0}(k)) \\ &= \left( \overline{x}_{0}(0) + c_{0}k + c_{1} \frac{1 - e^{-\alpha(k-1)}}{1 - e^{-\alpha}} \right) \\ &- \left( \underline{x}_{0}(0) - c_{0}k - c_{1} \frac{1 - e^{-\alpha(k-1)}}{1 - e^{-\alpha}} \right) - 2\varepsilon_{0}(k). \end{aligned}$$
(15)

Then by substituting  $\overline{x}_0(0) = \overline{x}(0) - \sigma_0$  and  $\underline{x}_0(0) = \underline{x}(0) + \sigma_0$  into the right-hand side of (15), we obtain

$$\begin{aligned} &(\overline{x}_{0}(k) - \varepsilon_{0}(k)) - (\underline{x}_{0}(k) + \varepsilon_{0}(k)) \\ &= (\overline{x}(0) - \underline{x}(0)) - 2\sigma_{0} + 2c_{0}k + 2c_{1}\frac{1 - e^{-\alpha(k-1)}}{1 - e^{-\alpha}} - 2\varepsilon_{0}(k) \\ &= V(0) - 2\sigma V(0) + 2c_{0}k + 2c_{1}\frac{1 - e^{-\alpha(k-1)}}{1 - e^{-\alpha}} - 2\varepsilon_{0}(k). \end{aligned}$$
(16)

By (13) and  $0 < \gamma \leq 1/2$ , we easily have that  $\varepsilon_0(k+1) < \varepsilon_0(k)$ , and hence  $\varepsilon_0(k) < \varepsilon_0(0) = \varepsilon V(0)$ . We thus obtain

$$\begin{split} & (\overline{x}_0(k) - \varepsilon_0(k)) - (\underline{x}_0(k) + \varepsilon_0(k)) \\ & > (1 - 2\sigma - 2\varepsilon)V(0) + 2c_0k + 2c_1\frac{1 - \mathrm{e}^{-\alpha(k-1)}}{1 - \mathrm{e}^{-\alpha}} > 0, \end{split}$$

where the last inequality holds since  $\sigma + \varepsilon = 1/2$  from (14). Thus,  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$  and  $\underline{\mathcal{X}}_0(k, \varepsilon_0(k))$  are disjoint sets.

From the above, we have that the two sets  $\overline{\mathcal{X}_0}(0, \varepsilon_0(0))$  and  $\underline{\mathcal{X}_0}(0, \varepsilon_0(0))$  are nonempty with at least one regular node in each and moreover disjoint. Therefore, by the assumption of (F+1, F+1)-robustness, there are three cases:

- 1) All nodes in  $\overline{\mathcal{X}_0}(0, \varepsilon_0(0))$  have F+1 neighbors or more from outside.
- 2) All nodes in  $\underline{\chi_0}(0, \varepsilon_0(0))$  have F+1 neighbors or more from outside.

3) The total number of nodes in  $\overline{\mathcal{X}_0}(0, \varepsilon_0(0))$  and  $\underline{\mathcal{X}_0}(0, \varepsilon_0(0))$  having F + 1 neighbors or more from outside of its own set is no smaller than F + 1.

Notice that in any of the three cases, there exists at least one regular agent  $i \in \mathcal{R}$  in either  $\overline{\mathcal{X}_0}(0, \varepsilon_0(0))$  or  $\underline{\mathcal{X}_0}(0, \varepsilon_0(0))$  that has F + 1 neighbors or more from outside of its own set. Here, suppose that this node *i* belongs to  $\overline{\mathcal{X}_0}(0, \varepsilon_0(0))$ . A similar argument holds for the case when it is in  $\underline{\mathcal{X}_0}(0, \varepsilon_0(0))$ .

Now, we go back to (9) and rewrite it by partitioning the neighbor node set  $\mathcal{M}_i(k)$  of node *i* into two parts: The nodes which belong to  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$  and those that do not. Since node *i* has at least F + 1 neighbors outside  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$ , the latter set is nonempty. Hence, we obtain

$$\begin{aligned} x_i(k+1) &= a_{ii}(k)x_i(k) + \sum_{j \in \mathcal{M}_i(k) \cap \overline{\mathcal{X}}_0} a_{ij}(k)x_j(k) \\ &+ \sum_{j \in \mathcal{M}_i(k) \setminus \overline{\mathcal{X}}_0} a_{ij}(k)x_j(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k)\hat{e}_j(k-1), \end{aligned}$$

where we use the shorthand notation  $\overline{\mathcal{X}}_0$  for  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$ . Then, we can bound this from above as

$$x_{i}(k+1) \leq a_{ii}(k)\overline{x}(k) + \sum_{j \in \mathcal{M}_{i}(k) \cap \overline{\mathcal{X}}_{0}} a_{ij}(k)\overline{x}(k) + \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k) (\overline{x}_{0}(k) - \varepsilon_{0}(k)) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k)\hat{e}_{j}(k-1) = \left(1 - \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k)\right) \overline{x}(k) + \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k) (\overline{x}_{0}(k) - \varepsilon_{0}(k)) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k)\hat{e}_{j}(k-1).$$
(17)

