Abstract

ASASSN-14dx showed an extraordinary outburst whose features are the small outburst amplitude (~ 2.3 mag) and long duration (> 4 years). Because we found a long observational gap of 123 d before the outburst detection, we propose that the main outburst plateau was missed and that this outburst is just a “fading tail” often seen after the WZ Sge-type superoutbursts. In order to distinguish between WZ Sge and SU UMa-type dwarf novae (DNe), we investigated *Gaia* DR2 statistically. We applied a logistic regression model and succeeded in classifying by using absolute *Gaia* magnitudes M_G and *Gaia* colors $G_{BP} - G_{RP}$. Our new classifier also suggests that ASASSN-14dx is the best candidate of a WZ Sge-type DN. We estimated distances from the Earth of known WZ Sge stars by using *Gaia* DR2 parallaxes. The result indicates that ASASSN-14dx is the third nearest WZ Sge star (next to WZ Sge and V455 And), and hence the object can show the third brightest WZ Sge-type superoutburst whose maximum is $V = 8-9$ mag.

Key words: accretion, accretion disks — stars: novae, cataclysmic variables — stars: dwarf novae, WZ Sge — stars: individual (ASASSN-14dx)

1 Introduction

Cataclysmic variables (CVs) are close binaries composed of a white dwarf (WD) primary and a Roche lobe-filling secondary. An accretion disk is formed around the primary because the secondary transfers its mass to the primary. Dwarf Novae (DNe), which are a subclass of CVs, are characterized by a sudden increase of the disk brightness called “outburst”. There are two competing models to explain a dwarf nova outburst: the mass-transfer burst model (Bath 1973) and the thermal instability model (Osaki 1974; Hōshi 1979). At the present time, the latter is widely accepted at least for typical dwarf nova outbursts. For instance, Dubus et al. (2018) estimated the mass-transfer rates of 130 CVs by using the parallax distances of the *Gaia* Data Release 2 (DR2). The estimated mass-transfer rates of dwarf novae and nova-like stars are consistent with their theoretical values predicted by the thermal instability model, respectively. (for a review of CVs and DNe, see e.g. Warner 1995).

SU UMa-type DNe show not only normal outbursts but also superoutbursts with larger scales. During superoutbursts, we can observe “superhumps” whose amplitude is 0.1–0.5 mag and period is a few percent longer than the orbital period P_{orb} . Superoutbursts and superhumps are thought to be a result of the thermal-tidal instability (Osaki 1989). When an outburst begins, the disk expands. If the object has a sufficiently low mass ratio q , the outer edge of the disk can reach the 3:1 resonance radius which causes the tidal instability (Whitehurst 1988; Osaki 1989; Lubow 1991a; Lubow 1991b; Hirose, Osaki 1990).

WZ Sge-type DNe are a subclass of SU UMa-type ones and considered to be objects at the terminal stage of the CV evolution. WZ Sge stars are characterized by the large amplitude and long duration superoutbursts which are accompanied by “early superhumps” in the early terms of the superoutbursts. According to the modern criteria provided by Kato (2015), WZ Sge stars are defined by the presence of an early superhump phase. It is thought that early superhumps are triggered by the 2:1 resonance (Lin, Papaloizou 1979; Osaki, Meyer 2002). Early superhumps are double-peaked modulations whose periods are close to P_{orb} . Because the early superhumps are caused by a geometrical effect, their amplitudes depend on their inclination angles. Thus, in low-inclination systems, we can observe a long outburst plateau with no superhumps instead of an early superhump phase. SU UMa stars evolve into WZ Sge ones as the mass transfer proceeds because only CVs with extremely low mass ratios (typically $q < 0.09$) and low mass-transfer rates can reach the 2:1 resonance radius, (for a review of WZ Sge-type DNe, see Kato 2015).

