## Abstract

We reveal the classical and quantum regimes of free electron interaction with radiation, common to the general variety of radiation sources (e.g. FEL, Smith-Purcell), Laser Accelerator (DLA) and Photo-Induced Near-Field Electron Microscopy (PINEM). Modelling the electron with initial conditions of a coherent quantum electron wavepacket (QEW), its topology in phase-space uniquely defines a universal distinction of three interaction regimes (and their particle-wave duality transition): point-particle-like acceleration, quantum wavefunction (PINEM), and a newly reported regime of anomalous PINEM (APINEM). Furthermore, capturing these momentum/energy bunches of APINEM is capable of improving the spectral resolution of post-selectively filtered microscopies, and of testing the history-dependent nature of wavefunction in quantum mechanics.

Here we address a large class of light-matter interaction schemes and devices, in which free electrons are stimulated to emit/absorb light quanta (i.e., photons) when interacting with a coherent radiation field (laser beam). This class of radiative interactions includes numerous schemes of radiation sources and laser accelerators, such as Free Electron Laser (FEL) [1-3], Smith-Purcell Radiators (SPR) [6] and Dielectric Laser Acceleration (DLA) [4-5]. On the other hand, this class also includes the advanced ultrafast electron microscopy schemes of Photon-Induced Near-field Electron Microscopy (PINEM) [9-11] and coherent manipulation of quantum wavefunction with light [11-13].

The radiative interaction of free electrons is made possible due to the involvement of an external periodic force (magnetic wigglers in FEL) or a polarizable medium (such as a grating in SPR and DLA, dielectric medium in Cherenkov Radiation [7], and surface polarization in Transition Radiation (TR) [8]). In terms of quantum theory, the stimulated interaction of the radiation emission schemes can be described as multiphoton emission, accompanied by electron deceleration, keeping up the conservation of energy condition [20], and vice versa in laser acceleration. In extended interaction schemes, such as FEL, SPR, DLA, conservation of momentum condition is kept with the aid of a ‘reciprocal lattice momentum’ of a periodic structure (magnetic undulator, optical grating), whereas, in short interaction length schemes like TR, there is no momentum conservation requirement. With proper particle-wave phasing, all of these free-electron interactions can operate reciprocally as photon emitters of radiation with corresponding electron energy loss, or as laser-induced accelerators with corresponding photon absorption of the stimulating radiation wave. [17]

The PINEM-kind schemes are based on a quantum process of multiphoton emission and absorption of light quanta ( $\hbar\omega$ ) that takes place simultaneously when an electron wavefunction passes through the near field or the confined plasmonic excitation field of a nanostructure, nano-tip or foil, illuminated by an ultrafast laser beam pulse [4-5, 11-13, 18-19]. This can be described as a stimulated TR process, in which the monoenergetic spectrum of the passing-by electron develops discrete symmetric photon sidebands, spaced  $\hbar\omega$  apart ( $\omega$  is the frequency of the incident laser field) due to discrete energy quanta emission and absorption from the incident radiation field. In order to distinguish

the energy sidebands in the PINEM spectrum in the quantum mechanical operating regime of electron-photon interaction, one must require that the photon energy spacing ( $\hbar\omega$ ) of the sidebands exceeds the energy spread  $\Delta E$  of the beam [9, 14]:

$$\Delta E < \hbar\omega, \text{ or } \Delta p < \hbar\omega/v_0, \quad (1)$$

This condition is equivalent to the “large recoil condition” for quantum FEL [14, 20] where  $\hbar\omega/v_0$  is the emission/absorption electron quantum recoil momentum, and  $\Delta p = \Delta E/v_0$  is the energy momentum spread,  $v_0$  is the electron group velocity.

In this letter, we refer to the entire class of all of these free electron stimulated radiative interaction schemes (Fig.1a), and report the operating characteristics of a hitherto non-investigated light-matter interaction regime, where the electron is not presented as a plane-wave, as in conventional quantum FEL and PINEM models, or as a point-particle, as in classical electrodynamics models of FEL and accelerators, but instead as a finite duration and finite energy spread coherent Quantum Electron Wavepacket (QEW) (e.g., a Gaussian envelope wavefunction) satisfying the minimal Heisenberg uncertainty:  $\sigma_{E_0} \sigma_{t_0} = \hbar/2$ ,  $(\sigma_{p_0} \sigma_{z_0} = \hbar/2)$ , where  $\sigma_{E_0}$  ( $\sigma_{p_0} = \sigma_{E_0}/v_0$ ) is the standard deviation of the wavepacket energy (momentum) and  $\sigma_{t_0}$  ( $\sigma_{z_0} = v_0 \sigma_{t_0}$ ) is the standard deviation of its duration (spatial size) at the minimal waist point of the Gaussian wavepacket propagation. As the wavepacket drifts in free space, its intrinsic energy spread is retained, but the wavepacket size expands as a function of drift time  $t_D$  according to:

$$\sigma_z(t_D) = \sqrt{\sigma_{z_0}^2 + \left( \frac{\lambda_c^* ct_D}{4\pi \sigma_{z_0}} \right)^2}, \text{ where we defined } \lambda_c^* = \lambda_c/\gamma^3 \text{ with } \lambda_c = h/mc - \text{ the Compton wavelength [17].}$$

The free propagation of the QEW leads to spatial stretching in the axial dimension, accompanied by energy (phase) chirping effect. This expansion suggests a different condition for operating in the quantum (PINEM) regime, where the wavepacket, long enough, acts as a plane wave with no phase relation to the light wave - the “long wavepacket” condition [17,20]:

$$\sigma_t(t_D) > T = 2\pi / \omega, (\sigma_z(t_D) > \lambda\beta / 2\pi). \quad (2)$$

In order to understand the validity ranges of these two different quantum limit conditions (1-2), it is most instructive to present the electron at entrance and after interaction in an energy-time (E-t) phase-space, as shown in Fig.1, or in the corresponding momentum-space (p-z) phase-space. Based on the topology of the electron distribution in this phase-space, we report here distinction between three universal operating regimes, common to all light-electron interaction schemes: Acceleration, PINEM and anomalous PINEM (APINEM). This distinction depends solely on the initial conditions of the wavepacket, and the phase-space presentation demonstrates the transition of these schemes from the point-particle classical regime to the quantum regime. We thus define (here in p-z phase space) the Wigner function (WF) representation of the QEW [15], i.e.,

$$W(z, p, t) = \frac{1}{2\pi} \int \psi^*(p - q/2) \psi(p + q/2) e^{-i(E_{p+q/2} - E_{p-q/2})t/\hbar} e^{iqz/\hbar} dq, \quad (3)$$

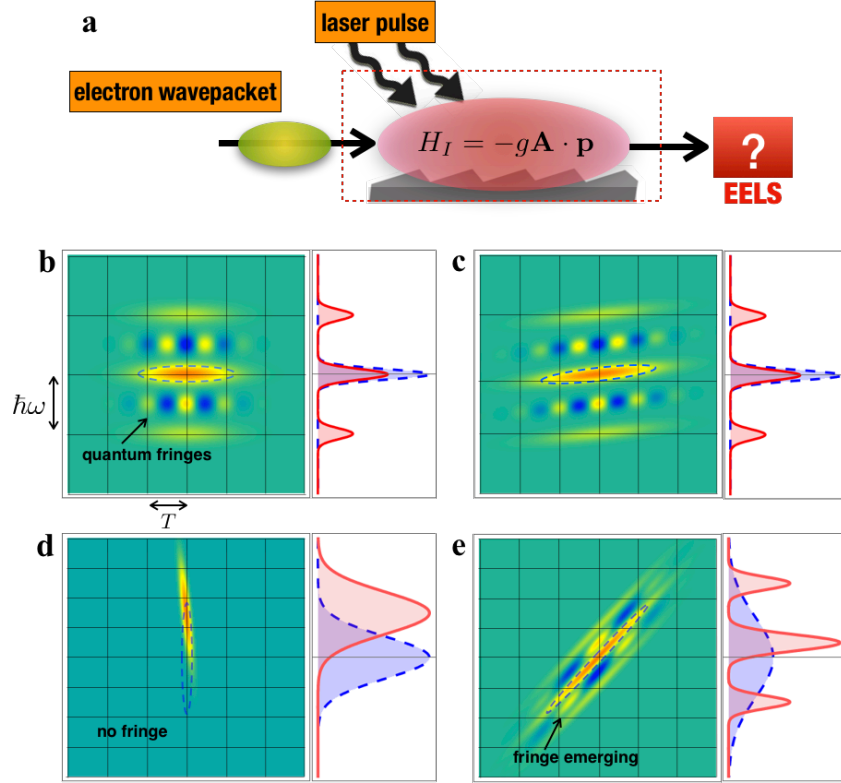

where  $\int W(z, p, t) dz dp = \hbar / 2$  and  $E_p \approx \varepsilon_0 + v_0(p - p_0) + \frac{(p - p_0)^2}{2m^*}$  is the relativistic energy dispersion expanded to second-order around the incoming energy  $\varepsilon_0$  [17, 20].