We next show that  $\overline{x}(k) \leq \overline{x}_0(k) + \sigma_0$  (and similarly,  $\underline{x}(k) \geq \underline{x}_0(k) - \sigma_0$ ) by induction. For k = 0, by definition, we have  $\overline{x}(0) = \overline{x}_0(0) + \sigma_0$ . Suppose that  $\overline{x}(k) \leq \overline{x}_0(k) + \sigma_0$ . Then, from (10) and (11), we have

$$\overline{x}(k+1) \le \overline{x}(k) + \max_{j} |\hat{e}_{j}(k-1)| \le \overline{x}(k) + c_{0} + c_{1}e^{-\alpha(k-1)}$$
$$\le \overline{x}_{0}(k) + \sigma_{0} + c_{0} + c_{1}e^{-\alpha(k-1)} = \overline{x}_{0}(k+1) + \sigma_{0}.$$

Then, (17) can be further bounded as

$$x_{i}(k+1) \leq \left(1 - \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k)\right) (\overline{x}_{0}(k) + \sigma_{0})$$
$$+ \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k) (\overline{x}_{0}(k) - \varepsilon_{0}(k))$$
$$+ \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k) \hat{e}_{j}(k-1)$$
$$\leq \overline{x}_{0}(k) + \left(1 - \sum_{j \in \mathcal{M}_{i}(k) \setminus \overline{\mathcal{X}}_{0}} a_{ij}(k)\right) \sigma_{0}$$

$$-\sum_{j\in\mathcal{M}_{i}(k)\setminus\overline{\mathcal{X}}_{0}}a_{ij}(k)\varepsilon_{0}(k)+\sum_{j\in\mathcal{M}_{i}(k)}a_{ij}(k)|\hat{e}_{j}(k-1)|.$$
(18)

We also show that  $\varepsilon_0(k) > 0$  holds for k = 0, 1, ..., N. It is clear from (13) that  $\varepsilon_0(k+1) < \varepsilon_0(k)$ . Thus we only need to guarantee  $\varepsilon_0(N) > 0$ . By (13),  $\varepsilon_0(N)$  can be written as

$$\varepsilon_0(N) = \gamma^N \varepsilon_0(0) - \sum_{i=0}^{N-1} \gamma^i (1-\gamma) \sigma_0$$
$$= \gamma^N \varepsilon V(0) - \frac{1-\gamma^N}{1-\gamma} (1-\gamma) \sigma V(0)$$
$$= \left(\gamma^N \varepsilon - (1-\gamma^N) \sigma\right) V(0).$$

This is positive because we have chosen  $\sigma$  as in (14).

Hence, (18) can be written as

$$x_i(k+1) \leq \overline{x}_0(k) + (1-\gamma)\sigma_0 - \gamma\varepsilon_0(k) + c_0 + c_1 e^{-\alpha(k-1)}$$
  
=  $\overline{x}_0(k+1) - \varepsilon_0(k+1),$  (19)

where in the inequality, we used the fact that there always exists j not in  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$ . This relation shows that if an update happens at node i, then this node will move out of  $\overline{\mathcal{X}}_0(k+1, \varepsilon_0(k+1))$ . We note that inequality (19) also holds for the regular nodes that are not inside  $\overline{\mathcal{X}}_0(k, \varepsilon_0(k))$  at time k. This means that such nodes cannot move in  $\overline{\mathcal{X}}_0(k+1, \varepsilon_0(k+1))$ . It is also similar with  $\underline{\mathcal{X}}_0(k+1, \varepsilon_0(k+1))$ .

Thus, after N time steps, all regular nodes will be out of at least one of the two sets  $\overline{\mathcal{X}}_0(N, \varepsilon_0(N))$  and  $\underline{\mathcal{X}}_0(N, \varepsilon_0(N))$ . We suppose that  $\overline{\mathcal{X}}_0(N, \varepsilon_0(N)) \cap \mathcal{R}$  is empty. Then we have  $\overline{x}(N) \leq \overline{x}_0(N) - \varepsilon_0(N)$ . It hence follows that

$$\begin{split} V(N) &= \overline{x}(N) - \underline{x}(N) \\ &\leq \overline{x}_0(N) - \varepsilon_0(N) - \underline{x}_0(N) + \sigma_0 \\ &= \overline{x}_0(0) - \underline{x}_0(0) + 2c_0N + 2\sum_{i=0}^{N-1} c_1 e^{-\alpha i} - \varepsilon_0(N) + \sigma_0 \\ &= (\overline{x}(0) - \sigma_0) - (\underline{x}(0) + \sigma_0) + 2c_0N + 2c_1 \frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}} \\ &\quad - \varepsilon_0(N) + \sigma_0 \\ &= V(0) + 2c_0N + 2c_1 \frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}} - \sigma V(0) \\ &\quad - (\gamma^N \varepsilon - (1 - \gamma^N) \sigma) V(0) \\ &= (1 - \gamma^N (\varepsilon + \sigma)) V(0) + 2c_0N + 2c_1 \frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}}. \end{split}$$

