October 2018

Abstract. While link prediction in networks has been a hot topic over the years, its robustness has not been well discussed in literature. In this paper, we study the robustness of some mainstream link prediction methods under various kinds of network attack strategies, including the random attack (RDA), centrality based attacks (CA), similarity based attacks (SA), and simulated annealing based attack (SAA). Through the variation of precision, a typical evaluation index of link prediction, we find that for the SA and SAA, a small fraction of link removals can significantly reduce the performance of link prediction. In general, the SAA has the highest attack efficiency, followed by the SA and then CA. Interestingly, the performance of some particular CA strategies, such as the betweenness based attacks (BA), are even worse than the RDA. Furthermore, we discover that a link prediction method with high performance probably has lower attack robustness, and the vice versa.

*Keywords*: Link Prediction, Network Attacks, Robustness

### 1. Introduction

The link prediction problem [1], originated from the area of data mining, has achieved great progress with the booming of network science [2]. Its goal is to estimate the link possibility of two unconnected nodes based on the available network data and tools, such as machine learning [3, 4] and complex networks theory [5, 6]. Various link prediction methods haven been proposed [7–10], and they can be broadly divided into three categories: similarity-based methods (such as the common neighbors (CN) [1], Adamic-Adar (AA) [11] and resource allocation (RA) [12] indices), maximum likelihood based methods (such as hierarchical structure model [13] and stochastic block model [14, 15]), and probabilistic models (such as probabilistic relational model [16] and probabilistic entity-relationship models [17]). The established link prediction methods can be widely used in online product recommendation [18], bionetwork reconstruction [19], community detection [20], etc.

Though tremendous efficient prediction methods emerge, their robustness has not been seriously discussed in literature. Unfortunately, real-world networks suffer from random failures and various targeted attacks. For instance, it has been shown that many scale-free networks, such as the Internet, are pretty vulnerable to degree-based targeted attacks [21–23]. A small initial attack can trigger the large-scale cascading failure [24–26], which is one of the main security issues in power networks. In addition, many novel attack strategies have been proposed, including edge attacks [27, 28], path attacks [29, 30], etc. These random or intentional disturbances significantly affect the structure and dynamics of real-world networks [31]. In particular, the predictability of real-world networks keeps change as the network disturbance continues. Thus, it is very necessary to explore the robustness of link prediction under network attacks.

Recently, Zhang et al. [32] studied the robustness of several link prediction algorithms in noisy environments. Their results showed that while different prediction algorithms may have different attack robustness, in general they are robust to random disturbances. However, their work has the following limitations:

(i) Only the AUC is considered in the evaluation of prediction accuracy, while the precision is another mainstream index, which should be considered in the link prediction problem.

(ii) The perturbation methods used are relatively simple. Only random disturbances are considered. The robustness of link prediction under various targeted attacks needs more attention.

In this paper, we study the robust of some typical link prediction methods under various network attacks. Our main contributions are as follows:

(i) We investigated the link prediction robustness under the typical target attacks including the betweenness based attacks (BA) [33] and weight based attacks (WA) [34] and found that the WA has higher attack efficiency than the BA.

(ii) To further study the attack robustness, we proposed the similarity-based attack strategies by considering some typical similarity indices, such as the CN, AA and RA. Furthermore, we proposed the simulated annealing based attack (SAA) strategy.

(iii) Through simulation, we found that the SAA has the largest attack efficiency, followed by the similarity-based strategies and then centrality-based strategies. Furthermore, we discovered that a link prediction method with high performance probably has lower robustness, and the vice versa.

This paper is organized as follows. In the next section, we introduce the evaluation metrics as well as the link prediction methods used in the paper. In Section 3, we provide the typical attack strategies and our proposed attack strategies. Section 4 presents the experimental results and related analysis. Finally, Section 5 is our conclusion.

### 2. Link prediction methods and their evaluation

We consider the structural similarity based methods of link prediction, which are popular in the recent years [7]. In this type of methods, each unconnected node pair is given a similarity score according to a certain similarity index, and the node pairs of large similarity scores have relatively large link probability. Different from Ref. [32], we use the precision, another typical metric, to quantify the accuracy of link prediction.

