(Dated: August 20, 2019)

Classical scale invariance represents a promising framework for model building beyond the Standard Model. However, once coupled to gravity, any scale-invariant microscopic model requires an explanation for the origin of the Planck mass. In this paper, we provide a minimal example for such a mechanism and show how the Planck mass can be dynamically generated in a strongly coupled gauge sector. We consider the case of hidden  $SU(N_c)$  gauge interactions that link the Planck mass to the condensation of a scalar bilinear operator that is nonminimally coupled to curvature. The effective theory at energies below the Planck mass contains two scalar fields: the pseudo-Nambu–Goldstone boson of spontaneously broken scale invariance (the dilaton) and a gravitational scalar degree of freedom that originates from the  $R^2$  term in the effective action (the scalaron). We compute the effective potential for the coupled dilaton-scalaron system at one-loop order and demonstrate that it can be used to successfully realize a stage of slow-roll inflation in the early Universe. Remarkably enough, our predictions for the primordial scalar and tensor power spectra interpolate between those of standard  $R^2$  inflation and linear chaotic inflation. For comparatively small gravitational couplings, we thus obtain a spectral index  $n_s \approx 0.97$  and a tensor-to-scalar ratio as large as  $r \approx 0.08$ .

## <span id="page-1-0"></span>I. INTRODUCTION

What is the origin of the Planck mass? This fundamental question, which we will address in this paper, attracted much attention in the past, particularly in field theory  $[1-18]$ . If we start with a theory that contains dimensionful parameters, we cannot explain its origin. Thus, within the framework of Einstein's theory of gravity, the origin of the Planck mass cannot be explained. In the references cited above, conformal symmetry is imposed, as the Planck mass and hence Einstein gravity can arise through its breaking. Conformal symmetry can be global  $[1-4]$  $[1-4]$  or local  $[5-18]$  $[5-18]$ , and the theory can contain fundamental scalar fields from the beginning  $[1-11]$  $[1-11]$ , as in the Brans–Dicke theory  $[19]$ , or no scalar field as in the case of induced gravity  $[12-18]$  $[12-18]$ . Conformal gravity, i.e., gravity supplemented by a local conformal symmetry, has also been strongly motivating because of its possible renormalizability (see, e.g., [\[18,](#page-17-2) [20,](#page-17-8) [21\]](#page-17-9)). If conformal symmetry is imposed in the presence of a scalar field and if it is an anomaly-free local symmetry, the scalar field can be eliminated by a gauge fixing [\[5–](#page-17-4)[11\]](#page-17-5). Alternatively, a certain boundary condition may be responsible for the generation of Einstein gravity [\[8,](#page-17-10) [22\]](#page-18-0). For recent work on the possible connection between conformal gravity and the origin of the electroweak scale, see also [\[23\]](#page-18-1). In contrast to this, if conformal symmetry is global and spontaneously broken, the Nambu–Goldstone (NG) boson associated with the breaking appears as a physical degree of freedom (DOF). This bosonic DOF may be present from the start and become the NG boson after symmetry breaking.

Bosonic DOFs are welcome because they may play the role of the inflaton field, which is a crucial element [\[24–](#page-18-2)[26\]](#page-18-3) to overcome the problems of old inflation [\[27\]](#page-18-4) (see, e.g., [\[28\]](#page-18-5) for a historical account). Since the inflaton field should roll down very slowly at first, the scalar potential for the inflaton field needs to satisfy the so-called slow-roll conditions (see, e.g., [\[29,](#page-18-6) [30\]](#page-18-7) for reviews). Moreover, the shape of the potential is these days very restricted in order to agree with the PLANCK observations [\[31\]](#page-18-8). Symmetry principles such as the concept of conformal symmetry can help to explain the origin of the inflaton field in combination with its specific potential. It can also help if the inflaton field is absent at the beginning as in the case of  $R^2$  inflation [\[32–](#page-18-9)[34\]](#page-18-10) (see also [\[35\]](#page-18-11) and references therein) or if the scalar field plays a dual role as in the case of Higgs inflation [\[36\]](#page-18-12) (see also [\[37\]](#page-18-13) and references therein).

Motivated by these observations and guided by the hints above, we consider in this paper a model with global conformal symmetry, which is spontaneously broken by the strong dynamics in a hidden  $SU(N_c)$  gauge theory. The model contains a complex scalar field S in the fundamental representation of  $SU(N_c)$  with the curvature portal coupling  $S^{\dagger} S R$ , where R represents the Ricci curvature scalar. Due to the strong dynamics, a nonzero scalar bilinear condensate forms,  $\langle S^{\dagger}S \rangle \neq 0$ , which breaks conformal symmetry spontaneously [\[38,](#page-18-14) [39\]](#page-18-15). The Planck mass is generated dynamically in this way, and the lowest excitation around the symmetry-breaking condensate can be identified with the NG boson, i.e., the dilaton. Note that this mechanism eliminates the generic asymmetry between gravity with a built-in scale and quantum field theory, where overall scales have no meaning. The breaking of conformal symmetry in our scenario sets the scale in both sectors in a symmetric way. The potential for the dilaton field and its coupling to the gravitational field is generated at the same time in this scenario. Through an appropriate Weyl transformation, the resulting action can be brought into the Einstein frame. In this way, we are able to identify the origin of the Planck mass and the inflaton; it is a mixture of the dilaton and the scalaron, which appears due to the  $R^2$  term.

Our basic idea to generate the Planck mass and at the same time to induce inflation is similar to that of [\[40\]](#page-18-16) in that our construction is based on global scale invariance in the starting classical theory.<sup>1</sup> However, our concept to arrive at the Einstein-Hilbert kinetic term for the gravitational field that couples to the inflaton field is different: We rely on the strong dynamics in a non-Abelian gauge theory that break scale invariance spontaneously, while the model of [\[40\]](#page-18-16) has

<sup>&</sup>lt;sup>1</sup> References  $[41-47]$  $[41-47]$  are a partial list of articles that discuss inflation in classically scale-invariant models (see also the references in these articles). None of them uses strong dynamics in a non-Abelian gauge theory to break scale invariance. Nonperturbative chiral symmetry breaking to produce a robust energy scale in a classically scale-invariant hidden sector [\[48–](#page-18-19)[50\]](#page-19-0) has been applied to an inflation model [\[51\]](#page-19-1), but scale invariance is explicitly broken in their starting classical theory.

no strongly interacting gauge sector, so the hard breaking of conformal symmetry by the conformal anomaly [\[52–](#page-19-2)[54\]](#page-19-3) (i.e., the running of coupling constants) plays a crucial role. Finally, we mention that the supersymmetric models discussed in [\[55](#page-19-4)[–61\]](#page-19-5) also make use of strongly coupled gauge dynamics in a hidden sector to generate the energy scale of inflation. However, these models simply assume the presence of the Einstein-Hilbert term from the very beginning and hence offer no dynamical explanation for the origin of the Planck scale.

Our starting tree-level action in Eq. [\(1\)](#page-2-2) below has the the most general form consistent with general diffeomorphism invariance,  $SU(N_c)$  local gauge invariance and global scale invariance. Then, along the lines of the Nambu–Jona-Lasinio (NJL) model [\[62,](#page-19-6) [63\]](#page-19-7), we proceed to an effective-theory description of the scalar bilinear condensate. In the mean-field approximation, we are not only able to identify the dilaton but can also derive its potential by integrating out the fluctuations of the scalar field  $S$  around its background. In doing so, we arrive at the one-loop effective action, which is the starting action in the Jordan frame in order to subsequently discuss inflation in section III. In this part of our analysis, we assume that the Weyl tensor squared is negligible for the purposes of inflation, which is why we suppress it in the effective action. The final effective Lagrangian in the Einstein frame involves the scalaron field as well. We find that the scalar potential is such that the coupled dilaton-scalaron system gives rise to an effective singlefield model of inflation. In the last part of section III, we perform a numerical analysis to compute the inflationary observables encoded in the cosmic microwave background (CMB) and to compare our predictions with the latest data from the PLANCK satellite mission [\[31\]](#page-18-8). Our model contains four independent parameters, two of which are used to fix the values of the reduced Planck mass  $M_{\text{Pl}}$  and the amplitude  $A_s$  of the primordial scalar power spectrum. We are hence left with two free parameters to describe the inflationary Universe. The last section is devoted to conclusions.

# <span id="page-2-0"></span>II. DYNAMICAL ORIGIN OF THE PLANCK MASS

# <span id="page-2-1"></span>A. Spontaneous breaking of scale invariance in a hidden strongly coupled sector

The starting point of our analysis is the most general action that complies with the symmetry principles of general diffeomorphism invariance, local gauge invariance, and global scale invariance at the classical level,

$$
S_{\rm C} = \int d^4x \sqrt{-g} \left[ -\hat{\beta} S^{\dagger} S R + \hat{\gamma} R^2 - \frac{1}{2} \operatorname{Tr} F^2 + g^{\mu\nu} \left( D_{\mu} S \right)^{\dagger} D_{\nu} S - \hat{\lambda} (S^{\dagger} S)^2 + a R_{\mu\nu} R^{\mu\nu} + b R_{\mu\nu\alpha\beta} R^{\mu\nu\alpha\beta} \right].
$$
 (1)

Here, R denotes the Ricci curvature scalar,  $R_{\mu\nu}$  is the Ricci tensor,  $R_{\mu\nu\alpha\beta}$  is the Riemann tensor, F is the matrix-valued field-strength tensor of the  $SU(N_c)$  gauge theory, and S is the complex scalar field in the fundamental representation of  $SU(N_c)$ , with  $D_\mu$  being the covariant derivative. Note that the action  $S_C$  also features an accidental global  $U(1)$ symmetry corresponding to S number conservation. The last two terms in Eq.  $(1)$  can be written as

<span id="page-2-3"></span><span id="page-2-2"></span>
$$
\left(\frac{1}{2}a+2b\right)W_{\mu\nu\alpha\beta}W^{\mu\nu\alpha\beta} - \left(\frac{1}{2}a+b\right)E + \frac{1}{3}(a+b)R^2,
$$
\n<sup>(2)</sup>

where  $W_{\mu\nu\alpha\beta} = R_{\mu\nu\alpha\beta} + \frac{1}{2} \left(-g_{\mu\alpha}R_{\nu\beta} + g_{\mu\beta}R_{\nu\alpha} + g_{\nu\alpha}R_{\mu\beta} - g_{\nu\beta}R_{\mu\alpha}\right) + \frac{1}{6} \left(g_{\mu\alpha}g_{\nu\beta} - g_{\nu\alpha}g_{\mu\beta}\right)R$  denotes the Weyl tensor and  $E = R_{\mu\nu\alpha\beta}R^{\mu\nu\alpha\beta} - 4R_{\mu\nu}R^{\mu\nu} + R^2$  is the Gauß-Bonnet term, which we will suppress because the corresponding action is a surface term. The  $R^2$  term in Eq. [\(2\)](#page-2-3) can be absorbed into a redefinition of the coefficient  $\gamma$ , so the last two terms in Eq. [\(1\)](#page-2-2) can be replaced by a term of the form  $\kappa W_{\mu\nu\alpha\beta}W^{\mu\nu\alpha\beta}$ , which, multiplied with  $\sqrt{-g}$ , is invariant under local conformal transformations,  $g_{\mu\nu}(x) \to g'_{\mu\nu}(x) = \Omega^2(x) g_{\mu\nu}(x)$ .