By  $\varepsilon + \sigma = 1/2$  in (14), we have

$$V(N) \le \left(1 - \frac{\gamma^N}{2}\right) V(0) + 2c_0 N + 2c_1 \frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}}.$$

If there are more updates by node i after time k = N, this

argument can be extended further as

$$V(lN) \leq \left(1 - \frac{\gamma^{N}}{2}\right) V((l-1)N) + 2c_{0}N + 2c_{1}\frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}}e^{-(l-1)\alpha N}$$

$$\leq \left(1 - \frac{\gamma^{N}}{2}\right)^{l}V(0) + \sum_{t=0}^{l-1}\left(1 - \frac{\gamma^{N}}{2}\right)^{l-1-t} \times \left(2c_{0}N + 2c_{1}\frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}}e^{-(t-1)\alpha N}\right)$$

$$\leq \left(1 - \frac{\gamma^{N}}{2}\right)^{l}V(0) + \frac{1 - \left(1 - \frac{\gamma^{N}}{2}\right)^{l}}{1 - \left(1 - \frac{\gamma^{N}}{2}\right)^{2}}2c_{0}N + 2c_{1}\frac{1 - e^{-\alpha N}}{1 - e^{-\alpha}}\left(1 - \frac{\gamma^{N}}{2}\right)^{l}\frac{1 - (1 - \frac{\gamma^{N}}{2})^{-l}e^{-\alpha Nl}}{1 - \left(1 - \frac{\gamma^{N}}{2}\right)^{-l}e^{-\alpha Nl}}.$$
(20)

From (6), we can easily obtain

$$\limsup_{l \to \infty} V(lN) \le \frac{2c_0 N}{1 - \left(1 - \frac{\gamma^N}{2}\right)} = \frac{4c_0 N}{\gamma^N} \le c.$$
(21)

Now, we show the dynamics of V(lN + t) for t = 0, 1, ..., N - 1. The analysis is similar, and we can obtain an inequality like (20), where the only difference is that in the derivation, V(0) is replaced with V(t). From the safety condition, we know that  $V(k) \leq |S|$  for all k. Therefore, we finally arrive at

$$\limsup_{l \to \infty} V(lN+t) \le \frac{4c_0 N}{\gamma^N} \le c.$$

This completes the proof of the consensus condition.  $\Box$ 

The above result shows that the multi-agent system is guaranteed to reach resilient consensus despite the presence of F-total malicious agents. First, the width of the safety interval  $\mathcal{S}$  is determined by the initial states of the regular agents. Second, the error that may remain after achieving resilient consensus meets the specified bound c by selecting the key parameter in the triggering function  $c_0$ , proportionally to c. This parameter can be set by the designer and, clearly, by taking  $c_0 = 0$ , exact consensus can be achieved at the expense of having more communications. The role of  $c_1$  and  $\alpha$  is to reduce the communication during the transient stage by making the threshold in the triggering function large. We note that the exponential decaying bound by  $c_1$  and  $\alpha$  can also decrease the communication in the long run. We will see the effects of the parameters of the event-triggering function through a numerical example in Section V.

In the literature of event-based consensus, conventional schemes often employ triggering functions whose thresholds go to zero over time, in both continuous- and discrete-time domains (e.g., [5], [7], [18], [20], [21]). By contrast, [11], [29] use thresholds which always take positive values as in our study. In comparison, our upper bound for the consensus error is more conservative. Because of the malicious agents, the analysis cannot apply the methods in previous works and

must follow those in resilient consensus problems such as [3]; as a consequence, the bound on consensus errors grows exponentially with N (see (21)). In the conventional results of [11], [29], the bounds depend on N linearly as well as on the Laplacian matrix.

A related result for the case of F-local model for the adversarial nodes can be found in [14] with a particular application to clock synchronization in WSNs. It studies a resilient consensus problem with decaying noise that arises in the system due to the interactions among clock states.

**Remark 1.** We should highlight that in the discrete-time domain, event-based consensus algorithms must be carefully designed especially in the resilient case. We can construct another resilient consensus algorithm motivated by the structures found in [29], [35], which deal with continuous-time multiagent systems, as

$$x_i(k+1) = x_i(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k) \left( \hat{x}_j(k) - \hat{x}_i(k) \right).$$
(22)

The modification may be minor as the only difference is that  $\hat{x}_i(k)$  is used instead of  $x_i(k)$  in the second term of the right-hand side. Compared with Protocol 1, to guarantee the consensus error level of c, the choice of  $c_0$  must be half as  $c_0 \leq \gamma^N/8N$ , which may increase the communication load. These results can be obtained by following a proof similar to that of Theorem 1.

In the next section, we present yet another protocol by further changing the terms in the update rule.

#### IV. PROTOCOL 2

In this section, we provide our second resilient consensus algorithm, referred to as Protocol 2.

