(Dated: June 2, 2020)

From the point of view of statistical mechanics, a full characterisation of a molecular system requires the experimental determination of its possible states, their populations and the respective interconversion rates. Well-established methods can incorporate in molecular dynamics simulations experimental information about states using structural restraints, and about populations using thermodynamic restraints. However, it is still unclear how to include experimental knowledge of interconversion rates. Here we introduce a method of imposing known rate constants as constraints in molecular dynamics simulations, which is based on a combination of the maximum entropy and maximum caliber principles. Starting from an existing ensemble of trajectories, obtained from either molecular dynamics or enhanced trajectory sampling, this method provides a minimally perturbed path distribution consistent with the kinetic constraints, as well as a modified free energy and committor landscape. We illustrate the application of the method to simple toy systems, as well as to all atom molecular simulations of peptide association and folding. We find that by combining experimental rate coefficient data and molecular dynamics simulations we are able to determine new transition states, reaction mechanisms and free energies. For instance, in the case of chignolin protein folding we find that imposing a slower folding rate shifts the transition state to more native like conformations, while it increases the stability of the unfolded region. We foresee this method can extend the applicability of both atomistic and coarse-grained molecular simulations as an accurate kinetic tool in structural biology as well as assist amending imperfections in current atomistic force fields to reproduce the kinetics and thermodynamic observables. Finally, the approach is general, and applicable to a wide range of systems in biology, physics, chemistry, and material science.

## I. INTRODUCTION

The first step in the study of a molecular system typically consists in the determination of its conformation, as for example most commonly done by using X-ray crystallography (X-ray), cryo-electron microscopy (cryo-EM) or nuclear magnetic resonance spectroscopy (NMR) for obtaining the structures of proteins and of nucleic acids [1]. By revealing a wide range of structure-function relationships, this approach has enabled major advances in molecular biology [1]. From a procedural point of view, experimental measurements, such as electron densities in X-ray and cryo-EM or interproton distances in NMR, combined with well-established theoretical chemistry rules, facilitates the building of molecular structures using computational methods [2].

As at the molecular level under physiological conditions thermal fluctuations are relevant, it is becoming increasingly common to perform a second step, which involves the determination of the structures of the thermally excited states of a molecular system, together with their populations [3][4]. This goal is typically achieved by incorporating experimental measurements as structural restraints in molecular dynamics simulations to sample the free energy landscape [5]. The maximum entropy principle (MaxEnt) provides a rigorous framework to implement this strategy. To carry out this step, a range of methods are now available [6, 7], resulting in the determination of a 'thermodynamic ensemble' of structures [8].

One may not, however, stop at this level if kinetic properties are to be characterized. As a third step in the determination of a molecular system, one would like to obtain a 'kinetic ensemble', comprising the structures of the different states of a molecular system, their populations and their interconversion rates [8]. Approaches for determining kinetic ensembles are not readily available, as there is no well-established method of incorporating experimental information about kinetic rates in molecular modeling procedures. Our aim here is to make a first step in this direction.

To achieve this goal, we start, as seems quite natural, from a MaxEnt approach, where one maximizes a configurational entropy, subject to constraints given by experimental data, in order to predict a new configurational probability distribution. MaxEnt can also model uncertainties in the data effectively turning constraints into restraints [6, 7]. Addressing the problem in various ways as a Bayesian or a maximum likelihood problem [7, 9–13], leads to numerous applications for example in cases where force fields are less accurate, such as for intrinsically disordered proteins (IDPs) and RNA [9, 14–17]. Apart from ensemble refinement, application of MaxEnt yields perturbative correction terms to the potential energy along order parameters or collective variables relating to the experimental data [5, 9, 18].

To enforce experimental information about rate constants the MaxEnt method can be combined with the maximum caliber principle (MaxCal) [19]. This approach seems again quite natural, as MaxCal is a general