**First order perturbation analysis** - In a first-order perturbation solution of Schrodinger equation of any of the above light matter interaction scheme, the perturbed wavefunction after interaction, is given in momentum space as:  $\psi(p) = \psi^{(0)}(p) + \psi^{(1)}(p)$ , where  $\psi^{(0)}(p)$  is the initial wavefunction and  $\psi^{(1)}(p)$  the scattered component. Thus, after interaction, the laser-induced Wigner function is composed of three terms:

$$W(z, p) = W^{(00)}(z, p) + 2\Re(W^{(01)}(z, p)) + W^{(11)}(z, p), \quad (4)$$

where  $W^{(00)} = \frac{1}{\aleph} \left( \frac{2}{\pi^3} \right)^{1/2} \exp\left( -\frac{(z - pt_D/m^*)^2}{2\sigma_{z_0}^2} - 2\frac{(p - p_0)^2}{\sigma_{p_0}^2} \right)$  is the initial Gaussian Wigner function, rescaled by normalization  $(1/\aleph)$ ,  $W^{(11)}$  is the scattered term, and  $2\Re(W^{(01)})$  is an interference term between the zero order and the first order scattering term of the

wavefunction. Keeping this interference term, which has been neglected in previous quantum analyses, is a pivotal methodological step in this work, since it is essential for the identification of the the APINEM effect and the point particle to quantum transition in the QEW regime.

*Fig.1: Illustrations of PINEM, Acceleration and APINEM processes in phase space representation before (broken-line ellipses) and after interaction (positive- red, yellow, negative- blue) and their momentum distributions. (a) The light-matter interaction schemes and its EELS measurement. (b-c) PINEM with quantum fringes in-between the photon sidebands, for expanded un-chirped (b) and pre-chirped (c) quantum electron wavepackets. (d) Particle-like acceleration with net momentum shift and no quantum fringes. (e) Anomalous PINEM with quantum fringes emerging after interaction between the tilted separable branches of the initially stretched and chirped wavepacket.*

Fig. 1b-d displays the pre-interaction Wigner function (WF) of the QEW (in broken line) and the post-interaction WF (in color code) in  $(E-t)$  phase-space, overlaid over a quantization grid of  $\hbar\omega \times T = h$ , with  $T = 2\pi/\omega$  (or  $(\hbar\omega/v_0) \times (\beta\lambda) = h$  in  $p-z$  phase-space). It reveals the different possible interaction regimes in dependence on the QEW initial condition, based alone on the topology in phase space of the initial electron WF.

Note that the Gaussian QEW distribution has a phase area of half Planck constant at the minimal waist point ( $2\pi\sigma_{E_0}\sigma_{t_0} = h/2$ ), and this area stays constant under the horizontal stretching transformation of drift before interaction. For QEW entering the interaction region at its waist, namely as an erect ellipse with no chirp (Fig.1b&d), the phase-space topology leaves only two qualitatively different scenarios. In one case (Fig.1b) the Wigner function extrudes out of the quantization box in the horizontal dimension, satisfying the “long wavepacket” quantum regime condition (2)  $-2\sigma_{t_0} > T$ , and because  $\sigma_{t_0} = \hbar/2\sigma_{E_0}$ , it satisfies also the “large recoil” condition (1):  $2\sigma_{E_0} < \hbar\omega$ , (or  $2\sigma_{p_0} < \hbar\omega/v_0$ ). The other possibility (Fig.1d) is a narrow wavepacket case,  $2\sigma_{t_0} < T$  (narrow broken line ellipse), that necessarily corresponds also to extruding out of the quantization box in the vertical dimension:  $2\sigma_{E_0} > \hbar\omega$ , (or  $2\sigma_{p_0} > \hbar\omega/v_0$ ), namely, violating both kinds of quantum regime conditions (1-2). After interaction, the  $\pm\hbar\omega$  vertically shifted energy sidebands do not overlap in case (1b), and their horizontal projection produce the PINEM-kind multi-sidebands energy spectrum as shown aside the WF picture. On the other hand, in case (1d), where the vertical projection corresponds to a point-particle-like wavepacket with distinguishable phase relative to the radiation wave, the horizontal projection of the distribution produces a point-particle-like acceleration spectrum of the classical limit.