To this end, we modify the update rule (4) in a way different from the protocol (22) discussed in Remark 1. It is pointed out that in Protocol 1, for obtaining the new state  $x_i(k+1)$ of agent *i*, its own data appears only through the current state  $x_i(k)$ . On the one hand, this means that even when the new state is not communicated, it still needs to be stored at every time step. On the other, as the current state  $x_i(k)$  is newer than  $\hat{x}_i(k)$ , it seems desirable for speeding up the convergence. We will however show that it may be better to use only  $\hat{x}_i(k)$  for both storage and convergence reasons. The protocol introduced below is motivated by those in [10], [35].

In the local update, for  $k \in \mathbb{Z}_+$ , every regular node  $i \in \mathcal{R}$ updates its current state by

$$x_i(k+1) = \hat{x}_i(k) + \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k) \left( \hat{x}_j(k) - \hat{x}_i(k) \right).$$
(23)

Note that the new state  $x_i(k+1)$  need not be stored until the next time step, but is merely used for checking the condition of the triggering function  $f_i(k)$  in (3). Accordingly, in the E-MSR, steps 1 and 2 should be adjusted so that agent i uses  $\hat{x}_i(k)$  instead of  $x_i(k)$  in determining the neighbor set  $\mathcal{M}_i(k)$ .

Then we are ready to present our second main result of this paper, which is regarding Protocol 2.

Theorem 2. Under the F-total malicious model, the normal agents with E-MSR using (23) and (5) reach resilient consensus if and only if the underlying graph is (F + 1, F + 1)robust. The safety interval is given by  $\mathcal{S} = [\hat{x}(0), \hat{x}(0)]$ , and the consensus error level c is achieved if the parameter  $c_0$  in the triggering function (3) satisfies

$$c_0 \le \frac{\gamma^{N-1}(1-\gamma)c}{1-\gamma^{N-1}}.$$
 (24)

*Proof.* The necessity part follows similar lines as those in the proof of Theorem 1. In the following, we thus give the sufficiency part.

First, we establish the safety condition in the sense of  $x_i(k), \hat{x}_i(k) \in \mathcal{S}$  for regular nodes *i*. This is done by induction. At k = 0, for each  $i \in \mathcal{R}$ , it holds  $x_i(0), \hat{x}_i(0) \in \mathcal{S}$  by definition. Next, assume that at time k, we have  $x_i(k), \hat{x}_i(k) \in$ S for  $i \in \mathcal{R}$ . Then, for agent *i*, its neighbors  $j \in \mathcal{M}_i(k)$  satisfy  $\hat{x}_i(k) \in \mathcal{S}$  since there are at most F agents with values outside S, and they are ignored in step 2 of the E-MSR. From the update rule (23), we have

$$x_{i}(k+1) = a_{ii}(k)\hat{x}_{i}(k) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k)\hat{x}_{j}(k)$$
$$\leq a_{ii}(k)\overline{\hat{x}}(k) + \sum_{j \in \mathcal{M}_{i}(k)} a_{ij}(k)\overline{\hat{x}}(k) = \overline{\hat{x}}(k), \quad (25)$$

where  $a_{ii}(k) = 1 - \sum_{j \in \mathcal{M}_i(k)} a_{ij}(k)$ . The inequality (25) means that the upper bound of every regular node is nonincreasing. Similarly, we have  $x_i(k+1) \ge \underline{\hat{x}}(k)$ , so we obtain  $x_i(k) \in S$  for  $k \geq 0$ . Furthermore, by (5), it holds that  $\hat{x}_i(k+1) \in \mathcal{S}$ . Hence, we have  $\mathcal{S}$  as the safety interval.

For the consensus condition part, we first sort the regular communicated values  $\hat{x}_i(k), i \in \mathcal{R}$ , at time k in the entire graph from the smallest to the largest. Denote by  $s_i(k)$  the index of the agent taking the *i*th value from the smallest. Hence, the values are sorted as  $\hat{x}_{s_1}(k) \leq \hat{x}_{s_2}(k) \leq \cdots \leq \hat{x}_{s_N}(k)$ .

Introduce two sequences of conditions for the relation of each gap between two nodes. The first is given from below as

- $A_1: \hat{x}_{s_2}(k) \hat{x}_{s_1}(k) \le (c_0 + c_1 e^{-\alpha k})/\gamma,$   $A_2: \hat{x}_{s_3}(k) \hat{x}_{s_2}(k) \le (c_0 + c_1 e^{-\alpha k})/\gamma^2,$
- $A_{N-1}: \hat{x}_{s_N}(k) \hat{x}_{s_{N-1}}(k) \le (c_0 + c_1 e^{-\alpha k})/\gamma^{N-1}.$

The other sequence is from above as

- $B_N$ :  $\hat{x}_{s_N}(k) \hat{x}_{s_{N-1}}(k) \le (c_0 + c_1 e^{-\alpha k})/\gamma$ ,  $B_{N-1}$ :  $\hat{x}_{s_{N-1}}(k) \hat{x}_{s_{N-2}}(k) \le (c_0 + c_1 e^{-\alpha k})/\gamma^2$ ,
- $B_2: \hat{x}_{s_2}(k) \hat{x}_{s_1}(k) \le (c_0 + c_1 e^{-\alpha k}) / \gamma^{N-1}.$