In our scenario [\[64–](#page-19-8)[66\]](#page-19-9), the condensation of the gauge-invariant scalar bilinear  $\langle S^{\dagger}S \rangle$  in the confining phase breaks scale symmetry spontaneously, in a way similar to how the chiral fermion condensate breaks chiral symmetry in QCD.<sup>2</sup>

<sup>&</sup>lt;sup>2</sup> A gauge boson condensate  $\langle \text{Tr } F^2 \rangle$  can also form in the confining phase. This condensate breaks scale invariance dynamically and can be used to generate the Planck mass [\[17,](#page-17-11) [18,](#page-17-2) [67\]](#page-19-10). In this paper, we shall ignore this dynamical breaking of scale invariance.

However, a consistent formulation of the quantum theory for the classical action in Eq. [\(1\)](#page-2-2) is not yet available. One possibility of such a formulation utilizes the notion of asymptotic safety [\[68\]](#page-19-11) (see, e.g., [\[69\]](#page-19-12) and references therein), which assumes the existence of a nontrivial ultraviolet fixed point. At the ultraviolet fixed point, conformal symmetry is restored as an unbroken symmetry of the full quantum theory. In the following discussion, we are implicitly assuming that the hard breaking of scale invariance by the scale anomaly is weak enough, so we may ignore it for the purposes of describing the spontaneous breaking of scale invariance. Related to that, we recall Ref. [\[70\]](#page-19-13), in which it has been pointed out that spontaneous scale symmetry breaking can be associated with the chiral condensate in QCD if the running of the gauge coupling is slow (i.e., if the hard breaking by the scale anomaly is weak). To realize a slow running of the gauge coupling as well as of the quartic coupling  $\lambda$  in our model, a certain set of fermion fields should be introduced [\[71\]](#page-19-14). But we will not go into such details, which are beyond the scope of the present work.

Even if gravity is switched off, it is nontrivial to investigate whether or not a scalar condensate really forms [\[38,](#page-18-14) [39\]](#page-18-15). In the following, instead of investigating this problem from first principles, we will rely on an effective theory for the order parameter  $\langle S^{\dagger}S \rangle$  (strictly speaking, it is an approximate order parameter [\[38,](#page-18-14) [39\]](#page-18-15)). Let us outline the basics of the effective theory that has been proposed in [\[65,](#page-19-15) [66\]](#page-19-9) by applying the concepts of the NJL model [\[62,](#page-19-6) [63\]](#page-19-7), which is an effective theory for the chiral condensate, i.e., the order parameter of chiral symmetry breaking in QCD. As in the case of the NJL model, the effective Lagrangian does not contain the gauge fields because they are integrated out, while it contains the "constituent" scalar field  $S$ , similar to the constituent quarks in the NJL model,

$$
S_{\text{C,eff}} = \int d^4x \sqrt{-g} \left[ -\beta S^{\dagger} S R + \gamma R^2 + \kappa W_{\mu\nu\alpha\beta} W^{\mu\nu\alpha\beta} + g^{\mu\nu} (\partial_{\mu} S)^{\dagger} \partial_{\nu} S - \lambda (S^{\dagger} S)^2 \right]. \tag{3}
$$

This is again the most general action that is consistent with general diffeomorphism invariance, global  $SU(N_c) \times U(1)$ symmetry, and classical global scale invariance.<sup>3</sup> In writing down Eq.  $(3)$ , we omitted all higher-dimensional operators arising from integrating out the gauge fields that explicitly break scale invariance. These operators reflect the explicit breaking of scale invariance at the quantum level, which we assume to be subdominant compared to the spontaneous breaking of scale invariance by the scalar condensate at low energies. The couplings  $\hat{\beta}$ ,  $\hat{\gamma}$ , and  $\hat{\lambda}$  in the fundamental action  $S_{\rm C}$  are not the same as  $\beta$ ,  $\gamma$ , and  $\lambda$  in the effective action  $S_{\rm C,eff}$  because the latter are effective couplings that are dressed by gauge field contributions. Introducing the auxiliary field (mean field)  $f$ , we can rewrite Eq. [\(3\)](#page-3-0) as

$$
S_{\text{C,eff}} = \int d^4x \sqrt{-g} \left[ \gamma R^2 + \kappa W_{\mu\nu\alpha\beta} W^{\mu\nu\alpha\beta} + g^{\mu\nu} (\partial_{\mu} S)^{\dagger} \partial_{\nu} S - (2 \lambda f + \beta R) S^{\dagger} S + \lambda f^2 \right]. \tag{4}
$$

The action in Eq. [\(3\)](#page-3-0) can be obtained from Eq. [\(4\)](#page-3-1) by inserting the equation of motion for the auxiliary field  $f$ ,

<span id="page-3-3"></span><span id="page-3-2"></span><span id="page-3-1"></span><span id="page-3-0"></span>
$$
f = S^{\dagger} S. \tag{5}
$$

Next, let us compute the one-loop effective potential for the field f. Scalar and fermionic loop corrections to the vacuum energy density in a curved (de Sitter) background were computed for the first time in [\[73\]](#page-19-16) (see also [\[74\]](#page-19-17)). To obtain the effective potential for f, we integrate out the fluctuations of the field  $S$  around its background value  $S$ ,

$$
V_{\text{eff}}\left(f,\bar{S},R\right) = \left(2\lambda f + \beta R\right)\bar{S}^{\dagger}\bar{S} - \lambda f^{2} + \frac{N_{c}}{32\pi^{2}}\left(2\lambda f + \beta R\right)^{2}\ln\frac{2\lambda f + \beta R}{\Lambda^{2}},\tag{6}
$$

where  $\Lambda = e^{3/4} \mu_{\overline{\text{MS}}}$ . We used dimensional regularization together with renormalization according to the modified minimal subtraction scheme,<sup>4</sup> where the divergences are absorbed in the coupling constants as follows,  $\lambda \to \lambda - 4 \lambda^2 L$ ,  $\beta \to \beta - 4 \beta \lambda L, \gamma \to \gamma + \beta^2 L$ , together with the shift  $f \to f + (4 \lambda f + 2 \beta R) L$ , where  $L = (1/\epsilon + \ln 4\pi - \gamma_E) N_c/32\pi^2$ .

<sup>&</sup>lt;sup>3</sup> An attempt at taking into account the effect of confinement was made in [\[72\]](#page-19-18).

<sup>4</sup> The Gaussian path integral has been performed assuming a flat spacetime metric. If the fluctuations around the flat metric are taken into The Gaussian path integral has been performed assuming a nat spacetime metric. It the fluctuations around the nat metric are taken into<br>account, a term  $\propto \sqrt{-g} (R_{\mu\nu}R^{\mu\nu} - R_{\mu\nu\alpha\beta}R^{\mu\nu\alpha\beta})$  as well as an additi They can be absorbed into redefinitions of  $\kappa$  and  $\gamma$  in Eq. [\(4\)](#page-3-1), respectively, if the topological E term is ignored.

<span id="page-4-0"></span>
$$
\langle f \rangle = f_0 = \frac{\Lambda^2}{2\,\lambda} \exp\left(\frac{8\pi^2}{N_c\lambda} - \frac{1}{2}\right) \quad \text{and} \quad \langle \bar{S} \rangle = 0. \tag{7}
$$

Our result for  $f_0$  is controlled by the one-loop contribution to the effective potential. This may raise the concern that  $f_0$  in Eq. [\(7\)](#page-4-0) actually lies outside the range of validity of the effective potential. At this point, it is, however, important to recognize that  $V_{\text{eff}}$  in Eq. [\(6\)](#page-3-2) is the outcome of a nonperturbative calculation based on the mean-field approximation. Within this approximation, Eq. [\(7\)](#page-4-0) therefore represents a consistent expression for the expectation value of the mean field f. In fact, the expression for  $f_0$  in Eq. [\(7\)](#page-4-0) is a central result of our analysis: In view of the action in Eq.  $(3)$ , together with Eq.  $(5)$ , we now see that the strong dynamics in the non-Abelian gauge theory can break conformal symmetry spontaneously and consequently generate the Planck mass dynamically,

<span id="page-4-1"></span>
$$
M_{\rm Pl}^2 = 2 \beta f_0 = \frac{N_c \beta}{16\pi^2} (2 \lambda f_0) \left( 1 + 2 \ln \frac{2 \lambda f_0}{\Lambda^2} \right),\tag{8}
$$

where  $M_{\text{Pl}}$  is the reduced Planck mass. At the same time, the constituent scalar field does not acquire a nonvanishing vacuum expectation value,  $\langle \bar{S} \rangle = 0$ . The global  $U(1)$  symmetry associated with the conservation of S particle number therefore remains unbroken.