If the electron arrives to the interaction region after drift (Fig.1c&e), the stretching transformation of free drift produces a chirped long wavepacket distribution at the entrance to the interaction region (slanted broken line ellipse extruding horizontally out of the quantization box), satisfying in both cases the “long wavepacket” PINEM condition (2). In case (1c) this condition is still kept consistently with the “large recoil” condition, since the momentum  $\sigma_{p_0}$  does not change in drift, and consequently the horizontal projection of the post-interaction WD produces the conventional multi-sidebands PINEM spectrum as in (1b).

Of special interest is the case (1e), where the narrow QEW distribution of (1d) stretching due to drift before entering the interaction region, satisfies the long wavepacket

condition, but violates the conventional PINEM quantum recoil condition (1). Nevertheless, the horizontal projection of the post-interaction distribution produces an (anomalous) sidebands PINEM (APINEM) spectrum, indicating that the large recoil condition (1) is not a necessary condition for the quantum limit in the QEW regime, and APINEM can be generated in the intermediate regime  $2\sigma_t(t_D) > T > \sigma_{t_0}$ , (or  $2\sigma_z(t_D) > \beta\lambda / 2\pi > \sigma_{z_0}$ ). However, the nature of this APINEM spectrum is quite different from conventional PINEM. The projections of the phase-space sidebands overlap in both dimensions. The APINEM spectrum is a result of coherent quantum interference of the sidebands due to the mixed first-order term in Eq.5. This produces density modulation in real time and space dimensions with period  $T$  ( $\beta\lambda$ ). In the energy (momentum) vertical dimension the horizontal projection of the slanted post-interaction WF, modulated at frequency  $\omega$ , produces PINEM-like interference fringes of approximate period:

$$\delta E = \frac{\sigma_{E0}}{\sigma_t(t_D)} T, \text{ or } \delta p = \frac{\sigma_{p0}}{\sigma_z(t_D)} \beta\lambda \approx m^* v_0 \left( \frac{\beta\lambda}{L_D} \right). \quad (5)$$

We confirm this observation of a universal phase-space classification of electron-wave interactions by explicit solution of the relativistic modified Schrodinger equation [20,17]  $i\hbar\partial\psi(z,t)/\partial t = (H_0 + H_I(t))\psi(z,t)$  with the free space Hamiltonian  $H_0 = \varepsilon_0 + v_0(-i\hbar\nabla - p_0) + \frac{(-i\hbar\nabla - p_0)^2}{2m^*}$ , and with general QEW initial conditions. This is exemplified here for a specific example of SPR (and TR) with an interaction term  $H_I(t) = -\frac{e\hbar}{2\gamma_0 m\omega} \{ e^{-i(\omega t - \phi_0)} \tilde{E}(z) \cdot \nabla - e^{i(\omega t - \phi_0)} \tilde{E}^*(z) \cdot \nabla \}$ , where  $\tilde{E}(z) = \sum_m \tilde{E}_m e^{iq_{zm}z}$  is the near field of a Floquet radiation mode on a grating, interacting with the electron through one of the slow-wave space harmonics  $E_0 = \tilde{E}_m, q_z = q_{zm}$  that is synchronous with the electron  $v_0 \cong \omega/q_z$ . We solved this equation both by first order perturbation theory and by exact numerical computation for the different initial conditions [17].

The third term in the Wigner function (4) results in the PINEM spectrum (with only two sidebands in first order perturbation analysis) in the quantum plane-wave (PINEM) limit (Fig.1b):

$$\rho_p^{(f)} = \int W(z, p, t) dz \simeq (1 - 2\Upsilon^2) \rho^{(0)}(p) + \Upsilon^2 [\rho^{(0)}(p + \hbar\omega/v_0) + \rho^{(0)}(p - \hbar\omega/v_0)] \quad (6)$$

where  $\rho^{(0)}(p) = |\psi^{(0)}(p)|^2 = (2\pi\sigma_{p_0}^2)^{-\frac{1}{2}} \exp\left(-\frac{(p-p_0)^2}{2\sigma_{p_0}^2}\right)$ ,  $\Upsilon = eE_0L/2\hbar\omega$ ,  $E_0$  is the interacting electric component,  $L$  is the interaction length. This expression is the same as in the conventional PINEM analysis in the short interaction limit [11], where to first order  $\Upsilon = e \int E_0(z) dz / 2\hbar\omega$ .