According to the theoretical CV evolution calculated by Kolb (1993), 70% of CVs have already passed the period minimum. Such objects are called “period bouncers”. The secondary masses of the period bouncers are below the substellar limit. Their q and mass-transfer rates are thus extremely low as compared with DNe before the period minimum. Empirically, we know many objects around the period minimum show WZ Sge-type superoutbursts. These facts imply that most of DNe are WZ Sge stars. However, the number of WZ Sge stars is much smaller than that of SU UMa ones. The gap between the theory and observation can be caused by the observational bias because WZ Sge stars are fainter and their outburst intervals are longer in comparison to SU UMa ones. Thus, it is important to dig up the hidden WZ Sge stars. In addition, there are some unsolved problems in WZ Sge stars, e.g. the detailed mechanism of early superhumps or rebrightenings. The increasing number of WZ Sge stars will give us more opportunities to observe such phenomena.

We report on the outburst and classification of ASASSN-14dx. The outburst was detected at $V = 13.95$ on June 25, 2014 by the All-Sky Automated Survey for Supernovae (ASAS-SN) (Shappee et al. 2014). The coordinates are RA = 02:34:27.73 and Dec = -04:54:30.7 at J2000.0. The Sloan Digital Sky Survey (SDSS) magnitudes are $u = 16.42, g = 16.26, r = 16.37, i = 16.55, z = 16.63$ (Ahn et al. 2012). The object is an XMM-Newton source and has a GALEX counterpart with an NUV and FUV magnitudes of 16.4 and 16.6 (Martin et al. 2005). The spectra were obtained in August 2014 (Kaur et al. 2014) and in October 2014 (Thorstensen et al. 2016). They reported double-peaked emission lines with broad and narrow absorption ones on a blue continuum, and thus the object was confirmed as a CV. Since follow-up photometries by our group and Hardy et al. (2017) reported the superhump-like modulations, the object was initially classified as an SU UMa star. Hardy et al. (2017) confirmed that the object doesn’t show any eclipses. On the basis of our light curve analyses and new classification method by using the *Gaia* Data Release 2 (DR2) (Gaia Collaboration et al. 2016; Gaia Collaboration et al. 2018b), we propose that ASASSN-14dx is a WZ Sge star rather than SU UMa one.

2 Observation and Analysis

Our time-series observations are summarized in table E1. The data were acquired by time-resolved unfiltered CCD photometry using 30-40cm class telescopes by the VSNET Collaboration (Kato et al. 2004). The times of the observations were corrected to Barycentric Julian Date (BJD).

Fig. 1. Overall light curves of ASASSN-14dx. Filled circles, crosses, open diamonds and “V”-mark represent our observations, the ASAS-SN data, the CRTS data and the upper limit, respectively. Our time-series observations were binned to 0.01 d. The observation period of *Gaia* DR2 is indicated by the arrows.

We adjusted the zero-point of each observer to Franz-Josef Hamsch’s data.

We used the phase dispersion minimization (PDM) method for analyzing the periodic modulations. We estimated 1σ errors by using the methods in Fernie (1989) and Kato et al. (2010). Before our period analyses, we subtracted the global trend of the light curve which was calculated by using locally-weighted polynomial regression (LOWESS, Cleveland 1979).

3 Results

3.1 Overall Light Curve

Figure 1 shows the overall light curve of ASASSN-14dx. The light curve also includes the public data of the CRTS (Drake et al. 2009) and ASAS-SN Sky Patrol (Shappee et al. 2014; Kochanek et al. 2017). Before the outburst, the object was stable around $V = 16.36$ mag. The outburst was detected at $V = 13.95$ mag on June 25, 2014 (BJD 2456833), then the object gradually decreased to $V \sim 15.7$ mag until 2018. Such a small-amplitude and long-duration outburst is very unusual for DN outbursts.

We found an upper limit of 14.0 mag on February 22, 2014 (BJD 2456710) indicated in figure 1 as “V”-mark. After this observation, we don’t have any data until the outburst detection due to seasonal reason, namely, there is a long observational gap of 123 d. This gap implies that we missed the initial phase of the outburst and that this outburst is just a “fading tail”.