At the minimum in Eq. [\(7\)](#page-4-0) (and still neglecting higher-order terms in R), the expectation value of  $V_{\text{eff}}$  is given by

<span id="page-4-3"></span>
$$
\langle V_{\text{eff}} \rangle = -\frac{N_c}{64\pi^2} (2\lambda f_0)^2 = -\frac{N_c \lambda^2}{64\pi^2 \beta^2} M_{\text{Pl}}^4 = -U_0 \,. \tag{9}
$$

The spontaneous breaking of scale symmetry thus generates a negative vacuum energy, which is  $U_0 = -8 \times 10^{-9} M_{\text{Pl}}^4$ for  $\lambda = 1, N_c = 5, \beta = 10^3$ . The zero-point energy density  $U_0$  is finite in dimensional regularization because of the scale invariance of the action in Eq. [\(4\)](#page-3-1). If we use another regularization scheme, it can be different or even divergent. This reflects the fact that the zero-point energy density cannot be uniquely determined within the framework of quantum field theory in flat spacetime: The cosmological constant problem remains still unsolved, although we established a link between particle physics and gravity via spontaneous breaking of global conformal symmetry. Here we are not attempting to solve this problem and proceed with our discussion in the hope that there will be a mechanism in, e.g., quantum gravity that solves this problem. In the following discussion, we thus simply subtract this vacuum energy density from the potential and continue with the potential  $V_{\text{eff}} \to V_{\text{eff}} + U_0$  so that the potential has zero cosmological constant. Consequently, the effective potential at the minimum (now restoring the  $R$  dependence) can be written as

$$
V_{\text{eff}}(f_0, 0, R) = U_0 - \lambda f_0^2 + \frac{N_c}{32\pi^2} (2\lambda f_0)^2 \ln \frac{2\lambda f_0}{\Lambda} + \frac{N_c}{32\pi^2} (2\lambda f_0) \left(1 + 2\ln \frac{2\lambda f_0}{\Lambda^2}\right) \beta R + \frac{N_c}{64\pi^2} \left(3 + 2\ln \frac{2\lambda f_0}{\Lambda^2}\right) \beta^2 R^2 + \mathcal{O}\left(\frac{\beta^3 R^3}{2\lambda f_0}\right),
$$
\n(10)

from which we see that the Planck mass is correctly identified in Eq. [\(8\)](#page-4-1) and that the parameter  $\gamma$  is shifted to

<span id="page-4-2"></span>
$$
\bar{\gamma} = \gamma - \frac{\beta^2}{2\lambda} \left(\frac{1}{2} + \ell\right) \quad \text{with} \quad \ell = \frac{N_c \lambda}{16\pi^2},\tag{11}
$$

where Eq. [\(7\)](#page-4-0) has been used.

### <span id="page-5-0"></span>B. Effective action for the dilaton field at low energies

The mean field  $f$  is a scalar field with canonical mass dimension two, and it can describe the excitations above the vacuum expectation value  $f_0$ . At the one-loop level, the mean field f obtains a kinetic term, and the excitations can be described by a propagating real scalar field. It is important to realize that this result is a characteristic outcome of our nonperturbative analysis based on the mean-field approximation. Indeed, studying our effective model in Eq. [\(4\)](#page-3-1) for the original gauge theory in Eq.  $(1)$  in the mean-field approximation allows us to identify the mean field f as the propagating dilaton field,  $f \sim \chi^2$  [see Eq. [\(15\)](#page-5-1) below], which we know must exist in the confining phase at low energies because of the spontaneous breaking of scale invariance by the scalar condensate. We emphasize that this would not be possible if we simply treated our effective model in Eq. [\(4\)](#page-3-1) according to the rules of conventional perturbation theory. In this case, the mean field  $f$  would remain an auxiliary field, and we would have no chance of describing the  $S^{\dagger}S$  bound state. In particular, we would be unable to correctly identify the propagating dilaton field at low energies.

Suppressing the complex scalar  $S$ , we now proceed with the effective action

<span id="page-5-2"></span>
$$
\Gamma_{\text{eff}} = \int d^4x \sqrt{-g} \left[ \frac{1}{2} Z^{-1} g^{\mu\nu} \partial_{\mu} f \partial_{\nu} f - V_{\text{eff}} (f, R) + \gamma R^2 + \kappa W_{\mu\nu\alpha\beta} W^{\mu\nu\alpha\beta} \right],
$$
\n(12)

where

$$
V_{\text{eff}}(f, R) = U_0 - \lambda f^2 + \frac{N_c}{32\pi^2} (2\lambda f)^2 \ln \frac{2\lambda f}{\Lambda^2} + \frac{N_c}{32\pi^2} (2\lambda f) \left(1 + 2 \ln \frac{2\lambda f}{\Lambda^2}\right) \beta R + \frac{N_c}{64\pi^2} \left(3 + 2 \ln \frac{2\lambda f}{\Lambda^2}\right) \beta^2 R^2 + \frac{N_c \beta^3 R^3}{96\pi^2 (2\lambda f)} + \mathcal{O}\left(\frac{\beta^4 R^4}{(2\lambda f)^2}\right).
$$
\n(13)

The wave function renormalization constant  $Z^{-1}$  is given by

<span id="page-5-4"></span>
$$
Z^{-1} = \frac{N_c \lambda^2}{24\pi^2 (2\lambda f + \beta R)} = \frac{N_c \lambda^2}{24\pi^2 (2\lambda f)} \left[ 1 - \frac{\beta R}{2\lambda f} + \frac{\beta^2 R^2}{(2\lambda f)^2} + \dots \right].
$$
 (14)

An explicit derivation of this result for the wave function renormalization constant can be found in [\[77\]](#page-19-21). Next, we proceed from f with canonical dimension two to the canonically normalized field  $\chi$  with canonical dimension one, i.e.,

$$
f = \left(\frac{48\pi^2}{N_c\lambda}\right)(\chi + \chi_0)^2 \quad \text{with} \quad \chi_0 = \left(\frac{N_c\lambda f_0}{48\pi^2}\right)^{1/2} = \left(\frac{\ell}{6\beta}\right)^{1/2}M_{\text{Pl}}\,,\tag{15}
$$

where  $\ell$  is defined in Eq. [\(11\)](#page-4-2). We find that the effective action in Eq. [\(12\)](#page-5-2) can be written as  $\Gamma_{\text{eff}} = \int d^4x \mathcal{L}_{\text{eff}}$ , where

$$
\frac{\mathcal{L}_{\text{eff}}}{\sqrt{-g}} = -\frac{1}{2} M_{\text{Pl}}^2 B(\chi) R + G(\chi) R^2 + \kappa W_{\mu\nu\alpha\beta} W^{\mu\nu\alpha\beta} + \frac{1}{2} g^{\mu\nu} \partial_{\mu} \chi \partial_{\nu} \chi - U(\chi) + \dots \tag{16}
$$

Here, the ellipsis stands for higher-order terms such as  $g^{\mu\nu}\partial_{\mu}\chi\,\partial_{\nu}\chi\,\beta R/\chi^2_0$ ,  $\beta^3R^3/\chi^2_0$ , etc. The dilaton-dependent functions  $B(\chi)$ ,  $G(\chi)$ , and  $U(\chi)$  are given by

<span id="page-5-6"></span><span id="page-5-5"></span><span id="page-5-3"></span><span id="page-5-1"></span>
$$
B\left(\chi\right) = \left(1 + \frac{\chi}{\chi_0}\right)^2 \left[1 + 2\,\ell\ln\left(1 + \frac{\chi}{\chi_0}\right)^2\right],\tag{17}
$$

$$
G\left(\chi\right) = \bar{\gamma} - \frac{N_c \beta^2}{32\pi^2} \ln\left(1 + \frac{\chi}{\chi_0}\right)^2,\tag{18}
$$

<span id="page-5-7"></span>
$$
U\left(\chi\right) = U_0 \left(1 + \frac{\chi}{\chi_0}\right)^4 \left[2\ln\left(1 + \frac{\chi}{\chi_0}\right)^2 - 1\right] + U_0. \tag{19}
$$

 $U_0$  and  $\bar{\gamma}$  are defined in Eqs. [\(9\)](#page-4-3) and [\(11\)](#page-4-2), respectively. The effective action  $\mathcal{L}_{\text{eff}}$  in Eq. [\(16\)](#page-5-3) illustrates that the dilaton field  $\chi$  is, in fact, not a true NG boson in the sense that it parametrizes an exactly flat direction in the scalar potential.

$$
\ln\left(\frac{2\lambda f}{\Lambda^2}\right) = \ln\left(\frac{96\pi^2\chi_0^2}{N_c\Lambda^2}\right)\left(1+\frac{\chi}{\chi_0}\right)^2 = \frac{8\pi^2}{N_c\lambda} - \frac{1}{2} + \ln\left(1+\frac{\chi}{\chi_0}\right)^2.
$$
\n(20)

 $V_{\text{eff}}$  in Eq. [\(13\)](#page-5-4) is obtained from Eq. [\(6\)](#page-3-2) by expanding in powers of  $\beta R$ . This expansion makes sense only if  $2 \lambda f \gg \beta R$ , which means  $M_{\rm Pl}^2 (1 + \chi/\chi_0)^2 \gg (\beta^2/\lambda) R$ . Otherwise, it is impossible to generate Einstein gravity. Furthermore, even if  $M_{\text{Pl}}^2 (1 + \chi/\chi_0)^2 \gg (\beta^2/\lambda) R$  is satisfied, the coefficient of R in Eq. [\(16\)](#page-5-3) still vanishes as soon as  $B(\chi) = 0$ .

# <span id="page-6-2"></span><span id="page-6-0"></span>III. DILATON-SCALARON INFLATION

# <span id="page-6-1"></span>A. Full scalar potential of the dilaton-scalaron system

In the previous section, we discussed how the condensation of a scalar bilinear operator nonminimally coupled to the Ricci scalar leads to the dynamical generation of the Planck mass. In this section, we shall now turn to the effective theory at energies below the Planck scale and demonstrate how the scalar DOFs at low energies can give rise to a stage of inflationary expansion in the early Universe. The starting point of our analysis is the effective Jordan-frame Lagrangian in Eq. [\(16\)](#page-5-3), truncated after the second order in the Jordan-frame Ricci scalar  $R_J$ ,

$$
\frac{\mathcal{L}_{\text{eff}}^J}{\sqrt{-g_J}} = -\frac{1}{2} B(\chi) M_{\text{Pl}}^2 R_J + G(\chi) R_J^2 + \frac{1}{2} g_J^{\mu\nu} \partial_\mu \chi \partial_\nu \chi - U(\chi) . \tag{21}
$$

Here,  $g_{J}^{\mu\nu}$  and  $g_{J}$  denote the inverse and the determinant of the Jordan-frame spacetime metric  $g_{\mu\nu}^{J}$ , respectively. By construction, the kinetic term of the dilaton field  $\chi$  is canonically normalized in the Jordan frame. In this work, we shall assume that the term involving the Weyl tensor squared is negligible for the purposes of inflation. The equation of motion for the dilaton field is, in any case, independent of this term. Moreover, we recall that the dimensionless function  $B(\chi)$  given in Eq. [\(17\)](#page-5-5) parametrizes the nonminimal coupling of the dilaton field  $\chi$  to the Ricci scalar  $R_J$ , while the dimensionless function  $G(\chi)$  given in Eq. [\(18\)](#page-5-6) denotes the field-dependent coefficient of the  $R_J^2$  term. The dimensionful function  $U(\chi)$  given in Eq. [\(19\)](#page-5-7) stands for the Jordan-frame scalar potential. A similar Lagrangian with a priori arbitrary functions  $B, G$ , and U has been studied in [\[78\]](#page-20-0) for purely phenomenological reasons.