Let  $j_A$  be the minimum j = 1, ..., N-1 such that condition  $A_j$  is not satisfied. Also, let  $j_B$  be the maximum  $j = 2, \ldots, N$ such that condition  $B_i$  is not satisfied. Thus we have

$$\hat{x}_{s_{j_{A}+1}}(k) - \hat{x}_{s_{j_{A}}}(k) > \frac{c_{0} + c_{1}\mathbf{e}^{-\alpha k}}{\gamma^{j_{A}}},$$

$$\hat{x}_{s_{j_{B}}}(k) - \hat{x}_{s_{j_{B}-1}}(k) > \frac{c_{0} + c_{1}\mathbf{e}^{-\alpha k}}{\gamma^{N-j_{B}+1}}.$$
(26)

Moreover, conditions  $A_1$  to  $A_{j_A-1}$  and  $B_{j_B+1}$  to  $B_N$  are satisfied. Then, for  $0 \le k \le k'$ , we introduce two sets

$$\mathcal{X}_{1}(k,k') = \left\{ j \in \mathcal{V} : \ \hat{x}_{j}(k') < \hat{x}_{s_{j_{A}}}(k) + c_{0} + c_{1}e^{-\alpha k} \right\},\$$
$$\mathcal{X}_{2}(k,k') = \left\{ j \in \mathcal{V} : \ \hat{x}_{j}(k') > \hat{x}_{s_{j_{B}}}(k) - c_{0} - c_{1}e^{-\alpha k} \right\}.$$

There are two cases concerning the relationship between  $j_A$  and  $j_B$ . We study them separately below.

Case 1:  $j_A < j_B$ . Let the two subsets of the regular nodes be  $\mathcal{V}_1 = \{s_1(k), s_2(k), \ldots, s_{j_A}(k)\}$  and  $\mathcal{V}_2 = \{s_{j_B}(k), \ldots, s_N(k)\}$ . Note that all nodes in  $\mathcal{V}_1$  are inside  $\mathcal{X}_1(k, k)$ , and those in  $\mathcal{V}_2$  are inside  $\mathcal{X}_2(k, k)$ . Hence,  $\mathcal{X}_1(k, k)$  and  $\mathcal{X}_2(k, k)$  are nonempty. They are moreover disjoint. This is because by using the two inequalities in (26), from  $1 \leq j_A < j_B \leq N$  and  $0 < \gamma \leq 1/2$ , it follows that

$$\hat{x}_{s_{j_B}}(k) - \hat{x}_{s_{j_A}}(k) > \max\left\{\frac{1}{\gamma^{j_A}}, \frac{1}{\gamma^{N-j_B+1}}\right\} \left(c_0 + c_1 e^{-\alpha k}\right) \\ \ge 2\left(c_0 + c_1 e^{-\alpha k}\right).$$

Thus, the (F + 1, F + 1)-robust graph guarantees that some regular node *i* in  $\mathcal{X}_1(k, k)$  or  $\mathcal{X}_2(k, k)$  has at least F + 1neighbors outside. We suppose that  $i \in \mathcal{X}_1(k, k)$ . By (23),

$$\begin{aligned} x_i(k+1) &= a_{ii}(k)\hat{x}_i(k) + \sum_{j \in \mathcal{M}_i(k) \cap \mathcal{X}_1} a_{ij}(k)\hat{x}_j(k) \\ &+ \sum_{j \in \mathcal{M}_i(k) \setminus \mathcal{X}_1} a_{ij}(k)\hat{x}_j(k), \end{aligned}$$

where the simplified notation  $\mathcal{X}_1$  is used for  $\mathcal{X}_1(k, k)$ . Since  $\mathcal{M}_i(k) \setminus \mathcal{X}_1(k, k)$  is not empty, we have

$$x_i(k+1) \ge (1-\gamma)\hat{x}_{s_1}(k) + \gamma \hat{x}_{s_{j_A+1}}(k).$$
(27)

Using conditions  $A_1$  to  $A_{j_A-1}$ , we can bound  $\hat{x}_{s_1}(k)$  as

$$\begin{aligned} \hat{x}_{s_1}(k) &\geq \hat{x}_{s_2}(k) - \frac{c_0 + c_1 \mathbf{e}^{-\alpha k}}{\gamma} \\ &\geq \hat{x}_{s_3}(k) - \left(\frac{1}{\gamma} + \frac{1}{\gamma^2}\right) \left(c_0 + c_1 \mathbf{e}^{-\alpha k}\right) \geq \cdots \\ &\geq \hat{x}_{s_{j_A}}(k) - \left(\frac{1}{\gamma} + \frac{1}{\gamma^2} + \cdots + \frac{1}{\gamma^{j_A - 1}}\right) \left(c_0 + c_1 \mathbf{e}^{-\alpha k}\right). \end{aligned}$$