A fading tail is a well-known phenomenon seen after WZ Sge-type superoutbursts. Specifically, Kuulkers et al. (2011) reported the moderate declines of WZ Sagittae after the end of the superoutbursts plateau. The brightness just after the superoutbursts is about 0.5 mag brighter than in quiescence. They proposed that the decline can be caused by the development of a cavity in the inner disk and that the time scale is about a decade. For another example,

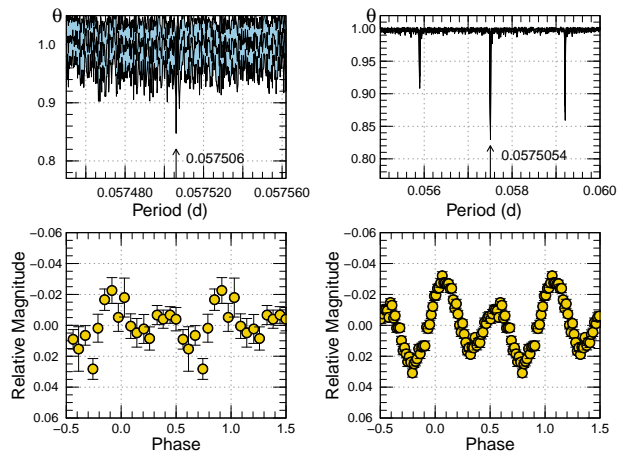

Fig. 2. Results of the period analyses of orbital modulations in quiescence (BJD 2453627.89–2456591.85) (Left) and outburst (BJD 2456854.82–2457014.09) (Right). (Upper): θ diagram of our PDM analysis of superhumps. The shaded area means 1σ errors. (Lower): Phase-averaged profiles of orbital modulations. The zero phases were defined to be BJD 2456945.8837, which is the time of the inferior conjunction obtained by Thorstensen et al. (2016).

SSS J122221.7-311523 (hereafter J1222) showed a fading tail lasting at least 500 d and the brightness just after the superoutburst is about 3 mag brighter (Neustroev et al. 2017). The outburst profile of ASASSN-14dx is in good agreement with them rather than ordinary outbursts.

3.2 Double-wave modulations

During the outburst, the object showed persistent double-wave modulations. The result of the period analysis of our observations in BJD 2456854.82–2457014.09 is indicated in figure 2. The estimated period is 0.0575054(4) d. The interval of two peaks is nearly 0.5 phase. Since the modulations were initially interpreted as superhumps, the object was classified as an SU UMa-type DN (cf. vsnet-alert 17598, Hardy et al. 2017).

4 Discussion

4.1 Orbital Modulations

The left panel of figure 2 shows the period analysis of the CRTS data in quiescence (BJD 2453627.89–2456591.85). We reported a weak signal of a possible orbital period of 0.0575060(2) d (vsnet-alert 18017). Thorstensen et al. (2016) estimated the orbital period to be 0.05756(6) d from $H\alpha$ radial velocities via spectroscopy, and they confirmed that this value is consistent with our result. These values are close to the period detected during the outburst of 0.0575054(4) d. The averaged profiles are also similar to each other (the lower panels in figure 2). Thus we propose

that the modulations in the outburst are not superhumps but orbital modulations. We adopted the period in quiescence of 0.0575060(2) d as the orbital one because of the small error and the long baseline of the data.

WZ Sge-type DNe, especially in high-inclination systems, often show double-wave orbital modulations in quiescence or fading tail (e.g. Patterson et al. 1996). Skidmore et al. (2000) investigated the disk structure of WZ Sagittae in quiescence from the Doppler mapping. They found that the bright spot exists along the ballistic trajectory, and considered that a low-density disk allows accretion stream to penetrate and thus can explain double-wave modulations originated from the change of the line-of-sight. Kononov et al. (2015) simulated the humps of WZ Sge stars by using the three-dimensional computation. They proposed that a spiral density wave and four kinds of shocks can cause such modulations. Because the density wave undergoes a slow retrograde precession in the observer's frame and the interaction between the density wave and four shocks generates the modulations, they succeeded in reproducing the profile variations and phase shifts of humps, which are sometimes seen in WZ Sge stars. Note that the period of such humps can be shorter than the orbital one in a strict sense. The modulations of ASASSN-14dx could also be explained by these mechanisms.