The Lagrangian in Eq. [\(21\)](#page-6-2) admits solutions of the equations of motion that describe an inflationary stage of expansion. To see this more clearly, we need to transform Eq. [\(21\)](#page-6-2) from the Jordan frame to the Einstein frame. In a first step, let us introduce an auxiliary field  $\psi$  with mass dimension two that allows us to remove the  $R_J^2$  term,

$$
\frac{\mathcal{L}_{\text{eff}}^J}{\sqrt{-g_J}} = -\left[\frac{1}{2}B\left(\chi\right)M_{\text{Pl}}^2 - 2G\left(\chi\right)\psi\right]R_J + \frac{1}{2}g_J^{\mu\nu}\partial_\mu\chi\partial_\nu\chi - U\left(\chi\right) - G\left(\chi\right)\psi^2.
$$
\n(22)

Indeed, varying this Lagrangian w.r.t. the auxiliary field,  $\delta_\psi \mathcal{L}_{\text{eff}}^J = 0$ , results in  $\psi = R_J$ , which restores the Lagrangian in Eq. [\(21\)](#page-6-2). In a second step, we perform a Weyl rescaling of the metric,  $g_{\mu\nu} = \Omega^2 g_{\mu\nu}^J$ , where we choose the conformal factor  $\Omega$  such that the kinetic term for the gravitational field obtains its standard Einstein-Hilbert form,

<span id="page-6-4"></span><span id="page-6-3"></span>
$$
\Omega^{2}\left(\chi,\psi\right) = B\left(\chi\right) - \frac{4\,G\left(\chi\right)\psi}{M_{\rm Pl}^{2}}\,. \tag{23}
$$

At this point, it is helpful to remember that the Ricci scalar  $R_J$  behaves as follows under a Weyl transformation,

$$
R_J = \Omega^2 \left( R + 3 g^{\mu\nu} \partial_\mu \partial_\nu \ln \Omega^2 - \frac{3}{2} g^{\mu\nu} \partial_\mu \ln \Omega^2 \partial_\nu \ln \Omega^2 \right).
$$
 (24)

Neglecting the total derivative in this expression, we thus arrive at the Einstein-frame Lagrangian

$$
\frac{\mathcal{L}_{\text{eff}}^{E}}{\sqrt{-g}} = -\frac{1}{2} M_{\text{Pl}}^{2} \left( R - \frac{3}{2} g^{\mu\nu} \partial_{\mu} \ln \Omega^{2} \left( \chi, \psi \right) \partial_{\nu} \ln \Omega^{2} \left( \chi, \psi \right) \right) + \frac{g^{\mu\nu}}{2 \Omega^{2} \left( \chi, \psi \right)} \partial_{\mu} \chi \partial_{\nu} \chi - V \left( \chi, \psi \right) , \tag{25}
$$

where V denotes the scalar potential in the Einstein frame,

$$
V(\chi, \psi) = \frac{U(\chi) + G(\chi)\,\psi^2}{\Omega^4(\chi, \psi)} = \frac{U(\chi) + G(\chi)\,\psi^2}{\left(B(\chi)\,M_{\rm Pl}^2 - 4\,G(\chi)\,\psi\right)^2}M_{\rm Pl}^4\,. \tag{26}
$$

The Lagrangian in Eq. [\(25\)](#page-7-1) indicates that the function  $\ln \Omega^2$ , which we extracted from the Jordan-frame Ricci scalar  $R_J$  in Eq. [\(24\)](#page-6-3), can be regarded as a propagating scalar field that possesses its own kinetic term. In the following, we will refer to this new scalar field as the scalaron  $\phi$ ; the canonically normalized scalaron is defined as follows,

<span id="page-7-2"></span><span id="page-7-1"></span>
$$
\phi = \sqrt{\frac{3}{2}} M_{\rm Pl} \ln \Omega^2. \tag{27}
$$

Making use of this definition, the conformal factor  $\Omega^2$  can be written as an exponential function of the scalaron field,

$$
\Omega^2 = e^{\Phi(\phi)}, \quad \Phi(\phi) = \frac{\sqrt{2}\,\phi}{\sqrt{3}\,M_{\rm Pl}}.
$$
\n(28)

Similarly, thanks to Eqs. [\(23\)](#page-6-4) and [\(27\)](#page-7-2), the auxiliary field  $\psi$  can be traded for a function of the fields  $\chi$  and  $\phi$ ,

<span id="page-7-4"></span><span id="page-7-3"></span>
$$
\psi = \frac{M_{\rm Pl}^2}{4\,G\left(\chi\right)} \left[ B\left(\chi\right) - e^{\Phi\left(\phi\right)} \right] \,. \tag{29}
$$

The Einstein-frame Lagrangian for the coupled dilaton-scalaron system thus obtains the form

$$
\frac{\mathcal{L}_{\text{eff}}^{E}}{\sqrt{-g}} = -\frac{1}{2} M_{\text{Pl}}^{2} R + \frac{1}{2} g^{\mu\nu} \partial_{\mu}\phi \partial_{\nu}\phi + \frac{1}{2} e^{-\Phi(\phi)} g^{\mu\nu} \partial_{\mu}\chi \partial_{\nu}\chi - V(\chi, \phi) , \qquad (30)
$$

where the Einstein-frame scalar potential V as a function of  $\chi$  and  $\phi$  now reads

$$
V(\chi,\phi) = e^{-2\Phi(\phi)} \left[ U(\chi) + \frac{M_{\rm Pl}^4}{16\,G(\chi)} \left( B(\chi) - e^{\Phi(\phi)} \right)^2 \right]. \tag{31}
$$

This scalar potential can be used as the starting point for the analysis of slow-roll inflation.

We mention in passing that a scalar potential similar to the one in Eq.  $(31)$  has recently also been obtained in [\[79\]](#page-20-1), which presents a study of Coleman-Weinberg inflation supplemented by a nonminimal inflaton coupling to gravity and an additional  $R^2$  term. It is therefore intelligible that our analysis shares a number of similarities with the one in [\[79\]](#page-20-1). On the other hand, one should notice that the model in [\[79\]](#page-20-1) builds upon the assumption of simple polynomial expressions in the initial Jordan-frame Lagrangian, whereas our functions  $B, G$ , and  $U$  in Eq. [\(21\)](#page-6-2) all include logarithmic terms that are generated radiatively in the low-energy effective action. This explains why the field dependence of our scalar potential is more complicated, after all, than in the case of the scalar potential discussed in [\[79\]](#page-20-1).

### <span id="page-7-0"></span>B. Effective single-field description along the inflationary trajectory

The scalar potential in Eq. [\(31\)](#page-7-3) is a complicated function in the two-dimensional field space spanned by  $\chi$  and  $\phi$ . In principle, one could therefore imagine that Eq. [\(31\)](#page-7-3) allows one to realize inflation in various parameter regimes and different parts of field space. In particular, this might include scenarios in which both scalar fields act as slowly rolling inflatons, such that inflation needs to be described by a full-fledged two-field analysis. In the following, however, we will refrain from attempting to identify such intricate scenarios. Instead, we will focus on a particularly simple

$$
\frac{\partial V}{\partial \phi}\Big|_{(\chi,\phi_{\star}(\chi))} = 0 \qquad \Rightarrow \qquad \phi_{\star}(\chi) = \sqrt{\frac{3}{2}} \, M_{\text{Pl}} \ln\left[\left(1 + 4 \, A\left(\chi\right)\right) B\left(\chi\right)\right] \,,\tag{32}
$$

where we introduced the dilaton-dependent function  $A$ , which will allows us to simplify our notation in the following,

<span id="page-8-5"></span><span id="page-8-3"></span><span id="page-8-0"></span>
$$
A\left(\chi\right) = \frac{4\,G\left(\chi\right)U\left(\chi\right)}{B^2\left(\chi\right)M_{\rm Pl}^4} \,. \tag{33}
$$

The presence of this extremum motivates us to seek inflationary solutions along the following contour in field space,

$$
\mathcal{C}\left(\sigma\right) = \left\{\chi\left(\sigma\right), \phi\left(\sigma\right)\right\} = \left\{\sigma, \phi_{\star}\left(\sigma\right)\right\},\tag{34}
$$

where  $\sigma$  can be regarded as the physical inflaton field that parametrizes the one-dimensional contour C in the twodimensional field space. Along this trajectory, the dilaton-scalaron system can be effectively described by a single-field model in terms of the real scalar  $\sigma$ . Interestingly enough, a similar observation has recently also been made in [\[80\]](#page-20-2), which contains a study of Higgs inflation in the presence of an extra  $R^2$  term. The model in [\[80\]](#page-20-2) describes a coupled Higgs-scalaron system that can also be reduced to an effective single-field model along a local extremum in the scalar potential. We point out that the model [\[80\]](#page-20-2) simply assumes the presence of the Einstein-Hilbert term from the outset. The particle spectrum of this model therefore does not contain a dilaton field that could couple to the scalaron; the role of our dilaton field  $\chi$  is thus played by the only other available scalar DOF: the standard model Higgs boson.