### 2.1. Link prediction methods

We select five mainstream prediction methods, including the Common Neighbors (CN) [1], Adamic-Adar (AA) [11], Resource Allocation (RA) [12], Local Path (LP) [35] and Katz [36]. In the following, the degree of node x is denoted by  $k_x$ , and the set of common neighbors of nodes x and y is represented by  $\Gamma(x) \cap \Gamma(y)$ .

(i) CN: assuming the set of neighbor nodes of node x to be  $\Gamma(x)$ , the CN index of nodes x and y is defined as

$$s_{xy}^{CN} = |\Gamma(x) \cap \Gamma(y)|. \tag{1}$$

(ii) AA: this index accounts for the contribution of common neighbors with a penalization term that is dependent on the logarithm of common neighbors' degree,

$$s_{xy}^{AA} = \sum_{z \in \Gamma(x) \cap \Gamma(y)} \frac{1}{\log k_z}.$$
(2)

(iii) RA: it is originated from the resource allocation problem [37]. Suppose that node x delivers resources to node y (they are not directly connected) through their common neighbors. Each common neighbor gets one unit of resources from x, and then evenly distributes the unit to all its neighbors. The similarity between x and y can be defined as the amount of resources y receives from x,

$$s_{xy}^{RA} = \sum_{z \in \Gamma(x) \cap \Gamma(y)} \frac{1}{k_z}.$$
(3)

(iv) LP: this index considers the contribution of paths of lengths 2 and 3, which is defined as:

$$\mathbf{S}^{LP} = \mathbf{A}^2 + \alpha \cdot \mathbf{A}^3. \tag{4}$$

Where **A** is the adjacency matrix. The (x, y) entry of  $\mathbf{A}^i$  is the number of paths of length *i* between nodes *x* and *y*.  $\alpha$  is a tunable parameter controlling the contribution of paths with length 3.

(v) Katz: it takes all the paths between two nodes into account, that is

$$s_{xy}^{Katz} = \sum_{l=1}^{\infty} \alpha^l \cdot |paths_{x,y}^{}|.$$
(5)

Where  $\alpha$  is a tunable parameter and  $|paths_{x,y}^{<l>}|$  represents the number of paths of length l between nodes x and y.

### 2.2. Evaluation metric

We assume an undirected and unweighted network G(V, E), where V is the set of nodes and E is the set of links. In the link prediction problem, we divide E into a training set  $E_T$  and a probe set  $E_P$  to evaluate the prediction method. Usually,  $E_P$  consists of 10% (or 20%) links randomly extracted from E, and  $E_T$  includes the remaining 90% (or 80%) links. In  $E_T$ , each unconnected node pair is given a similarity score by the similarity index, and then all the unconnected node pairs are ranked in decreasing order of similarity scores. The precision index for the evaluation of prediction accuracy is defined as

$$precision = \frac{m}{L}.$$
(6)

Where m is the number of desired node pairs, whose links are previously removed to the probe set, among the top L unconnected node pairs [7].

### 3. Network attack strategies

Real-world networks suffer from various kinds of failures or attacks. These disturbances should affect the predictability of networks. To explore this, we consider the representative attack strategies, including the random attack strategy (RDA) and centrality based attack strategies (CA) [31]. For the category of CA, we study the betweenness based attack (BA) [33] and the weight based attack (WA) [34]. Furthermore, we propose two additional types of attack strategies: similarity based attacks (SA) and simulated annealing attack (SAA). Note that all the attack strategies mentioned here are for link attacks, which further means removing the targeted links. All there strategies are described below in detail.

(1) RDA: the RDA is a very simple attack strategy, and usually works as a baseline of other strategies. In the RDA, we randomly remove links from the network.