variational framework of non-equilibrium and equilibrium statistical mechanics with a wide scope, from flux-fluctuation relationships to pathway distributions [19, 20]. In MaxCal, one maximizes a path entropy over all possible pathways, subject to dynamical constraints such as average fluxes, in order to predict relative path weights [21]. Rigorous and general MaxCal implementations have found so far fewer applications compared to MaxEnt approaches due to the difficulty both in sampling path distributions of complex systems and in acquiring experimental data about rate constants. For example MaxCal enabled reweighting of the equilibrium distribution of macrostates given experimental rate constants for Markov State Models (MSM) or time discrete pathways [22, 23]. A recent implementation of the MaxCal for time-resolved data imposed time-dependent constraints along a few degrees of freedom of the system, or collective variables (CV), to agree with time-resolved experimental data [24]. MaxCal methods have also been extended to non-equilibrium dynamics [21, 25]. An important aspect, however, is that such methods rely on spatially discrete models, on limited time resolved data, or on biased dynamics, while in practice one usually only has access to experimental rate or diffusion constants. As starkly captured by Jaynes, “reconstructing MaxCal path ensembles containing the microscopic space and time dynamics is difficult” [26]. While theoretically rigorous, the MaxCal formalism has not been implemented to date for reweighting purposes in time and space continuous unbiased trajectories.

Here we present a method of determining kinetic ensembles using the MaxCal strategy, by reweighting path ensemble distributions a posteriori, according to both kinetic and thermodynamic experimental data. The methodology yields experimentally-corrected free energy and committor landscapes, and provides structural ensembles that exhibit accurate configurations, including in the regions of the barrier between states.

Given experimental forward and backward rate constant constraints we combine MaxEnt with MaxCal to find a biasing function that simultaneously acts on equilibrium and rate constants. This bias function gives correcting weights to the pathways of the equilibrium path ensemble distribution. The equilibrium path ensemble distribution is generated from computing reweighted path ensembles (RPEs) [27] based on either long molecular dynamics trajectories, or on enhanced sampling of trajectories, e.g., using Transition Interface Sampling (TIS) simulations [28], or in one step using the Virtual Interface Exchange Transition Path Sampling (VIE-TPS) method [29] for pathways sampled by Transition Path Sampling (TPS) [30]. Such TPS based methods focus on reactive or partially reactive pathways, thereby bypassing the computationally expensive sampling of the stable states. In the remainder of the text, RPE will refer to the reconstructed equilibrium (reweighted) path ensemble distribution from simulation, while “kinetic ensemble” will refer to the equilibrium path ensemble distribu-

tion after imposing the experimental kinetic constraints.

While our method applies constraints to the distributions, uncertainties in the experimental and simulations data can be taken into account [12]. While constraints impose strict equality with experimental data, restraints impose equality within errors in the data. MaxEnt and MaxCal allow to model uncertainties in the data, effectively turning constraints into restraints

In this work we focus on biological problems without losing the generality of our statements. Thus, our approach can be applied to all molecular dynamics simulations where trajectory reweighting to match target kinetics is possible and helpful.

This paper is organised as follows. In Section II we introduce the background theory and new concepts of our approach. In Section III we illustrate the approach, and we end with an outlook in Section IV.

## II. THEORY

### A. MaxEnt in configuration space

In this section we briefly recapitulate how the MaxEnt can be used to combine simulations with experimental data [6, 7]. In its original formulation, MaxEnt states that the probability distribution of the states of a system maximally compatible with a set of observed data is the one maximizing the associated Shannon entropy. This principle has been extended to a maximum relative entropy principle, which has the advantage of being invariant with respect to changes of coordinates and coarse-graining, and has been shown to play an important role in multiscale problems [17]. The entropy is here computed relative to a given prior distribution  $P^0(x)$  and, for a system described by a set of continuous variables  $x$ , e.g. the positions and velocities of all atoms in a molecular system, is defined as

$$S[P||P^0] = - \int dx P(x) \ln \frac{P(x)}{P^0(x)}. \quad (1)$$

This entropy can be maximized as

$$P^{ME}(x) = \operatorname{argmax}_{P(x)} S[P||P^0] \quad (2)$$

$$\text{subject to: } \begin{cases} \int dx P(x) s_i(x) = \langle s_i(x) \rangle = s_i^{exp} \\ \int dx P(x) = 1 \end{cases}$$

where the experimental observations  $s_i^{exp}$  ( $i \in \{1, 2 \dots M\}$ ) constrain the ensemble average of  $M$  observables  $s_i(x)$ , computed over the distribution  $P(x)$ , to be equal to  $s_i^{exp}$ , and an additional constraint ensures that the distribution  $P(x)$  is normalized.  $P^0(x)$  is called the “prior” probability distribution, encoding the knowledge available before the experimental measurement.  $P^{ME}(x)$  instead represents the best estimate for the probability distribution after the experimental constraints have been

enforced, and is thus called the ‘‘posterior’’ probability distribution. The subscript ME denotes the fact that this is the distribution that maximizes the entropy.