Evaluating Eqs. [\(30\)](#page-7-4) and [\(31\)](#page-7-3) along  $\mathcal{C}$ , we obtain the following Lagrangian,

$$
\frac{\mathcal{L}_{\text{eff}}^{E}}{\sqrt{-g}}\bigg|_{\mathcal{C}} = -\frac{1}{2} M_{\text{Pl}}^{2} R + \frac{1}{2} N_{\sigma}^{2} (\sigma) g^{\mu\nu} \partial_{\mu} \sigma \partial_{\nu} \sigma - V_{\text{inf}} (\sigma) . \tag{35}
$$

Note that the field  $\sigma$  is not canonically normalized; its kinetic term is multiplied by the field-dependent function  $N_{\sigma}$ ,

$$
N_{\sigma}(\sigma) = \frac{1}{(1 + 4A(\sigma)) B(\sigma)} \left[ (1 + 4A(\sigma)) B(\sigma) + \frac{3}{2} M_{\rm Pl}^2 ((1 + 4A(\sigma)) B'(\sigma) + 4A'(\sigma) B(\sigma))^2 \right]^{1/2}.
$$
 (36)

Meanwhile, the scalar potential for the noncanonically normalized inflaton field  $\sigma$  obtains the following form,

<span id="page-8-2"></span>
$$
V_{\rm inf}(\sigma) = \frac{U(\sigma)}{(1 + 4A(\sigma)) B^2(\sigma)}.
$$
\n(37)

The canonically normalized inflaton field  $\hat{\sigma}$  follows from integrating the function  $N_{\sigma}$  over an appropriate field range,

<span id="page-8-7"></span><span id="page-8-6"></span><span id="page-8-1"></span>
$$
\hat{\sigma}(\sigma) = \int_0^{\sigma} d\sigma' N_{\sigma}(\sigma') . \tag{38}
$$

The relation between the three scalar fields  $\chi$ ,  $\phi$ , and  $\hat{\sigma}$  is illustrated in Fig. [1](#page-9-0) for a particular benchmark point in parameter space. The left panel of this figure shows a contour plot of the scalar potential  $V$  in Eq.  $(31)$  as a function of  $\chi$  and  $\phi$ , together with the inflationary trajectory C in Eq. [\(34\)](#page-8-0), while in the right panel of this figure, we plot the effective potential during inflation in Eq. [\(37\)](#page-8-1),  $V_{\text{inf}}$ , as a function of  $\hat{\sigma}$ .

Let us now discuss the various conditions that need to be satisfied so that the effective Lagrangian in Eq. [\(35\)](#page-8-2) can be used as a starting point for the description of inflation. (i) A first obvious condition is that inflation can only occur along the contour  $\mathcal C$  if the extremum in the scalaron direction corresponds to a local minimum. In this case, inflation will proceed along a slightly sloped valley. Otherwise, i.e., if the extremum corresponds to a local maximum, the contour  $\mathcal C$  will describe an unstable ridge in the potential landscape. Therefore, a necessary condition for successful inflation is that, along the trajectory  $C$ , the scalaron direction is always stabilized by a positive mass squared,

<span id="page-8-4"></span>
$$
m_{\phi}^{2}\left(\sigma\right) = \left. \frac{\partial^{2} V}{\partial \phi^{2}} \right|_{\mathcal{C}} > 0. \tag{39}
$$

<span id="page-9-0"></span>FIG. 1: Inflationary trajectory in field space (left panel) and effective scalar potential during inflation (right panel) for a particular benchmark point in parameter space:  $N_c = 5$ ,  $\lambda = 1$ ,  $\gamma = \beta^2 \approx 3.7 \times 10^7$ . These parameter values are chosen such that they reproduce the correct values for the amplitude and the spectral tilt of the scalar power spectrum. The black contour lines in the left plot represent equipotential lines. The color shading also indicates the height of the scalar potential.

Making use of the function A introduced in Eq.  $(33)$ , the scalaron mass during inflation can be written as

<span id="page-9-1"></span>
$$
m_{\phi}^{2}\left(\sigma\right) = \frac{M_{\text{Pl}}^{2}}{12\left(1 + 4A\left(\sigma\right)\right)G\left(\sigma\right)}\,. \tag{40}
$$

Successful inflation requires a positive vacuum energy density,  $V_{\text{inf}} > 0$ . The expression for the scalar potential in Eq. [\(37\)](#page-8-1) thus implies that A must always be larger than  $-1/4$ . For this reason, the condition of a positive scalaron mass squared in Eq.  $(39)$  translates into the statement that the function G must always be positive during inflation,<sup>5</sup>

$$
G\left(\sigma\right) = \bar{\gamma} - \frac{N_c \beta^2}{32\pi^2} \ln\left(1 + \frac{\sigma}{\chi_0}\right)^2 > 0. \tag{41}
$$

We remark that the radiative corrections to the Lagrangian parameter  $\gamma$  that are encoded in the function G always come with a negative sign. As a consequence, it is, in fact, impossible to satisfy the condition  $G > 0$  for all values of the scalar field  $\sigma$ . As soon as  $\sigma$  exceeds a certain critical value  $\sigma_{\rm crit}$ , the function G turns negative,

$$
\sigma > \sigma_{\text{crit}} = \left[ \exp\left( \frac{16\pi^2 \,\bar{\gamma}}{N_c \beta^2} \right) - 1 \right] \chi_0 \qquad \Rightarrow \qquad G\left(\sigma\right) < 0. \tag{42}
$$

However, for all practical purposes, it is sufficient if this critical field value is large enough compared to the typical field values during inflation. In addition, it may well be that the scalar potential receives further gravitational corrections at field values far above the Planck scale that regularize the singularity at  $G = 0$ . For these reasons, we content

 $5 G > 0$  implies in turn that A cannot become negative. As a matter of fact, A thus never obtains values in the interval  $-1/4 < A < 0$ .

<span id="page-10-4"></span><span id="page-10-2"></span><span id="page-10-1"></span><span id="page-10-0"></span>11

ourselves with the requirement that  $\sigma_{\rm crit}$  should be at least as large as the Planck scale,

$$
\sigma_{\text{crit}} = \left[ \exp\left( \frac{16\pi^2 \bar{\gamma}}{N_c \beta^2} \right) - 1 \right] \chi_0 > M_{\text{Pl}} \,. \tag{43}
$$

This condition ensures that the available field range in the  $\sigma$  direction will always be large enough to support inflation.

(ii) Merely requiring  $m_{\phi}^2$  to be positive is not enough to sufficiently stabilize the scalaron at  $\phi = \phi_{\star}$ . In fact, from the perspective of slow-roll inflation, we can only ignore the motion in the scalaron direction away from the trajectory C if the scalaron mass  $m_{\phi}$  is large compared to the inflationary Hubble rate  $H_{\text{inf}}$  for all times during inflation,

$$
\frac{m_{\phi}^{2}(\sigma)}{H_{\inf}^{2}(\sigma)} = \frac{1}{A(\sigma)} \gg 1.
$$
\n(44)

Here, we used the standard expression for  $H_{\text{inf}}$  in the slow-roll approximation,

$$
H_{\rm inf}(\sigma) = \frac{V_{\rm inf}^{1/2}(\sigma)}{\sqrt{3}M_{\rm Pl}} = \frac{U^{1/2}(\sigma)}{\sqrt{3}(1 + 4A(\sigma))^{1/2}B(\sigma)M_{\rm Pl}}.
$$
(45)

In view of Eq.  $(44)$ , we therefore conclude that the function A must always remain small during inflation,  $A \ll 1$ . The inflationary Hubble rate  $H_{\text{inf}}$  in Eq. [\(45\)](#page-10-1) also determines the curvature scalar during slow-roll inflation,  $\langle R \rangle \simeq 12 H_{\text{inf}}^2$ . One can show that, for typical field and parameter values during inflation,  $\langle R \rangle$  is therefore always much smaller than the expectation value of the mean field in Sec. [II,](#page-2-0)  $\langle R \rangle \ll \langle f \rangle$ . This justifies our assumption in deriving Eq. [\(7\)](#page-4-0).

Once the condition  $A \ll 1$  becomes violated, we can no longer fully trust our ansatz in Eqs. [\(32\)](#page-8-5) and [\(34\)](#page-8-0) and be sure that inflation will indeed proceed along the contour  $\mathcal{C}$ . In this case, we may alternatively look for local minima in the dilaton direction  $\chi$  and attempt to construct an inflationary trajectory C' along these minima,

$$
\left. \frac{\partial V}{\partial \chi} \right|_{(\chi_*(\phi), \phi)} = 0 \qquad \Rightarrow \qquad \mathcal{C}'(\sigma) = \{ \chi(\sigma), \phi(\sigma) \} = \{ \chi_*(\sigma), \sigma \} \ . \tag{46}
$$

However, this approach is complicated by the fact that the form of the scalar potential in Eq. [\(31\)](#page-7-3) does not allow us to compute the local minima in the dilaton direction analytically. The best we can do in order to determine the function  $\chi_{\star}$  is to adopt an iterative procedure. First, let us ignore for a moment the field dependence of all logarithmic terms in Eq. [\(31\)](#page-7-3). In this approximation, we are able to solve the extremal problem in Eq. [\(46\)](#page-10-2) exactly. Then, in the next step, we can use the result of the first step to find a better approximation for the logarithmic terms, which provides us in turn with a slightly improved solution for  $\chi_{\star}$ . After n iterations, this leads to the expression for  $\chi_{\star}$ ,

$$
x_{\star}^{(n+1)}(\phi) = 1 + \frac{\chi_{\star}^{(n+1)}(\phi)}{\chi_0} = \left[1 + 2\,\ell\,L^{(n)}(\phi) - \frac{1 - 2\,L^{(n)}(\phi)}{1 + 2\,\ell\,L^{(n)}(\phi)}\frac{16\,U_0}{M_{\rm Pl}^4} \,G^{(n)}(\phi)\right]^{-1/2} e^{\Phi(\phi)/2},\tag{47}
$$

with the logarithmic terms after *n* iterations,  $L^{(n)}$  and  $G^{(n)}$ , being defined as follows,

<span id="page-10-3"></span>
$$
L^{(n)}(\phi) = \ln\left(x_{\star}^{(n)}(\phi)\right)^2, \quad G^{(n)}(\phi) = \bar{\gamma} - \frac{N_c \beta^2}{32\pi^2} L^{(n)}(\phi) . \tag{48}
$$

The initial  $x_{\star}$  value is arbitrary and must be chosen by hand. For definiteness, we may, e.g., choose  $x_{\star}^{(0)} = \sqrt{e}$  such that  $L^{(0)} = 1$ . In an explicit numerical analysis, we are able to confirm that this iterative procedure performs very well. Over a broad range of parameter and field values, Eq.  $(47)$  manages to approximate the exact numerical result for  $x_*$  to high precision. Moreover, we are able to show that, for  $A \ll 1$ , the contours C and C' always lie very close together in field space. In this case, both approaches lead to the same inflationary dynamics and hence to identical predictions for the primordial power spectra. But on top of that, we are also able to confirm numerically that, even for  $A \gtrsim 1$ , inflation along the contours C and C' leads to very similar predictions. For this reason, we will from now on only focus on inflation along the trajectory C. In the regions of parameter space where  $A \gtrsim 1$ , this is still a sufficiently good approximation. A dedicated numerical analysis of inflation along the contour  $\mathcal{C}'$  is left for future work.