We draw attention now to the second (interference) term in (4), which is most important in our analysis, because it is the only contribution that produces the ‘point-particle-like’ acceleration regime[17] (Fig.1d):

$$\rho_p^{(f)} = \int W(z, p, t) dz \simeq \rho^{(0)}(p - \Delta p^{(1)}) \quad (7)$$

with  $\Delta p^{(1)} = \Delta p_{point} e^{-\Gamma^2/2}$ , where

$$\Delta p_{point} = -\frac{eE_0L}{v_0} \text{sinc}\left(\frac{\bar{\theta}}{2}\right) \cos\left(\phi_0 + \frac{\bar{\theta}}{2}\right), \quad (8)$$

is the classical point-particle acceleration,  $\bar{\theta} = \left(\frac{\omega}{v_0} - q_z\right)L$  is the classical ‘‘interaction detuning parameter’’ in FEL theory [3], and  $\phi_0$  is the initial relative phase between the electron and the laser-induced field. The detailed derivations can be found in the literature [17]. The decay parameter  $\Gamma$  is defined as

$$\Gamma = \left(\frac{\omega}{v_0}\right) \sigma_z(t_D) = \frac{2\pi\sigma_z(t_D)}{\beta_0\lambda}. \quad (9)$$

Defining the point-particle-like acceleration regime as the regime where the damping of the QEW acceleration due to the Gaussian decay factor is less than  $\Delta p^{(1)}/\Delta p_{point} = 1/e$ , then the point-particle regime is:

$$\Gamma < \sqrt{2}, \text{ or } \sigma_z(t_D) < \beta\lambda/\sqrt{2}\pi. \quad (10)$$

that is the same (except for factor  $\sqrt{2}$ ) as the “short wavepacket” classical regime condition: the opposite of the “long wavepacket” condition.

Using the relation  $\sigma_{E_0}\sigma_{t_0} = \hbar/2$ , we can now express also the “large recoil” condition (1) for the quantum (PINEM) regime in terms of the factor  $\Gamma_0 = \omega\sigma_{t_0} = 2\pi\sigma_{z_0}/\beta\lambda > \sqrt{2}$ , and thus we can define the APINEM regime in the range  $\Gamma_0 < \sqrt{2}$  and  $\Gamma > \sqrt{2}$ : satisfying the “long wavefunction” condition (2), but not the “large recoil” condition (1).

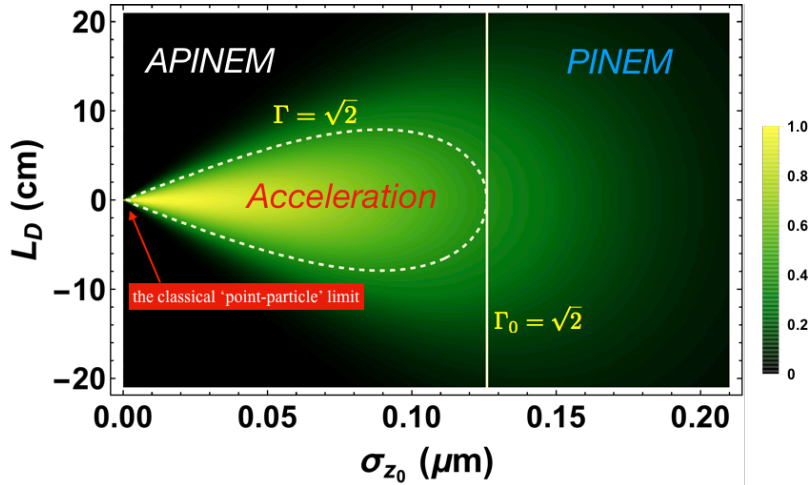

Fig.2: The classification of PINEM, Acceleration and APINEM regimes in light-matter interaction for optical wavelength  $\lambda = 0.8 \mu m$ . The PINEM regime is  $\Gamma_0 > \sqrt{2}$ , particle acceleration appears in the regime  $\Gamma_0 < \Gamma < \sqrt{2}$ , and APINEM in the regime  $\Gamma_0 < \sqrt{2} < \Gamma$ , respectively. The classical point particle picture appears at the limit  $\Gamma = 2\pi\sigma_z(L_D)/\beta\lambda \rightarrow 0$ .