The estimated period of ASASSN-14dx in the outburst is very slightly shorter than that in quiescence. According to the thermal instability model, a disk after an outburst gradually shrinks due to the accreting mass (cf. Osaki 1989). Shrinkage of a disk could lead to a phase shift of the modulations, e.g. a shift of the position of the bright spot. In principle, we cannot discriminate between a continuous phase shift and a period variation. On the other hand, the model of Kononov et al. (2015) can account for the shorter period owing to the change of the precession rate of the density wave. The small difference in the periods might be caused by these varying disk structure.

We drew the averaged profiles of orbital modulations (the lower panels of figure 2). We estimated the time of the inferior conjunction, the secondary star is the closest to the Earth, to be BJD 2456945.8837(7) on the basis of the time-resolved spectroscopies obtained by Thorstensen et al. (2016), and we defined the zero phases to be BJD 2456945.8837. For the purpose of understanding the mechanism of the humps, it may be worth mentioning that both of the peaks of the modulations are close to the conjunction. However, we must note that the time of the conjunction is estimated by using the disk emissions, whose light source is unclear. Therefore this value has an uncertainty, and we need to observe lines from the secondary star to obtain the accurate time of the conjunction. These

Fig. 3. Density distributions of corrected absolute *Gaia* magnitudes M_{G0} (upper) and *Gaia* colors G_{col0} (lower). Hatched and shaded boxes represent SU UMa and WZ Sge-type DNe, respectively. Solid and dashed vertical lines indicate ASASSN-14dx in the SDSS (quiescence) and *Gaia* DR2 (outburst), respectively. The error bars of ASASSN-14dx are shown only in the lower panel because of the large errors. We removed three WZ Sge-type DN candidates mentioned in section 4.3.

figures suggest that the phases of the peaks in quiescence and outburst are respectively $-0.06(2)$ and $0.08(1)$, namely the object showed a phase shift of $0.14(2)$. Note that the folding periods are different from each other. However, even if we fold the light curve in outburst by using the period in quiescence, the phase is little varied (less than 0.01 phase). It may be difficult to explain the large shift only by a simple bright spot and shrinking disk, while the model of Kononov et al. (2015) can explain it on the basis of the retrograde-precession density wave.

4.2 Classification by *Gaia* DR2

In order to distinguish WZ Sge stars from SU UMa ones, we investigated the known DNe of the *Gaia* DR2. By using the parallaxes ϖ and three broad band optical magnitudes (white light G , blue G_{BP} and red G_{RP}) provided by the *Gaia*, we can estimate the absolute *Gaia* magnitudes M_G and *Gaia* colors $G_{col} = G_{BP} - G_{RP}$ (Luri et al. 2018; Riello et al. 2018; Evans et al. 2018). Although the *Gaia* team has already studied on the color-absolute magnitude diagram about variable stars (Gaia Collaboration et al. 2018c), we concentrated more on the subclasses of DNe. The CV evolutionary track computed by Knigge et al. (2011) shows

Fig. 4. Corrected absolute *Gaia* magnitude M_{G0} versus orbital period P_{orb} (upper) and *Gaia* color $G_{\text{col}0}$ (lower). Regarding WZ Sge-type DNe whose orbital periods are unknown, we estimated the orbital periods from the superhump periods and equation (6) in Kato et al. (2012a). The filled squares, circles and star represent SU UMa, WZ Sge-type DNe and ASASSN-14dx, respectively. Three WZ Sge star candidates mentioned in section 4.3 are shown as filled triangles. The solid line in the lower panel indicates $P_{\text{WZ}} = 0.5$ which means the borderline between SU UMa and WZ Sge stars.

that absolute magnitudes become fainter and that the colors become bluer as CVs evolve. Actually, we can see WZ Sge-type DNe lying on the bluer area in the color-color diagram of the SDSS (Kato et al. 2012b). Furthermore, it is considered that M_G depends also on the mass-transfer rates from secondaries, i.e. the brightness of bright spots and disks (cf. Dubus et al. 2018).