Substitute this into (27) and obtain

$$\begin{aligned} x_{i}(k+1) &\geq \hat{x}_{s_{j_{A}}}(k) + \gamma \left( \hat{x}_{s_{j_{A}+1}}(k) - \hat{x}_{s_{j_{A}}}(k) \right) \\ &- \frac{1}{\gamma^{j_{A}-1}} (c_{0} + c_{1} \mathrm{e}^{-\alpha k}) + (c_{0} + c_{1} \mathrm{e}^{-\alpha k}) \\ &> \hat{x}_{s_{j_{A}}}(k) + \gamma \frac{c_{0} + c_{1} \mathrm{e}^{-\alpha k}}{\gamma^{j_{A}}} \\ &- \frac{1}{\gamma^{j_{A}-1}} (c_{0} + c_{1} \mathrm{e}^{-\alpha k}) + (c_{0} + c_{1} \mathrm{e}^{-\alpha k}) \\ &= \hat{x}_{s_{j_{A}}}(k) + (c_{0} + c_{1} \mathrm{e}^{-\alpha k}), \end{aligned}$$
(28)

where the second inequality follows by (26). Thus, this node i is moved out of set  $\mathcal{X}_1(k, k+1)$  at time k+1.

We next show that the regular nodes not in  $\mathcal{X}_1(k, k)$  at time k will not move in  $\mathcal{X}_1(k, k+1)$  at time k+1. If node j has some neighbors inside  $\mathcal{X}_1(k, k)$ , then (27) and (28) hold and

we know that the node does not move in  $\mathcal{X}_1(k, k+1)$ . If node j has neighbors only in  $\mathcal{V} \setminus \mathcal{X}_1(k, k)$ , then we have

$$x_j(k+1) \ge \hat{x}_{s_{j_A+1}}(k) > \hat{x}_{s_{j_A}}(k) + \frac{c_0 + c_1 \mathrm{e}^{-\alpha k}}{\gamma^{j_A}}$$

Clearly, node j does not move in  $\mathcal{X}_1(k, k+1)$  in this case.

Therefore, the regular nodes in  $\mathcal{X}_1(k, k+1)$  decrease in number as  $\mathcal{X}_1(k, k+1) \cap \mathcal{R} \subsetneq \underline{\mathcal{X}}_1(k, k) \cap \mathcal{R}$ . Similar results also hold if  $i \in \mathcal{X}_2(k, k)$ , and we have  $\hat{x}_i(k+1)$  decreases more than  $c_0 + c_1 e^{-\alpha k}$  compared with  $\hat{x}_{s_{j_B}}(k)$ .

As a result, if conditions  $A_{j_A}$  and  $B_{j_B}$  with  $j_A < j_B$  are not satisfied, after N steps, the set  $\mathcal{X}_1(k, k+N)$  or  $\mathcal{X}_2(k, k+N)$ becomes empty in regular nodes. It then follows that  $\underline{\hat{x}}(k+N)$ increases more than  $c_0 + c_1 e^{-\alpha k}$  or  $\overline{\hat{x}}(k+N)$  decreases more than  $c_0 + c_1 e^{-\alpha k}$ .

A special case in Case 1 is when  $j_A = j_B - 1$ . It corresponds to having only one pair of nodes whose difference in values does not satisfy the condition. By applying a similar analysis, we have that  $\underline{\hat{x}}(k+N)$  increases more than  $c_0 + c_1 e^{-\alpha k}$  or  $\overline{\hat{x}}(k+N)$  decreases more than  $c_0 + c_1 e^{-\alpha N}$ .

Case 2:  $j_A \ge j_B$ . This case is impossible. We can show this by contradiction as follows. Since  $j_A \ge j_B$ , we know that  $A_{j_B-1}$  and  $B_{j_A+1}$  are both satisfied. Combined with  $A_{j_A}$ and  $B_{j_B}$  not being satisfied, we have

$$\frac{c_0 + c_1 e^{-\alpha k}}{\gamma^{N-j_B+1}} < \hat{x}_{s_{j_B}}(k) - \hat{x}_{s_{j_B-1}}(k) \le \frac{c_0 + c_1 e^{-\alpha k}}{\gamma^{j_B-1}}, \quad (29)$$

$$\frac{c_0 + c_1 \mathbf{e}^{-\alpha k}}{\gamma^{j_A}} < \hat{x}_{s_{j_A+1}}(k) - \hat{x}_{s_{j_A}}(k) \le \frac{c_0 + c_1 \mathbf{e}^{-\alpha k}}{\gamma^{N-j_A}}.$$
 (30)

The inequalities in the first relations in (29) indicate that it must hold  $j_B > (N+1)/2$ . The second set of inequalities in (30) also implies  $j_A < N/2$ . Consequently, we have  $j_A < j_B$ , which is in contradiction with  $j_A \ge j_B$ .