Remarkably, the acceleration decay Gaussian factor ( $e^{-\Gamma^2/2}$ ) with the definition (9) of the decay parameter  $\Gamma$ , has sole dependence on the QEW size at entrance  $\sigma_z(t_D)$  and the radiation optical wavelength  $\beta\lambda$ . Considering the dependence of the wavepacket size

$$\sigma_z(t_D) = \sqrt{\sigma_{z_0}^2 + \left(\frac{\lambda_c^* c t_D}{4\pi \sigma_{z_0}}\right)^2}$$

on its minimal spot-size  $\sigma_{z_0}$  and its pre-interaction drift length  $L_D = v_0 t_D$ , it is instructive to display the Gaussian factor as a function of these two parameters. In Fig.2 we display this Gaussian attenuation factor dependence on  $(\sigma_{z_0}, L_D)$  in color code for the particular parameters example  $\beta = v_0/c = 0.7$ ,  $\lambda = 0.8 \mu m$  (corresponding to Feist's experiment [11]). Note that the diagram includes negative drift length  $L_D < 0$ , corresponding to the case of a QEW entering the interaction region with a converging phase and negative chirp.

The dashed contour in the phase diagram (Fig.2) marks the transition border  $\Gamma(\sigma_{z_0}, L_D) = \sqrt{2}$  where the acceleration momentum transfer decays by  $\Delta p^{(1)}/\Delta p_{point} = 1/e$ , within which the QEW exhibits ‘point-particle-like’ acceleration (the ‘‘acceleration’’ regime) corresponding to Fig.1d. The vertical solid line defines the transition point  $\Gamma_0 = \sqrt{2}$ , beyond which the QEW displays discrete PINEM-kind sideband energy spectrum (the ‘‘PINEM’’ regime –see Fig.1b&c). The third zone  $\Gamma_0 < \sqrt{2} < \Gamma$  defines the APINEM regime (1e). Only in the small recoil regime  $\Gamma_0 < \sqrt{2}$  it is possible to demonstrate the transition from the point-particle-like acceleration regime to the quantum APINEM interference regime by performing the radiative interaction after different drift lengths  $L_D$ , crossing the curve  $\Gamma_0 = \sqrt{2}$ . For fixed  $\sigma_{z_0}$ , transition from the acceleration to PINEM regime can only demonstrated by changing the interaction wavelength.

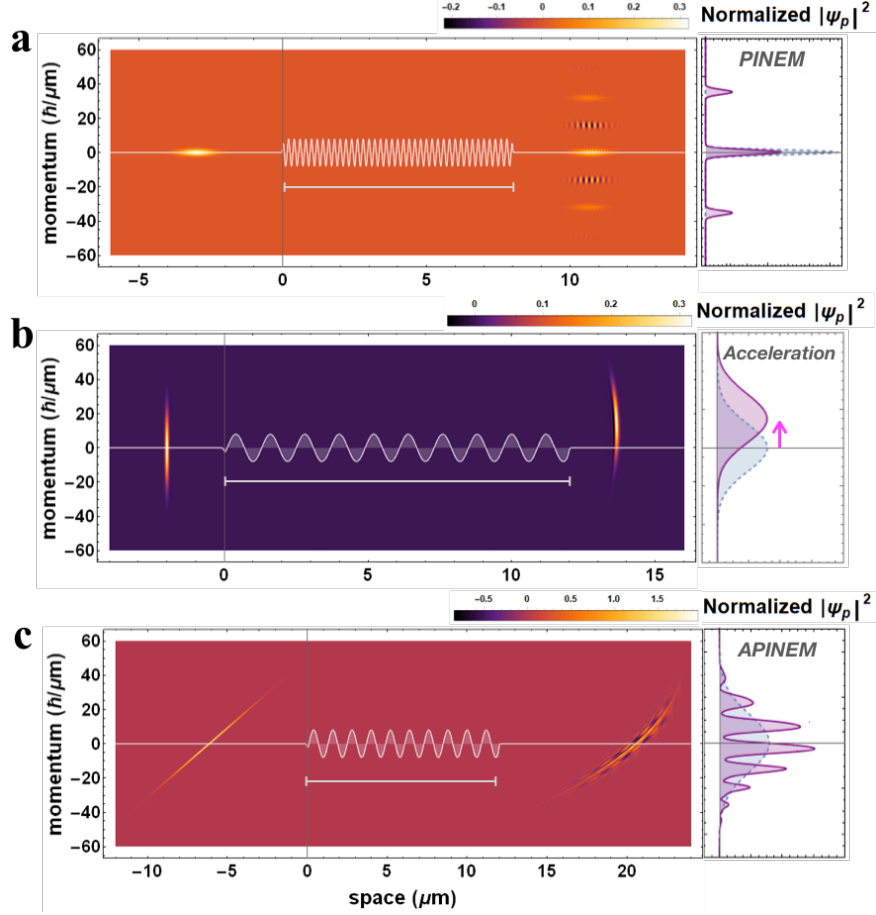

Fig.3: Numerical simulations of (a) PINEM, (b) Acceleration and (c) APINEM from solution of time-dependent Schrodinger's equation for a quantum electron wavepacket passing through the near-field of a grating, illuminated by a laser beam. Shown are the evolving quantum/classical features in phase space and the momentum distributions in momentum space. The parameters are listed in the text.