We identified known SU UMa/WZ Sge-type DNe with the *Gaia* DR2 sources. The list of known DNe was taken from the AAVSO VSX¹. We only used objects whose ϖ errors are within 20%. The galactic extinctions in *V* and *B* bands (A_V and A_B) for each object were obtained from the NED² (Schlafly, Finkbeiner 2011). Because the galactic extinctions are affected by the positions of the objects, we estimated the effects by using equation 2 in Ak et al.

¹ <<https://www.aavso.org/vsx/>>.

² The NASA/IPAC Extragalactic Database (NED) is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

(2008), the distances d calculated from ϖ and the assumed scale height for the interstellar dust $H = 100$ pc. Then we converted A_V and A_B to the extinctions in *Gaia* magnitudes (A_G, A_{BP}, A_{RP}) on the basis of equation 1 and table 1 in Gaia Collaboration et al. (2018a). Eventually, we used the corrected absolute magnitudes $M_{G0} = M_G - A_G$, dereddened colors $G_{\text{col}0} = G_{\text{col}} - (A_{BP} - A_{RP})$ and P_{orb} for the statistics. We note that the effects of galactic extinction have large uncertainties and are sometimes neglected (e.g. Gaia Collaboration et al. 2018c). Thus we removed the objects with large extinctions $A_G > 0.5$ in our statistics to suppress the uncertainty.

Figure 3 shows the density distributions of M_{G0} and $G_{\text{col}0}$. Hatched and shaded boxes represent SU UMa and WZ Sge stars, respectively. As expected by previous studies, WZ Sge stars are basically fainter and bluer. These features can give the interpretations that the mass-transfer rate is lower and that the WD's contribution to the color is more important in WZ Sge stars. The upper panel implies that there is a lower limit of $M_{G0} \sim 10.5$ as for WZ Sge stars. This fact is consistent with the interpretation of early superhumps by the TTI model. In other words, a low mass-transfer rate is needed to accumulate enough mass at the onset of an outburst to trigger the 2:1 resonance (Osaki 1995).

ASASSN-14dx is indicated by dashed lines in figure 3. Their positions are a little far from other WZ Sge-type objects. The reason is that the *Gaia* obtained the data during the outburst as indicated in figure 1. In order to estimate the *Gaia* magnitudes in quiescence, we converted the SDSS magnitudes, were observed before the outburst, to *Gaia* ones by using table A.2 in Evans et al. (2018). Then, we obtained the quiescent values of $M_{G0} = 11.711(43)$ and $G_{\text{col}0} = -0.112(74)$ indicated by solid lines in figure 3. These figures give the impression that ASASSN-14dx is indeed a WZ Sge-type DN.

Figure 4 shows the relations between M_{G0} and P_{orb} (upper), and M_{G0} and $G_{\text{col}0}$ (lower). The filled squares, circles and star represent SU UMa, WZ Sge-type DNe and ASASSN-14dx in quiescence, respectively. The triangles indicate new WZ Sge-type DN candidates discussed in section 4.3. We removed them from our statistics. Three WZ Sge-type stars around $P_{\text{orb}} \sim 0.076$ d are two long- P_{orb} WZ Sge stars (RZ Leo and ASASSN-16eg) and one period bouncer J1222. Wakamatsu et al. (2017) interpreted the long- P_{orb} WZ Sge stars as borderline objects between SU UMa and WZ Sge-type DNe, which have low mass-transfer rates in spite of their high-mass ratios. They are indeed fainter than other SU UMa stars having similar P_{orb} . On the other hand, their colors are redder in comparison with the other WZ Sge stars (see two objects with $G_{\text{col}0}$ of 0.6–

0.8 in the lower panels of figure 3 and 4).