(iii) The fact that the dilaton-scalaron system can be effectively described by a simple single-field model is also apparent from the scalar mass spectrum. After diagonalizing the dilaton-scalaron mass matrix and identifying the two mass eigenstates, one typically finds that one mass eigenvalue is extremely large. It is therefore well justified to integrate out the heavy DOF and describe inflation in terms of a single-field model. To see this explicitly, one requires knowledge of the scalar mass matrix along the contour  $\mathcal{C}$ . The mass squared of the scalaron field is given in Eq. [\(40\)](#page-9-1). The mass squared of the canonically normalized dilaton field  $\hat{\chi}$  as well as the dilaton-scalaron mass mixing parameter can be calculated as follows,

<span id="page-11-0"></span>
$$
m_{\tilde{\chi}}^2(\sigma) = \frac{1}{N_{\chi}^2(\sigma)} \left. \frac{\partial^2 V}{\partial \chi^2} \right|_{\mathcal{C}}, \quad m_{\tilde{\chi}\phi}^2(\sigma) = \frac{1}{N_{\chi}(\sigma)} \left. \frac{\partial^2 V}{\partial \chi \partial \phi} \right|_{\mathcal{C}}.
$$
 (49)

Here, we accounted for the noncanonical normalization of the dilaton field in Eq. [\(30\)](#page-7-4) by means of the factor  $N_{\chi}$ ,

$$
d\hat{\chi} = N_{\chi}(\sigma) d\chi, \quad N_{\chi}(\sigma) = e^{-\Phi(\phi_{\star}(\sigma))/2} = \frac{1}{\left[ (1 + 4 A(\sigma)) B(\sigma) \right]^{1/2}}.
$$
\n(50)

For simplicity, we shall neglect the field dependence of  $N_\chi$  for the time being and simply work with a symmetric mass matrix,  $m_{\phi\hat{\chi}}^2 = m_{\hat{\chi}\phi}^2$ , in the following. An explicit computation of the partial derivatives in Eq. [\(49\)](#page-11-0) results in

$$
\frac{m_{\tilde{\chi}}^2(\sigma)}{N_{\chi}^2(\sigma)} = U''(\sigma) + 2\left(\frac{2B'(\sigma)G'(\sigma)}{B(\sigma)G(\sigma)} - \frac{B''(\sigma)}{B(\sigma)}\right)U(\sigma) + 16\left(\frac{2G'^2(\sigma)}{B^2(\sigma)G(\sigma)} - \frac{G''(\sigma)}{B^2(\sigma)}\right)\frac{U^2(\sigma)}{M_{\text{Pl}}^4} + \frac{B'^2(\sigma)}{8G(\sigma)}M_{\text{Pl}}^4,
$$
\n
$$
\frac{m_{\tilde{\chi}\phi}^2(\sigma)}{N_{\chi}^3(\sigma)} = -\frac{\sqrt{8}}{\sqrt{3}M_{\text{Pl}}}\left[U'(\sigma) + \left(\frac{G'(\sigma)}{G(\sigma)} - \frac{B'(\sigma)}{B(\sigma)}\right)U(\sigma) + \frac{B(\sigma)B'(\sigma)}{16G(\sigma)}M_{\text{Pl}}^4\right].
$$
\n(51)

Together, the mass parameters  $m_{\phi}^2$ ,  $m_{\tilde{\chi}}^2$ , and  $m_{\tilde{\chi}\phi}^2$  can be used to determine the scalar mass eigenvalues  $m_{\pm}^2$  during inflation. Typically, we find one heavy mass eigenstate,  $0 < H_{\text{inf}}^2 \ll m_+^2$ , as well as one light tachyonic mass eigenstate,  $-H_{\text{inf}}^2 \ll m_{-}^2 < 0$ . The tachyonic mass eigenstate appears as a consequence of the negative curvature of the scalar potential in the direction of the inflationary trajectory. Similarly, the heavy mass eigenstate reflects the fact that the scalar potential is steeply rising in the direction orthogonal to the contour  $\mathcal{C}$ . In fact, an important condition for the validity of our analysis is that the mass eigenvalue  $m_+$  never exceeds the Planck scale,

<span id="page-11-1"></span>
$$
m_+(\sigma) \lesssim M_{\rm Pl} \,. \tag{52}
$$

Otherwise, we would no longer be able to trust our standard quantum field theory analysis. In our numerical study of slow-roll inflation (see Sec. [III C\)](#page-12-0), we explicitly compute  $m_{\pm}$  along the inflationary trajectory at each point in parameter space and check whether the condition in Eq.  $(52)$  is always fulfilled. As it turns out,  $m_{+}$  sometimes does become as large as  $\mathcal{O}(M_{\text{Pl}})$ , but the bound in Eq. [\(52\)](#page-11-1) is never severely violated. We thus argue that the mass spectrum of our model is under control and that we can trust our analysis in all relevant regions of parameter space.

(iv) The fourth and last condition for successful inflation is concerned with the perturbativity of our model. Recall that our construction is based on a strongly coupled gauge theory at high energies. This implies the risk that our effective single-field model at low energies may inherit some strong-coupling effects that would render a standard analysis in terms of perturbation theory invalid. Therefore, it is essential to study the self-interactions of the canonically normalized inflaton field  $\hat{\sigma}$  and examine whether or not they remain in the perturbative regime. The brute-force approach to this problem would be to explicitly compute the scalar potential  $V_{\text{inf}}$  as a function of  $\hat{\sigma}$  and to study its properties in the most general terms. However, to do so, one would have to invert the relation between  $\sigma$  and  $\hat{\sigma}$  in Eq. [\(38\)](#page-8-6), which, in practice, can only be done numerically. For this reason, we will adopt a different approach in the following that bypasses this technical complication. The crucial point is that we are mostly interested in the properties of the scalar potential in the vicinity of the origin in field space, where we expect the inflaton self-interactions to be the strongest (see Fig. [1\)](#page-9-0). For small field values, we are then able to expand  $V_{\text{inf}}$  in powers of the inflaton field,

$$
V_{\rm inf}(\sigma(\hat{\sigma})) = \frac{1}{2} \hat{a}_2 \hat{\sigma}^2 + \frac{1}{3} \hat{a}_3 \hat{\sigma}^3 + \frac{1}{4} \hat{a}_4 \hat{\sigma}^4 + \mathcal{O}(\hat{\sigma}^5) , \qquad (53)
$$

$$
\hat{a}_2 = \frac{V_{\text{inf}}^{\prime\prime}(\sigma)}{N_\sigma^2(\sigma)}\Big|_{\sigma=0},\tag{54}
$$
\n
$$
\hat{a}_3 = \frac{1}{2 N_\sigma^3(\sigma)} \left[ V_{\text{inf}}^{\prime\prime\prime}(\sigma) - 3 \frac{N_\sigma^{\prime}(\sigma)}{N_\sigma(\sigma)} V_{\text{inf}}^{\prime\prime}(\sigma) \right]_{\sigma=0},\,
$$
\n
$$
\hat{a}_4 = \frac{1}{6 N_\sigma^4(\sigma)} \left[ V_{\text{inf}}^{\prime\prime\prime\prime}(\sigma) - 6 \frac{N_\sigma^{\prime}(\sigma)}{N_\sigma(\sigma)} V_{\text{inf}}^{\prime\prime\prime}(\sigma) + 15 \frac{N_\sigma^{\prime\prime}(\sigma)}{N_\sigma^2(\sigma)} V_{\text{inf}}^{\prime\prime\prime}(\sigma) - 4 \frac{N_\sigma^{\prime\prime}(\sigma)}{N_\sigma(\sigma)} V_{\text{inf}}^{\prime\prime\prime}(\sigma) \right]_{\sigma=0}.
$$

Based on these results, one can show that the self-interactions of the field  $\hat{\sigma}$  remain perturbative for all parameter values of interest. On the analytical side, it is easy to see that the overall magnitude of the coefficients is universally controlled by  $U_0/M_{\text{Pl}}^4$ , i.e., the normalization of the Jordan-frame scalar potential in units of the Planck mass,

$$
\frac{U_0}{M_{\rm Pl}^4} = \frac{N_c \,\lambda^2}{64\pi^2 \,\beta^2} \,. \tag{55}
$$

As long as this parameter is small, the coefficients  $\hat{a}_{2,3,4}$  automatically obtain small values in Planck units. With regard to the quartic self-coupling  $\hat{a}_4$ , this means in particular that a sub-Planckian potential energy density in the Jordan frame,  $U_0 \ll M_{\text{Pl}}^4$ , readily results in perturbatively small values,  $\hat{a}_4 \ll 1$ . In our numerical slow-roll analysis, we are able to confirm these results by explicitly evaluating the coefficients  $\hat{a}_{2,3,4}$  at each point in parameter space.