**Simulation Setup** - The perturbation theory results for the QEW transition from the classical point-particle to the quantum PINEM and APINEM spectrum limits serve to delineate the operating regimes and classification of laser-induced quantum shaping summarized in Figs.1&2. To confirm our observations beyond perturbation analysis, we demonstrate the quantum characteristics of electron-light interaction in phase-space through numerical solution of the one-dimensional Schrodinger equation for the example of stimulated Smith-Purcell interaction that we have analyzed earlier with semiclassical [17] and quantum electrodynamics formulations [16].

Figure 3 displays the numerically computed phase-space evolution of the Wigner distribution of a single QEW for different initial conditions. Fig.3a shows quantum regime sideband momentum spectrum in a wave-like interaction regime for parameters of a grating period  $\lambda_G = 0.2\mu\text{m}$  (with synchronism condition satisfied), intrinsic wavepacket size  $\sigma_{t_0} = 1.9\text{fts}$  ( $\sigma_{z_0} = 0.4\mu\text{m}$ ),  $\beta = v_0/c = 0.7$ . Fig.3b shows the point-particle-like classical acceleration in the short wavepacket (small recoil) regime for  $\beta_0\lambda = 1.2\mu\text{m}$ ,  $\sigma_{z_0} = 0.04\mu\text{m}$  ( $\sigma_{t_0} = 0.2\text{fts}$ ),  $\beta = 0.7$  and relative phase  $\phi_0 = 0$ , consistent with [17]. The new APINEM case is demonstrated in Fig.3c for the same parameters of Fig.3b, but with a wavepacket entering stretched and chirped after a pre-drift length of  $L_D = 60\text{cm}$ , such that the long wavepacket condition  $\sigma_z(L_D) = 1.5\mu\text{m} > \beta_0\lambda$  is satisfied. It thus displays the emergence of the quantum interference branches in the WF and the interference fringes in the momentum distribution.

Figure 4 shows the dependence of the APINEM fringes period on the incident reduced radiation wavelength  $\beta\lambda$ , calculated for the two sets of parameters  $\sigma_{z_0} = 0.04\mu\text{m}$ ,  $L_D = 40\text{cm}$  (red points), and  $\sigma_{z_0} = 0.06\mu\text{m}$ ,  $L_D = 60\text{cm}$  (purple points), well matching the analytical expression (5) (two straight lines). Note that the linear dependence of the APINEM fringes period on the radiation wavelength is drastically different (inverse) than the sidebands period of the PINEM spectrum (dashed line, and blue points).

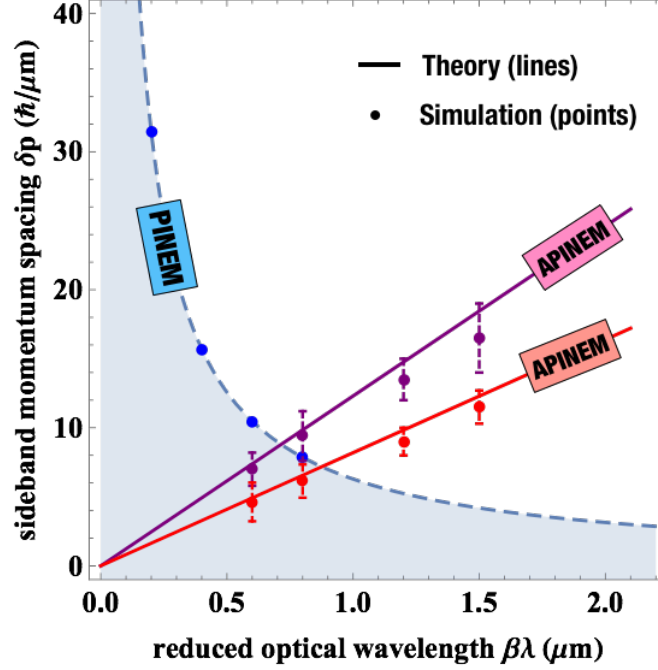

Fig.4 The sideband spacing of momentum/energy spectrum is proportional to the optical wavelength (Eq.4 in the text) in anomalous photon-induced near-field electron microscopy (APINEM), but inversely proportional to wavelength ( $\delta p = \hbar\omega/v_0 = 2\pi\hbar/\beta\lambda$ ) in PINEM. The lines (solid and dashed) are expected from theory with different initial electron wavepacket size and drift length, and the points (blue, red and purple) are from simulations. The parameters are listed in the text.