We can now conclude that after a finite number of time steps, all conditions from  $A_1$  to  $A_m$  and  $B_{m+2}$  to  $B_N$ , where  $0 \le m \le N - 1$ , must be satisfied. Otherwise the difference between  $\overline{\hat{x}}(k)$  and  $\underline{\hat{x}}(k)$  will decrease more than  $c_0$  by an update induced by an event. From the analysis for the safety condition, we know that  $\overline{\hat{x}}(k)$  is nonincreasing and  $\underline{\hat{x}}(k)$  is nondecreasing. Hence, if the events continuously occur,  $\overline{\hat{x}}(k) - \underline{\hat{x}}(k)$  will become smaller and eventually negative, which cannot happen. This completes the proof.

Protocol 2 enables us to achieve resilient consensus with data communicated via event-based protocols. We emphasize that our analysis for Protocol 2 is less conservative compared to Theorem 1 for Protocol 1. In fact, we can see by directly comparing the two theorems that the bound on the parameter  $c_0$  is larger for achieving the same level c of consensus error; this may result in less frequent transmissions. We will confirm this property later in Section V through numerical simulations.

A unique aspect of Protocol 2 is that the proof technique used in Theorem 2 is different from those used in the recent works such as [3], [4], [15], [16] and also in the proof of Theorem 1. The conventional technique could be employed here, but this will result in the same bound on  $c_0$  as in Theorem 1. In fact, as we see below, the bound obtained in Theorem 2 is tight for some graphs.

Fig. 2. Worst-case graph with N=4

**Remark 2.** We present an example of a multi-agent system whose error in consensus among the agents is equal to the bound obtained in Theorem 2. Such a graph may be called a worst-case graph. Consider the network in Fig. 2 with four nodes which are all regular and thus F = 0. Note that the graph contains a directed spanning tree. The initial values  $x_i(0)$  of the nodes and the (constant) weights  $a_{ij}(k)$  on the edges are indicated in the figure. Since the weights are all 1/2(and thus  $\gamma = 1/2$ ), for nodes having two neighbors, their own values are not used in the update rule (23). Moreover, for the node in the far left, a self-loop is shown to indicate that this node uses its own value. The node in the far right has no incoming edge, and thus its value will not change over time.

By setting the parameters for the triggering function as  $c_0 = 1$  and  $c_1 = 0$ , it follows that there will be no event at any time. The difference in their values is 14, which can be obtained as c by equating the inequality (24) in Theorem 2. In comparison, for Protocol 1, the bound c on the difference will be 256 by Theorem 1; this is much larger, indicating the conservatism of the analysis approach there. Note that the graph structure in Fig. 2 is obtained based on the proof of Theorem 2. It is a bit special in the sense that not all agents have self-loops. To comply with the theory, we can extend this example by adding self-loops; it will not be a worst-case graph any longer, but the difference among the values will be larger than other graphs.

#### V. NUMERICAL EXAMPLE

In this section, we illustrate the proposed resilient protocols via numerical simulations. We first examine a small-scale network and then focus on the scalability for larger systems.

## A. Small network

We consider the multi-agent system with seven nodes whose connectivity graph is shown in Fig. 1; as already mentioned, this graph is (3,3)-robust. We compare the performance of Protocols 1 and 2 using different parameters in event-triggering. In particular, we test the two cases of  $c_0 > 0$  and  $c_0 = 0$ . Here, nodes 5 and 7 are set to behave maliciously by continuously oscillating their values; in all simulations, we used the same state values for them. The initial state was chosen the same for each run as well at  $x(0) = [1 \ 2 \ 3 \ 5 \ 4 \ 6 \ 4]^T$ . We also took  $\gamma = 0.3$ .

First, we examine the case of  $c_0 > 0$ . We fixed the consensus error bound as c = 1. For Protocol 1, based on Theorem 1, we chose  $c_0 = 1.22 \times 10^{-4}$ . The remaining parameters were selected as  $c_1 = 0.5$  and  $\alpha = 0.03$ . The time responses are shown in Fig. 3, where the *x*-axis represents the sampling time *k*, and the *y*-axis the values of the agents. Moreover, the time instants when each node makes a broadcast are shown by the markers  $\bullet$  in the color corresponding to that

Fig. 3. Protocol 1 with  $c_0 = 1.215 \times 10^{-4}$ ,  $c_1 = 0.5$ , and  $\alpha = 0.03$ 

Fig. 4. Protocol 2 with  $c_0 = 5.72 \times 10^{-3}$ ,  $c_1 = 0.5$ , and  $\alpha = 0.03$ 

of its time response curve. On the other hand, for Protocol 2, we chose  $c_0 = 5.72 \times 10^{-3}$  according to Theorem 2, and other parameters were taken as above with  $c_1 = 0.5$  and  $\alpha = 0.03$ . The time responses of Protocol 2 are plotted in Fig. 4.

We observe that both protocols managed to achieve the desired level of consensus specified by c = 1 based on eventtriggered communication. Moreover, there is very little sign of being influenced by the behavior of the malicious nodes. In fact, for Protocol 1, after 600 steps, the consensus error among the regular nodes became  $5.24 \times 10^{-5}$ , with 5.4 times of transmissions on average for the regular nodes. On the other hand, for Protocol 2, the consensus error was  $8.63 \times 10^{-3}$ , with 4.6 times of transmissions on average, which is slightly smaller. Thus, we confirm that Protocol 2 is less conservative.