(2) BA: in this strategy, we use betweenness centrality [33] to evaluate the importance of links. Then, we remove the links of the largest betweenness. The betweenness of link e is

$$BC_e = \sum_{s,t \in V} \frac{\sigma(s,t|e)}{\sigma(s,t)}.$$
(7)

Where  $\sigma(s, t)$  is the number of shortest paths between nodes s and t, and  $\sigma(s, t|e)$  is the number of those paths that also pass through link e.

(3) WA: in this strategy, we remove the links of the largest weight. Assume the end nodes of link e are nodes x and y, the weight of link e is given as [34]:

$$W_e = k_x \cdot k_y. \tag{8}$$

Where  $k_x$  and  $k_y$  represent the degree of nodes x and y, respectively.

(4) SA: for this category of attacks, the importance of a link is quantified as the similarity score of its two end nodes. Then, we remove the links of the

largest importance. The CN, RA, and AA similarity indices are used here, and the corresponding attacks are denoted by SA-CN, SA-RA and SA-AA, respectively. Note that the other similarity indices can also be taken into account.

(5) SAA: this strategy is based on the simulated annealing algorithm [38]. It globally searches the best set of links, by removing which the link prediction accuracy of the network decreases at the most. The main procedures of the algorithm are as follows.

(i) we randomly select a set of links of a fixed number from the network as the initial solution, and set the initial maximum temperature  $t_{max}$  and minimum temperature  $t_{min}$ .

(ii) we randomly select a link from the network (except the current solution) and another link from the current solution, and then exchange them to generate a new solution. Let  $P_c$  ( $P_n$ ) be the precision of the remaining network corresponding to the current (new) solution.

(iii) If  $P_n < P_c$ , we replace the current solution with the new solution with probability 1, and otherwise with probability  $P = \exp((P_c - P_n)/t_c)$ , where  $t_c$  is the current temperature.

(iv) we update the temperature,  $t_c = c \cdot t_c$ , where c is the cooling coefficient and has range in (0, 1). If  $t_c < t_{min}$ , the algorithm ends; otherwise, it returns to the second step. For the SAA, we remove the optimal set of links from the network.

# 4. Result

We do experiments on various real-world network data downloaded from Refs. [39, 40], including USAir (American Airlines Network), PB (Political Blog Network), C.elegans (Nematode Neural Network), Metabolic (Nematode Metabolism Network), Jazz (Jazz Musician Network) and Email (Email Communication Network). The statistics of these networks are shown in Table 1. Note that we ignore the link directions and remove self-loops in the network data. When calculating the precision, we do 100 times of training and test set divisions and get the average value. The results of RDA and SAA are the average of 10 independent runs.

### 4.1. Comparison of efficiency between different attack strategies

We first compare the efficiency of the given attack strategies in terms of link prediction. The AA index is used as the prediction method in the experiments. The results are

Figure 1. Precision of the AA index under various attack strategies.

shown in Fig. 1. In each panel, the first data points are corresponding to the case of no attacks, whereas the last data points are the results that 10% of links are removed.

From this figure we can see that the SAA achieves the highest attack efficiency than the others, since it always attacks the optimal link set to suppress the precision. The SA is in the second place. The relative high efficiency of the SA lies in that removing the links, whose two end nodes are structurally similar, will greatly damage the structural similarity of the whole network, which further leads to the decrease of link predictability. Note that the difference of efficiency between distinct SA strategies is not significant.

The CA follows the SA. For different CA strategies, the efficiency is different. For instance, the WA is more efficient than the BA, which in some cases is even worse than the RDA. This is a little bit surprising, because the BA strategy is shown to be very efficient in other scenarios [27]. If a link has large betweenness, it is the intersection of many shortest paths, controlling the connectivity and communicability of the network. For example, link (4,5) in Fig. 2 has the largest betweenness and is critical to the network, since it connects two separate communities. However, nodes 4 and 5 have no common neighbor. Thus, they have a very small connection probability according to the rule of similarity based link prediction. Removing this kind of links (outliers) does not affect the link predictability, and sometimes may even favor link prediction, since these links may be kind of noise to link prediction.