# <span id="page-12-0"></span>C. Numerical analysis of the slow-roll dynamics

The effective single-field model specified in Eqs. [\(35\)](#page-8-2), [\(36\)](#page-8-7), and [\(37\)](#page-8-1) allows us to perform a standard single-field slow-roll analysis of inflation. The goal of this analysis is to compute the usual observables related to the primordial power spectra encoded in the temperature fluctuations of the CMB: the amplitude  $A_s$  and the spectral tilt  $n_s$  of the scalar power spectrum as well as the tensor-to-scalar ratio r. These three observables are measured or constrained by the latest data from the PLANCK satellite mission [\[31\]](#page-18-8). At  $68\%$  C. L., the scalar amplitude  $A_s$  is measured to be

$$
A_s = e^{3.044 \pm 0.014} \times 10^{-10} \qquad (\text{TT} + \text{TE} + \text{EE} + \text{lowE} + \text{lensing}). \tag{56}
$$

In the following, we will work with the best-fit value,  $A_s^{\text{obs}} = e^{3.044} \times 10^{-10} \approx 2.1 \times 10^{-9}$ , for definiteness. The combined constraints on  $n_s$  and r for various combinations of datasets are shown in the right panel of Fig. [2.](#page-14-0)

Our predictions for  $A_s$ ,  $n_s$ , and r can be conveniently computed in terms of the slow-roll parameters  $\varepsilon$  and  $\eta$ ,

<span id="page-12-2"></span><span id="page-12-1"></span>
$$
A_s = \frac{V_{\text{inf}}}{24\pi^2 \varepsilon M_{\text{Pl}}^4}, \quad n_s = 1 + 2\eta - 6\varepsilon, \quad r = 16\varepsilon,
$$
\n
$$
(57)
$$

where all field-dependent quantities  $(V_{\text{inf}}, \varepsilon, \text{ and } \eta)$  are supposed to be evaluated at the time of CMB horizon exit, i.e.,  $N_e \simeq 50 \cdots 60$  e-folds before the end of inflation. The parameters  $\varepsilon$  and  $\eta$  are defined in terms of partial derivatives of the scalar potential w.r.t. the canonically normalized inflaton field  $\hat{\sigma}$ . However, thanks to the chain rule, these derivatives can again be readily expressed as derivatives w.r.t. the noncanonically normalized field  $\sigma$ ,

$$
\varepsilon(\sigma) = \frac{M_{\rm Pl}^2}{2} \left( \frac{\partial_{\hat{\sigma}} V_{\rm inf}(\sigma(\hat{\sigma}))}{V_{\rm inf}(\sigma(\hat{\sigma}))} \right)^2 = \frac{M_{\rm Pl}^2}{2 N_{\sigma}^2(\sigma)} \left( \frac{\partial_{\sigma} V_{\rm inf}(\sigma)}{V_{\rm inf}(\sigma)} \right)^2,
$$
\n
$$
\eta(\sigma) = M_{\rm Pl}^2 \frac{\partial_{\hat{\sigma}} \partial_{\hat{\sigma}} V_{\rm inf}(\sigma(\hat{\sigma}))}{V_{\rm inf}(\sigma(\hat{\sigma}))} = \frac{M_{\rm Pl}^2}{N_{\sigma}^2(\sigma)} \left( \frac{\partial_{\sigma} \partial_{\sigma} V_{\rm inf}(\sigma)}{V_{\rm inf}(\sigma)} - \frac{\partial_{\sigma} N_{\sigma}(\sigma)}{N_{\sigma}(\sigma)} \frac{\partial_{\sigma} V_{\rm inf}(\sigma)}{V_{\rm inf}(\sigma)} \right).
$$
\n(58)

<span id="page-13-0"></span>
$$
\frac{d\,\sigma}{dN_e} = \frac{M_{\rm Pl}^2}{N_\sigma^2 \left(\sigma\right)} \frac{\partial_\sigma V_{\rm inf}\left(\sigma\right)}{V_{\rm inf}\left(\sigma\right)},\tag{59}
$$

with the field value at the end of inflation,  $\sigma_0 = \sigma(N_e = 0)$ , defined by the requirement that max  $\{\varepsilon(\sigma_0), |\eta(\sigma_0)|\} = 1$ .

Together, the relations in Eqs. [\(57\)](#page-12-1), [\(58\)](#page-12-2), and [\(59\)](#page-13-0) provide us with the necessary tools to determine our theoretical predictions for  $A_s$ ,  $n_s$ , and r. Because of the complicated form of the functions  $N_{\sigma}$  and  $V_{\text{inf}}$  in Eqs. [\(36\)](#page-8-7) and [\(37\)](#page-8-1), this can only be done numerically— at least as long as one intends not to make any simplifying assumptions. Consequently, we will content ourselves with a purely numerical analysis in this paper. Any analytical investigation based on further assumptions is left for future work. The parameter space of our inflationary model is spanned by three dimensionless coupling constants: (i) the quartic self-coupling  $\lambda$  of the scalar quark field S, (ii) the strength  $\beta$ of the nonminimal coupling between the field S and the Ricci scalar R, and (iii) the coefficient  $\gamma$  of the bare  $R^2$  term before accounting for any radiative corrections. We also recall that all three parameters are understood to correspond to those couplings that appear in the effective action for the constituent scalar field S after integrating out the strong  $SU(N_c)$  gauge dynamics. In the following, one of these parameters can be eliminated by requiring that the amplitude of the scalar power spectrum obtains the correct value,  $A_s = A_s^{\text{obs}}$ . For definiteness, we will take this parameter to be the nonminimal coupling constant  $\beta$ . This leaves us with a two-dimensional parameter space spanned by  $\lambda$  and  $\gamma$ , in which we can compute our predictions for  $n_s$  and r. The outcome of this analysis is shown in Fig. [2.](#page-14-0)

A remarkable feature of our results is that they include and extend the well-known results of  $R^2$  inflation [\[32\]](#page-18-9). This connection can be illustrated in the following intuitive way: First of all, let us consider the orientation of the inflationary trajectory  $\mathcal C$  in the dilaton-scalaron field space at the time of CMB horizon exit. At each point in parameter space, we would like to know the following: Does inflaton take place in the scalaron or dilaton direction? In other words, in view of the scalar potential in Eq. [\(31\)](#page-7-3), are the inflationary dynamics determined by the function  $e^{\Phi}$  or by the functions B, G, and U? A convenient way to answer these questions is to introduce the inclination angle

<span id="page-13-1"></span>
$$
\alpha = \arctan\left(\frac{\chi_0}{M_{\text{Pl}}} \frac{d\,\phi_\star}{d\chi}\right) \,,\tag{60}
$$

which measures the angle between the dilaton axis in field space and the inflationary trajectory.<sup>6</sup> An inclination angle close to 0 indicates that the dynamics of inflation are mostly governed by the dilaton-dependent functions in the scalar potential. Conversely, an inclination angle close to  $\pi$  points to inflation being dominated by the scalaron-dependent part of the scalar potential. In Fig. [2,](#page-14-0) we refer to these two scenarios as dilaton and scalaron inflation, respectively. In particular, we indicate the dependence of  $\alpha$  as a function of  $\lambda$  and  $\gamma$  by the color shading in the left panel of Fig. [2.](#page-14-0)

Interestingly enough,  $\alpha$  converges towards  $\alpha \simeq \pi$  as soon as  $\gamma$  approaches a characteristic value of  $\mathcal{O}(10^9)$ . This is nothing but the  $R^2$ -inflation limit of our model. In this limit, the dynamics of the dilaton field become increasingly irrelevant from the perspective of inflation. In fact, for large values of  $\gamma$ , the value of  $\beta$  that is required to obtain the correct scalar amplitude decreases. According to Eq. [\(17\)](#page-5-5), this results in a large value of  $\chi_0$ , such that

$$
\chi \ll \chi_0 \qquad \Rightarrow \qquad B(\chi) \approx 1, \quad G(\chi) \approx \bar{\gamma}, \quad U(\chi) \approx 0. \tag{61}
$$

As a consequence, the scalar potential in Eq.  $(31)$  approaches the well-known potential of  $R^2$  inflation [\[32\]](#page-18-9),

$$
\chi \ll \chi_0 \qquad \Rightarrow \qquad V(\chi, \phi) \approx \frac{M_{\rm Pl}^4}{16\,\bar{\gamma}} \left(1 - e^{-\Phi(\phi)}\right)^2. \tag{62}
$$

<sup>&</sup>lt;sup>6</sup> Here, we consider the dimensionless quantities  $\chi/\chi_0$  and  $\phi/M_{\rm Pl}$  as the relevant field variables in the scalar potential. Only after this rescaling of the fields  $\chi$  and  $\phi$  are we able to compare the importance of the functions  $e^{\Phi}$ ,  $B$ ,  $G$ , and U in a meaningful way.

<span id="page-14-0"></span>FIG. 2: Predictions for the CMB observables  $n_s$  and r in the parameter space of our model (left panel) as well as in the  $n_s - r$ plane (right panel). The gray-shaded area in the lower part of the left plot is excluded because it leads to a violation of the theoretical constraint in Eq. [\(43\)](#page-10-4). The inclination angle  $\alpha$  is defined in Eq. [\(60\)](#page-13-1). The PLANCK constraints in the right plot are taken from [\[31\]](#page-18-8). For more details on the various reference models of inflation, see the discussion and analysis in [\[31\]](#page-18-8). The black and white circle in both plots corresponds to the benchmark parameter point chosen in Fig. [1.](#page-9-0)

In this potential, we recognize the radiatively corrected parameter  $\bar{\gamma}$  as the coefficient of the  $R^2$  term in  $R^2$  inflation. The requirement of a correctly normalized scalar power spectrum then uniquely fixes  $\bar{\gamma}$  at a value of  $\mathcal{O}(10^9)$ ,

$$
A_s = A_s^{\text{obs}}, \quad 50 \le N_e \le 60 \qquad \Rightarrow \qquad 0.5 \times 10^9 \lesssim \bar{\gamma} \lesssim 0.7 \times 10^9 \,. \tag{63}
$$

Up to terms suppressed by higher powers of  $N_e^{-1}$ ,  $R^2$  inflation results in the following predictions for  $n_s$  and  $r$ ,

<span id="page-14-1"></span>
$$
n_s \simeq 1 - \frac{2}{N_e}, \quad r \simeq \frac{12}{N_e^2} \,. \tag{64}
$$

For  $N_e \simeq 50 \cdots 60$ , this means that r is expected to remain rather small,  $3 \lesssim r/10^{-3} \lesssim 5$ , in the  $R^2$ -inflation limit.