It is necessary to stress the significance of the quantum interference fringes in producing the PINEM and APINEM spectra. In the case of PINEM the periodic positive and negative areas in-between the sidebands of the post-interaction phase-space distribution null each other upon the projection (z-integration) of the Wigner function in Fig.1b&c. In the APINEM case (1d), the multi-sidebands spectrum is generated due to the horizontal interference of fringes that are generated by the mixed interference term of Eq.4 ( $2\Re(W^{(01)}) \propto \cos(\omega(t-z/v_0))$ ). This presently reported new term, is therefore essential for identifying the APINEM interaction regime (1e) and the transition from quantum sidebands (1d) to classical acceleration (1c) in the QEW regime. Note also that the vertical projection (E-integration) produces small density bunching. We note that it has been earlier shown [11] that density bunching appears after post-interaction drift because of the accumulating phase difference between the sidebands in dispersive vacuum. This

coherent phase space-dynamics appears to be similar to the interference features of Schrodinger's cat states with superposition of two coherent states in quadrature phase-space of quantum light. [15]

**Measurement Limit** - Finally, a note is in order regarding the experimental realization of the QEW regimes of electron interaction with light and observation of the anomalous PINEM and quantum particle-acceleration features. For practical measurement of the energy spectrum of individual electrons, an ensemble of particle or interaction event measurements has to be accounted statistically in an energy spectrum analyzer. This requires averaging of the single electron spectra over a classical statistical distribution of the ensemble that depends on the electron source (cathode temperature, gun voltage stability etc.) [17,21], and thus adds an extra classical uncertainty term ( $\sigma_{\text{part}}$ ) into the electron beam ensemble spread  $\Delta E = \sqrt{\sigma_{E_0}^2 + \sigma_{E,\text{part}}^2}$ . While in the single QEW regime the APINEM quantum interference regime (Fig.2) exists for  $\sigma_{E_0} > \hbar\omega$ , in violation of the large recoil condition (1), it is evident that the interference pattern would wash out in an ensemble, unless  $\sigma_{E,\text{part}} < \hbar\omega$ . Therefore, the ensemble should satisfy  $\sigma_{E,\text{part}} < \sigma_{E_0}$ . Since in conventional cathode electron guns (perhaps with the exception of some exotic electron sources [22]), the situation is opposite (the classical ensemble energy uncertainty is dominant), a preselection phase space filtering process is required to build up the required ensemble. Furthermore, both the APNEM and particle acceleration regimes are phase sensitive, and require phase-locking of the electron entrance time to the interaction region relative to the laser  $\Delta\phi_0 = \omega\Delta t_0 < 2\pi$  ( $\Delta t_0 < T$ ). Thus, the theoretical transition from the point-particle-like acceleration regime to the APINEM regime and the conventional quantum PINEM regime, can be demonstrated experimentally only with a preselected ensemble of electrons in phase-space, that possibly may be realizable with advancement of single electron wavepacket phase-space control and filtering in based on optical (or THz) streaking techniques [18-19].

**Conclusion** - In this work, we have revealed the different classical and quantum interaction regimes of free electrons with radiation. These regimes, which are

exemplified here for the setup of Smith-Purcell interaction, are universal, and apply to the large variety of free electron radiation sources and accelerators and to near-field photo-induced interactions. This classification is made possible by a formulation that presents the initial condition of the interacting electron as a finite size quantum electron wavepacket, solving the “relativistic” Schrodinger equation analytically (first order perturbation) and numerically, and retaining a hitherto neglected interference term of the incident and scattered components of the radiative interaction. Presentation in phase-space reveals three regimes of interaction, uniquely determined by the topology of the coherent (minimal Heisenberg uncertainty) QEW in phase-space: point-particle-like acceleration regime, quantum-wave (PINEM) regime, and a newly reported regime (APINEM) of quantum interference between a chirped incoming electron and its quantum side-band satellites. The model demonstrates the transition from the classical point-particle to quantum wavefunction interaction regime, thus resolving the particle-wave duality question in the context of radiative interaction, and assigning measurable physical reality to the history-dependent dimensions of the interacting electron wavefunction.