For the WA, the attack efficiency of assortative networks are much larger than the disassortative networks, which is indicated in Fig. 1 and Fig. 3. Note that the assortativity of the networks used in the experiments is given in Table 1, where positive value means assortative network, and the vice versa.

To quantify the efficiency of an attack strategy, we further study the fraction of links needed to be removed in order to decrease the precision by half, which is named as attack cost and can be expressed as

$$\Phi = \frac{E'}{E}.$$
(9)

Where E' is the number of links that need to be removed to decrease the precision by half, and E is the total number of links in the network. based on the definition, we know

Figure 2. An example network, in which link (4, 5) has the largest betweenness.

**Table 2.**  $\Phi$  (%) of three real-world networks. If  $\Phi > 10\%$ , we mark it as "-".

that the smaller  $\Phi$ , the larger attack efficiency. We still use the AA index as the link prediction method.  $\Phi$  of three real-world networks under different attack strategies is given in Table 2, in which "-" means  $\Phi > 10\%$ . As can be seen from this table, for most of the attack strategies, removing only a small portion of links can reduce the prediction accuracy by half, which indicates that the influence of network attacks on link prediction cannot be ignored. In other words, real-world networks are pretty vulnerable to network attacks in terms of link prediction. In addition, we can clearly see the difference of the efficiency of distinct attack strategies.

### 4.2. Comparison of robustness between different prediction methods

On the other hand, we compare the robustness of different link prediction methods. To be fair, we use the RDA as the attack strategy for all the prediction methods. The experimental results are shown in Fig. 4. As in Fig. 1, the first data point of each curve corresponds to the case of no attacks, and the last one is the result when 10% links are randomly removed. From Fig. 4, we observe that the precision of all the link prediction methods decreases as the number of removed links increases. For the considered network data, the RA has the largest prediction accuracy, followed by the AA. The prediction accuracy of CN, LP and Katz is relatively low and with small difference.

In order to quantify the robustness of a link prediction method against network attacks, we propose a new index of attack robustness as follows:

$$\Omega = \frac{1}{L} \cdot \sum_{i=1}^{L} \frac{|precision(i \cdot \Delta m) - precision(0)|}{precision(0)}.$$
(10)

Where  $\Delta m$  is a given constant, and *i* is a variable number and has range in [0, L]. precision(\*) is the result of precision when \* links are removed.  $\Omega$  measures the average decrease rate of precision under network attacks, and small  $\Omega$  value means large attack robustness.

With the given definition of attack robustness index and the results of Fig. 4, we calculate  $\Omega$  of the five considered link prediction methods, the results of which are shown in Table 3. We can see that although the RA has the highest prediction accuracy, its  $\Omega$  value is also the largest among all the prediction methods, which indicates that the RA has the smallest attack robustness. In contrast, the prediction accuracy of CN is not

very prominent. However, its  $\Omega$  value is smaller than the RA, which means that the CN is more robust than RA against network attacks. These results call for a comprehensive consideration of the performance of a link prediction method in application.

## 5. Conclusion

In summary, we study the robustness of link prediction methods under network attacks, a new dimension for the evaluation of link prediction methods. Specifically, we consider the random attacks (RDA) and centrality based attacks (CA), i.e., the betweenness and weight based link attacks (BA and WA). Furthermore, we propose the similarity based attacks (SA), which attack the links based on their similarity scores, and the simulated annealing based attack (SAA).

Through the experiments, we observe that network attacks have a great impact on the link prediction accuracy, measured by the prediction index. Generally, attacking a small portion of links can result in a significant decrease of prediction accuracy, except for the random and betweenness based attacks. For all the attack strategies, the SAA has the highest attack efficiency, followed by the SA, and then CA and RDA. Note that in the category of centrality based attacks, the BA has low attack efficiency, even worse than the RDA.

For all the considered similarity indices, we obtain that the RA can achieve better prediction performance than the others, but it is very vulnerable to network attacks. On the contrary, the CN has relatively large robustness against attacks compared to the others, although its prediction performance may be just acceptable. These results indicate that the robustness of link prediction methods should also be considered, when they are used in real applications.