From the lower panel of figure 4, we established a classification method between WZ Sge and SU UMa stars by using a logistic regression model (Verhulst 1845; Verhulst 1847). On the basis of the data in the lower panel, we can estimate the WZ Sge-type DN probability P_{WZ} as a function of M_{G0} and G_{col0} :

$$P_{WZ} = \frac{1}{1 + \exp(19.8573 + 6.7335G_{col0} - 1.9227M_{G0})}. \quad (1)$$

The solid line in figure 4 represents $P_{WZ} = 0.5$. We propose $P_{WZ} = 0.5$ as the classifier of WZ Sge/SU UMa-type DNe. For the sake of convenience, we obtained the WZ Sge probability without taking the galactic extinctions into account:

$$P'_{WZ} = \frac{1}{1 + \exp(15.9452 + 7.5695G_{col} - 1.5448M_G)}. \quad (2)$$

We note that this equation should not be used for high- A_G objects. We provide a sample R code to estimate P_{WZ} and the extinctions on our website³.

We estimated P_{WZ} for each object including large- A_G objects and summarized in table E2 and E3. P_{WZ} of ASASSN-14dx is 0.21(14) in the Gaia DR2 (outburst) but 0.97(1) in the SDSS (quiescence). Our new classifier also suggests that ASASSN-14dx is the best candidate of a WZ Sge star. We evaluated the validity of the $P_{WZ} = 0.5$ method, then 32 in 41 WZ Sge stars and 219 in 225 SU UMa ones are correctly classified, whereas $P'_{WZ} = 0.5$ classified 30 WZ Sge ones and 220 SU UMa ones. However, some WZ Sge stars could be classified as SU UMa ones due to the lacking data. Intensive observations for high- P_{WZ} systems will improve our classification method.

4.3 Exploration of WZ Sge-type DN candidates

We concluded that the following three objects are good candidates of WZ Sge-type DNe on the basis of P_{WZ} and the modern criteria provided in Kato (2015):

- PNV J19321040-2052505

The estimated P_{WZ} is 0.63(18). This object was detected on 2017 Nov. 11 by H. Nishimura⁴. A follow-up observation confirmed a possible signal of superhumps, and hence the object was classified as an SU UMa-type DN (vsnet-alert 21694). According to ASAS-3 data, the object showed an outburst in 2003 (Pojmański 2002). The duration of the outburst was longer than 27 days and the outburst amplitude was large (~ 8 mag). These values strongly suggest that the object is a WZ Sge-type DN.

³ <http://www.kusastro.kyoto-u.ac.jp/~isogai/Pwz/>

⁴ <http://www.cbat.eps.harvard.edu/unconf/followups/J19321040-2052505.html>.

- CRTS J200331.3-284941

The estimated P_{WZ} is 0.74(19). The ordinary superhumps were detected in the 2015 outburst. Kato et al. (2016) speculated that this object can be a WZ Sge-type DN on the basis of the low mass ratio of 0.084(1), long duration of growing (stage A) superhumps (more than 50 cycles), fading tail like WZ Sge-type DNe and long observational gap.

- ASASSN-17kg

The estimated P_{WZ} is 0.62(17). This object was detected on Jul. 31, 2016 by the ASAS-SN and the last observation before the detection was on Jul. 27 (Shappee et al. 2014). The follow-up observation on Aug. 3 detected growing superhumps (vsnet-alert 21326). In other words, there was an observational gap of seven days. Although the typical duration of the early superhump stage is 10 d or more (Kato 2015), table 9 in Nakata et al. (2013), which listed those of well-observed WZ Sge-type DNe, shows the minimum duration is 5 d. This fact suggests that the observational gap of one week could conceal the early superhump phase. Moreover, the object showed one rebrightening after the superoutburst (vsnet-alert 21360). We thus concluded that this object is a WZ Sge-type DN candidate.

Other SU UMa stars with a long observational gap could also be WZ Sge ones. In future, we should pay attention to high- P_{WZ} objects in order not to miss the early superhump phase. Note that there are some unusual WZ Sge stars. It may be difficult to discover them on the basis of P_{WZ} . Although AL Com was considered to be a typical WZ Sge star, the object showed SU UMa-type superoutburst in 2015 (Kimura et al. 2016). The estimated P_{WZ} of 0.11(19) is indeed low (we removed AL Com from our statistics due to the large error of ϖ). As mentioned in section 4.2, the long- P_{orb} WZ Sge stars (RZ Leo, ASASSN-16eg and BC UMa) have large G_{col0} , and hence the P_{WZ} are less than 0.15. In addition, the Gaia DR2 data are possibly contaminated by outbursts, eclipses and so on like ASASSN-14dx. Therefore, a complete classification based on the Gaia data may be essentially difficult.