However, this situation changes as soon as we make use of the parametric freedom of our model. For  $\gamma$  values smaller than those required by  $R^2$  inflation, the dilaton dynamics begin to become important. This helps us increase the tensor-to-scalar ratio (see Fig. [2\)](#page-14-0). In fact, for small values of  $\gamma$  and  $\lambda$ , the predictions of our model approach those of linear chaotic inflation [\[81\]](#page-20-3), which is described by a scalar potential that is linear in the inflaton field,  $V_{\text{inf}} \propto \sigma$ . This can be understood as follows: For small values of  $\gamma$  and  $\lambda$ , we may neglect the function A in Eqs. [\(36\)](#page-8-7) and [\(37\)](#page-8-1). In this approximation, it is possible to simplify the scalar potential  $V_{\text{inf}}$  and the normalization factor  $N_{\sigma}$  as follows,

$$
V_{\rm inf}(\sigma) \approx \frac{U(\sigma)}{B^2(\sigma)}, \quad N_{\sigma}(\sigma) \approx \frac{1}{B(\sigma)} \left[ B(\sigma) + \frac{3}{2} M_{\rm Pl}^2 B'^2(\sigma) \right]^{1/2}.
$$
 (65)

We are also able to neglect the logarithmic term in the function B in Eq. [\(17\)](#page-5-5), such that  $B(\sigma) \approx x^2(\sigma)$  and

$$
V_{\rm inf}(\sigma) \approx U_0 \left[ \frac{1}{x^4(\sigma)} - 1 + 2 \ln \left( x^2(\sigma) \right) \right], \quad N_{\sigma}(\sigma) \approx \left( 1 + \frac{6 M_{\rm Pl}^2}{\chi_0^2} \right)^{1/2} \frac{1}{x(\sigma)}, \tag{66}
$$

where x is defined similarly as in Eq. [\(47\)](#page-10-3),  $x(\sigma) = 1 + \sigma/\chi_0$ . Given this form of the normalization factor  $N_{\sigma}$  and making use of the relation in Eq. [\(38\)](#page-8-6), we are able to determine the canonically normalized inflaton field  $\hat{\sigma}$ ,

$$
\hat{\sigma}(\sigma) \approx 2 \sigma_0 \ln (x^2(\sigma)), \quad \sigma_0 = \frac{1}{4} (6 M_{\rm Pl}^2 + \chi_0^2)^{1/2}.
$$
\n(67)

Solving this relation for  $\sigma$  and inserting the result into  $V_{\text{inf}}$  in Eq. [\(66\)](#page-14-1) provides us with the scalar potential for  $\hat{\sigma}$ ,

<span id="page-15-1"></span>
$$
V_{\rm inf}(\sigma(\hat{\sigma})) \approx U_0 \left[ e^{-\hat{\sigma}/\sigma_0} - 1 + \frac{\hat{\sigma}}{\sigma_0} \right]. \tag{68}
$$

At large field values,  $\hat{\sigma} \gg \sigma_0$ , this is a linear potential just like in the case of linear chaotic inflation! At the same time, the exponential correction regularizes the derivative of the scalar potential around the origin in field space. In fact, thanks to this exponential term, the scalar potential exhibits a stable global minimum at  $\hat{\sigma} = 0$ . Interestingly enough, a scalar potential similar to the one in Eq. [\(68\)](#page-15-1) can also be derived in the context of Coleman-Weinberg inflation supplemented by a nonminimal inflaton coupling to gravity  $[82]$  (see also  $[83-85]$  $[83-85]$ ). The scenario in  $[82]$  is, however, distinct from ours in the sense that it employs weakly coupled interactions to generate the Planck scale, whereas our model is based on dimensional transmutation in a strongly coupled sector. In addition, we find that our predictions for the inflationary CMB observables approach those of linear chaotic inflation from below (see Fig. [2\)](#page-14-0), whereas in [\[82\]](#page-20-4), the predictions of linear chaotic inflation result in a lower bound on the tensor-to-scalar ratio.

We now understand why small values of  $\gamma$  and  $\lambda$  lead to the same predictions as linear chaotic inflation,

$$
n_s = 1 - \frac{3}{2 N_e}, \quad r = \frac{4}{N_e} \,. \tag{69}
$$

For  $N_e = 50$ , the tensor-to-scalar ratio can hence become as large as  $r \approx 0.08$ , while for  $N_e = 60$ , one can achieve values as large as  $r \approx 0.07$ . These are remarkable results, as they promise that our model can be probed in future CMB experiments that are sensitive to r values of the order of  $r \simeq$  few  $\times 10^{-2}$ . Moreover, it is important to note that our model populates regions in the  $n_s - r$  plane that are inaccessible in other popular inflation models (see Fig. [2\)](#page-14-0).

### <span id="page-15-0"></span>IV. CONCLUSIONS

In this paper, we studied the dynamical generation of the Planck mass in consequence of spontaneous conformalsymmetry breaking. To this end, we constructed an explicit field-theoretical model based on the idea that classical scale invariance becomes spontaneously broken because of the strongly coupled gauge dynamics in a hidden sector. Our construction led us to a remarkable realization: The stage of cosmic inflation in the early Universe may be a consequence of the microscopic physics that is responsible for the dynamical generation of the Planck mass! If correct, this observation would point to a deep connection between particle physics and cosmology. We emphasize that the pivotal element of our construction is the concept of classical scale invariance — a new approximate global symmetry that forbids any dimensionful coupling constant in the tree-level Lagrangian. At the quantum level, scale invariance is explicitly broken by the conformal anomaly, which reflects the logarithmic running of the renormalized coupling constants. However, as a working assumption, one may speculate that this explicit breaking is eventually going to vanish at very high energies because of the theory's renormalization group flow reaching an ultraviolet fixed point.<sup>7</sup>

Within the paradigm of classical scale invariance, explicit mass scales such as the Planck mass  $M_{\text{Pl}}$  can only be generated radiatively by means of spontaneous symmetry breaking. In our model, we follow this philosophy and show how classical scale invariance may be spontaneously broken by means of dimensional transmutation in a hidden

<sup>&</sup>lt;sup>7</sup> It has been suggested in [\[86\]](#page-20-7) that the infinite past (future) of the Universe may correspond to an ultraviolet (infrared) fixed point.

strongly coupled  $SU(N_c)$  gauge sector. In particular, we consider a scalar bilinear operator  $S<sup>\dagger</sup>S$  that is nonminimally coupled to the Ricci scalar and that condenses in the confining phase of the  $SU(N_c)$  gauge theory at low energies. Of course, a similar construction making use of a chiral condensate is also conceivable. In this work, we focused on a scalar condensate for simplicity. A study of the fermionic case is left for future work. Up to a dimensionless coupling constant  $\beta$ , the vacuum expectation value of the scalar condensate then directly determines the Planck mass,

<span id="page-16-1"></span><span id="page-16-0"></span>
$$
\frac{M_{\rm Pl}^2}{2} = \beta \left\langle S^\dagger S \right\rangle \,. \tag{70}
$$

The vacuum expectation value of the scalar condensate can be computed according to the following recipe:

- 1. Write down the most general action compatible with all global and local symmetries of our model.
- 2. Construct an effective model for the constituent scalar field S along the lines of the NJL model in QCD.
- 3. Apply the mean-field approximation to describe the dynamics of the order parameter  $f = S^{\dagger}S$ .
- 4. Compute the quantum effective action for f by integrating out the heavy constituent scalar S.
- 5. Determine the symmetry-breaking minimum of the effective scalar potential for the mean field  $f$ .

This procedure results in a Coleman-Weinberg-like correction to the Lagrangian of the gravitational sector,

$$
\frac{\mathcal{L}_{\text{eff}}}{\sqrt{-g}} \supset \gamma R^2 + \frac{N_c}{32\pi^2} M_R^4 \ln \frac{M_R^2}{\Lambda^2}, \quad M_R^2 = 2\lambda \left\langle S^\dagger S \right\rangle + \beta R. \tag{71}
$$

For small values of R, the logarithmic term can be expanded in powers of R, which generates among other terms the Einstein-Hilbert term in the gravitational action. The coefficient of this term is then identified as the Planck mass. An important aspect of this construction is that the gravitational scale  $M_{\text{Pl}}$  originates from an ordinary energy scale in quantum field theory, i.e., the vacuum expectation value of the scalar condensate [see Eq. [\(70\)](#page-16-0)]. Likewise, the absolute energy scale of the scalar potential after spontaneous conformal-symmetry breaking,  $U_0^{1/4}$ , is initially computed in field theory [see Eq. [\(9\)](#page-4-3)]. Therefore, before going the next step and making contact with gravity, the potential energy scale  $U_0^{1/4}$  is expected to be subjected to appropriate renormalization conditions on the field-theory side. This observation may be useful in more realistic attempts at solving the problem of the cosmological constant.

A remarkable consequence of our mechanism to generate the Planck mass is that it automatically results in the presence of an additional scalar DOF: the dilaton field  $\chi$ , which parametrizes the fluctuations around the symmetrybreaking vacuum and plays the role of the pseudo-NG boson of spontaneously broken scale invariance. As we were able to show in the second part of this paper, this dilaton field can be used to construct a successful model of inflation. In fact, the dilaton couples to a second scalar DOF, the scalaron field  $\phi$ , which originates from the  $R^2$ term in the effective action. A main result of our analysis is that the coupled dilaton-scalaron system gives rise to an effective single-field model of inflation in the Einstein frame. The predictions of this model for the inflationary CMB observables interpolate between those of standard  $R^2$  inflation and those of linear chaotic inflation. This important result represents a characteristic phenomenological feature of our model. As a consequence, we typically find values of the scalar spectral index in the range  $0.970 \leq n_s \leq 0.975$  and values for the tensor-to-scalar ratio as large as  $r \approx 0.08$ (see Fig. [2\)](#page-14-0). These are exciting predictions that will be tested in future CMB experiments.

Our study presented in this paper should be understood as a first step towards a better understanding of inflation in classically scale-invariant models. There are certainly several directions into which our discussion may be extended: (i) It would be worthwhile to study the full two-field dynamics of our model (see, e.g., [\[87,](#page-20-8) [88\]](#page-20-9)) and to investigate which other inflationary solutions one might be able to identify. In this context, one should also compute the degree of non-Gaussianities generated by our model and compare them to the current observational bounds. (ii) One may refrain

$$
f(R) = \gamma R^2 + V_{\text{CW}}(R) \tag{72}
$$

(iii) Reheating after inflation deserves a dedicated analysis, in particular, as this may allow to constrain the number of e-folds  $N_e$  during inflation more precisely (see, e.g., [\[30\]](#page-18-7)). However, all of these questions are beyond the scope of this paper. We leave them for future work, hoping that our analysis will only be the first in a series of papers that address the possible connection between the Planck mass, inflation, and the principle of classical scale invariance.

Acknowledgments: The authors would like to thank Marco Drewes, Jean-Marc Gérard, Kohei Kamada, and Christophe Ringeval for useful comments and discussions. K. S. is grateful to the Centre for Cosmology, Particle Physics, and Phenomenology at the Université Catholique de Louvain for its hospitality during the final stages of this project. The work of M. Y. is supported by the DFG Collaborative Research Centre SFB 1225 (ISOQUANT) and the Alexander von Humboldt foundation. The work of J. K. is partially supported by the Grant-in-Aid for Scientific Research (C) from the Japan Society for the Promotion of Science (Grant No. 16K05315).