Next, by setting  $c_0 = 0$ , we demonstrate that exact resilient consensus can be attained while reducing the number of transmissions. To this end, for both protocols, we set  $c_1 = 0.5$ and  $\alpha = 0.03$  as in the previous simulations. In this case, the threshold that determines the timings of events eventually goes to zero (due to  $c_0 = 0$ ). The time responses of the two protocols are shown in Figs. 5 and 6. For Protocol 1, after 600 steps, the consensus errors among the regular nodes became essentially zero at  $5.71 \times 10^{-9}$ , where the average number of triggering times for the regular nodes is 10. Similarly, for Protocol 2, the consensus error at time k = 600was  $1.73 \times 10^{-8}$  with 12.4 triggering times on average per regular node. Protocol 1 is particularly impressive in terms of limited communication. In contrast, for Protocol 2, information exchange among nodes takes place for a longer time.

Further comparisons were made by implementing timetriggering communication in both protocols. Periodic transmissions are made so that after 600 time steps, the regular nodes make the same number of triggering times as those in the event-triggered case with  $c_0 = 0$  above. This means that for Protocol 1, each node transmits every 60 steps and for Protocol 2 every 50 steps. At time k = 600, the consensus error was  $5.04 \times 10^{-8}$  for Protocol 1 and  $5.80 \times 10^{-3}$  for Protocol 2. It is clear that under both protocols, the event-

Fig. 6. Protocol 2 with  $c_0 = 0$ ,  $c_1 = 0.5$ , and  $\alpha = 0.03$ 

triggered schemes perform better. Their time responses are shown in Figs. 7 and 8. Due to the periodic transmission, the convergence is slow and the responses between the transmission times are oscillatory.

## B. Scalability of the proposed approach

In this part, we carry out a number of simulations to check the scalability of the proposed protocols using largescale networks. In particular, we focus on how the number of transmissions can be kept low even if the numbers of neighbors and the malicious ones are large. As in the previous simulations, the two cases of  $c_0 > 0$  and  $c_0 = 0$  are examined and compared with the time-triggered case. We employ three complete graphs with 10, 50, and 100 nodes. By Lemma 1, we know that a 10-node complete graph is (5, 5)-robust. Thus, we introduce four malicious nodes. Similarly, in the 50- and 100-node cases, we set 24 and 49 malicious nodes, respectively.

The first case is with  $c_0 > 0$ . In particular, for both Protocols 1 and 2, we chose  $c_0 = 0.1$ ,  $c_1 = 1$ , and  $\alpha = 2$ . For each graph, we performed Monte Carlo simulations for 100 runs by randomly taking initial states under uniform distribution between 0 and 100. Each agent made updates until the consensus error becomes 0.01 for Protocol 1 and 0.3 for Protocol 2. The malicious agents made oscillatory behaviors as in the simulations in the previous subsection. The performance of Protocols 1 and 2 is displayed in Tables I (a) and (b), respectively, in terms of the average number of triggering times per regular node.

It is noticed that in general, as the number of agents increases, triggering times increase only mildly to reach the same level of consensus error for both protocols. There is a difference in the achievable performance between the protocols as discussed after Theorem 2. In particular, for the same size of  $c_0$ , Protocol 1 is able to yield smaller error than Protocol 2.

We proceed to the second case with  $c_0 = 0$ . Other parameters were set as  $c_1 = 0.5$  for both protocols, and as  $\alpha$ , we used 0.05 for Protocol 1 and 0.05 for Protocol 2. The results are shown in the same tables. The numbers of triggering times

Fig. 7. Protocol 1 under periodic communication with period 60

Fig. 8. Protocol 2 under periodic communication with period 50

are similar to the case with  $c_0 > 0$ . For Protocol 2, we may say that the scalability is slightly less since as the graph sizes increase, the triggering times increase more.

Finally, in the two tables, we display the average number of triggering times for the time-triggered case, where every node transmits at every time step. It is evident that such a protocol requires more transmissions than event-triggered protocols. From these results, we conclude that the event-based protocols can efficiently eliminate the amount of communications.

## VI. CONCLUSION

In this paper, we considered a resilient approach for the multi-agent consensus problem to mitigate the influence of misbehaving agents due to faults and cyber-attacks. Two protocols for the updates of the regular nodes have been proposed, and their convergence properties as well as necessary network structures have been characterized. In both cases, resilient consensus can be achieved with reduced frequencies in communication among agents through event triggering. This is possible at the expense of certain errors in consensus determined by the parameters in the triggering function.

Future studies will focus on resilient consensus algorithms with time delays in communications for the event-triggered case and also those based on model predictive control. A more challenging problem for future research is to construct algorithms enabling the regular nodes to reach a consensus value which is determined only by their initial values and not influenced by the adversaries.