4.4 Distances of WZ Sge-type DNe

We calculated the probability distributions of the distances d of known WZ Sge stars by using the Gaia parallaxes ϖ and the method of Bailer-Jones et al. (2018), assumes a Galaxy model. We obtained the median values and the 16th and 84th percentiles of the distributions. Those of nearby object are listed in table 1. ASASSN-14dx seems to be the third nearest WZ Sge-type DN. This fact suggests that the superoutburst maximum of ASASSN-14dx

can reach $V = 8-9$ mag. Thus ASASSN-14dx is one of the best targets for the observational research of WZ Sge-type DNe.

Table 1. List of nearby WZ Sge-type DNe

Object	d^\ddagger	G^\parallel
ASASSN-14dx	80.8 [80.6, 81.1]	15.0
WZ Sge	45.1 [45.0, 45.2]	15.2
V455 And	75.4 [75.1, 75.7]	16.1
BW Scl	94.2 [93.3, 95.0]	16.3
V627 Peg	99.4 [98.8, 100.1]	15.7
GW Lib	112.5 [111.4, 113.5]	16.5
EZ Lyn	145.3 [142.1, 148.6]	17.8
V355 UMa	149.6 [147.7, 151.5]	17.4

† Population II CV below the period minimum which showed a WZ Sge-type superoutburst.

5 Summary

Although ASASSN-14dx was classified as an SU UMa-type DN due to the long observational gap, the object is likely to be the best candidate of a WZ Sge-type one judging from the outburst behavior, *Gaia* absolute magnitude and *Gaia* color. The double-wave modulations observed in the outburst seem to be orbital modulations, are often seen in WZ Sge stars, rather than superhumps. The estimated distances of known WZ Sge stars indicate that ASASSN-14dx

is the third nearest WZ Sge star and that the superoutburst maximum of ASASSN-14dx can reach $V = 8-9$ mag. ASASSN-14dx is one of the best targets for observational research of WZ Sge stars because such a bright object will give us high S/N data.

We examined a new classification method of WZ Sge/SU UMa-type DNe based on the *Gaia* DR2. The logistic regression model provided the probability of WZ Sge-type DNe P_{WZ} . We proposed $P_{WZ} = 0.5$ as a classifier which correctly identified 32 in 41 WZ Sge stars and 219 in 225 SU UMa ones. A sample R code to estimate P_{WZ} and the galactic extinctions is provided on our website³. The next *Gaia* data release and further observational studies to increase the statistics will improve our classification method. Our classifier will be a powerful tool to judge a priority target.

Supporting information

The following supplementary information is available in the online article: table E1, E2, and E3.

Acknowledgments

This work was supported by the Grant-in-Aid for JSPS Fellows (No. 17J10039). We are grateful to the survey projects CRTS and ASAS-SN. This work has made use of data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. We are also thankful to the AAVSO International Database contributed by many worldwide observers.

*Parallax ϖ obtained by *Gaia* DR2 in units of mas.

[†]*Gaia* G magnitude

[‡]*Gaia* color $G_{\text{col}} = G_{\text{BP}} - G_{\text{RP}}$ in units of magnitude

[§]Galactic extinction in G , G_{BP} and G_{RP} in units of magnitude. The estimation method is described in section 4.2.

^{||}Orbital period in units of day

^{††}WZ Sge-type DN probability P_{WZ} . $P_{\text{WZ}} = 0.5$ is a borderline between WZ Sge/SU UMa stars.

Objects with $P_{\text{WZ}} > 0.5$ are good candidates of WZ Sge stars.

** G and G_{col} in quiescence are calculated by using the SDSS DR9.

#Orbital periods estimated from superhump ones by using equation (6) in Kato et al. (2012a).