Since the relative entropy  $S[P||P^0]$  is the negative of the Kullback-Leibler (KL) divergence  $D_{KL}[P||P^0]$ , the procedure described above can be interpreted as a search for the posterior distribution that is as close as possible to the prior knowledge and agrees with the given experimental observations. In terms of information theory, the KL divergence measures how much information is lost when prior knowledge  $P^0(x)$  is replaced with  $P(x)$ . Always non-negative, the KL divergence is a measure of the difference between the distributions, and vanishes only if the two distributions are identical.

A powerful approach to solve the maximization problem in Eq. 1 is based on the method of Lagrange multipliers, namely searching for the stationary point of the following Lagrange function:

$$\mathcal{L} = S[P||P^0] - \sum_{i=1}^M \mu_i \left( \int dx s_i(x) P(x) - s_i^{exp} \right) - \nu \left( \int dx P(x) - 1 \right), \quad (3)$$

where  $\mu_i$  and  $\nu$  are suitable Lagrange multipliers taking care of the experimental observations and the probability normalization, respectively. The functional derivative of  $\mathcal{L}$  with respect to  $P(x)$  is

$$\frac{\delta \mathcal{L}}{\delta P(x)} = -\ln \frac{P(x)}{P^0(x)} - 1 - \sum_{i=1}^M \mu_i s_i(x) - \nu. \quad (4)$$

By setting  $\frac{\delta \mathcal{L}}{\delta P(x)} = 0$  and neglecting the normalization factor, the posterior reads

$$P^{ME}(x) \propto e^{-\sum_{i=1}^M \mu_i s_i(x)} P^0(x) \quad (5)$$

Solving Eq. 4 turns out to be equivalent to minimizing the function

$$\Gamma(\boldsymbol{\mu}) = \ln \left[ \int dx e^{-\sum_{i=1}^M \mu_i s_i(x)} P^0(x) \right] + \boldsymbol{\mu} \cdot \mathbf{s}^{exp} \quad (6)$$

with respect to  $\mu_i$ , leading to the equation(s)  $\langle s_i \rangle = \int dx s_i(x) P(x) = s_i^{exp}$ , and thus giving for each observable the Lagrange multiplier  $\mu_i$ .

We also note that MaxEnt can model uncertainties in the data, i.e the experimental errors[9, 12]. This is done by adding the expected error due to the perturbed distribution  $\langle e_i \rangle$  to the constraint average, i.e.  $\langle s_i \rangle = s_i^{exp} + \langle e_i \rangle$ . For a Gaussian distributed error with a standard deviation  $\sigma_i$  the average error is  $\langle e_i \rangle = -\mu_i \sigma_i^2$ , with  $\sigma_i$  the level of confidence in the data, e.g. experimental measurements. Adding this to Eq. 6 yields

$$\Gamma(\boldsymbol{\mu}) = \ln \left[ \int dx P^{ME}(x) \right] + \boldsymbol{\mu} \cdot \mathbf{s}^{exp} + \frac{1}{2} \sum_{i=1}^M \mu_i^2 \sigma_i^2. \quad (7)$$

Minimizing this function leads to a solution of the Lagrange multipliers  $\mu_i$  that account for the error. If  $\sigma = 0$  the situation is identical to Eq. 6, while if  $\sigma$  is large the Lagrange multiplier will be close to zero, almost not perturbing the original distribution. In this way the constraint on the distribution is turned into a restraint, depending on the level of confidence in the data. In most of our presentation, we will discuss imposing constraints, although one should keep in mind that it is always possible to extend the results to imposing restraints, using the above procedure.

## B. MaxCal in path space

The MaxEnt principle can be straightforwardly extended to trajectory space[21]. Consider a prior path probability distribution  $\mathcal{P}^0[\mathbf{x}]$  of trajectories  $\mathbf{x}$ , each consisting of  $L$  frames  $\mathbf{x} = \{x_0, x_1, \dots, x_L\}$ , where subsequent frames are separated by a time interface  $\Delta t$ , such that the total duration of a path is  $\mathcal{T} = L\Delta t$ . Here we assume that the path represents a dynamical evolution according to the equations of motion, as given e.g. by a MD simulation, and contains reliable dynamic information, of course up to the extent of the resolution and faithfulness of the force field. The (relative) path entropy, or caliber, for any path distribution  $\mathcal{P}[\mathbf{x}]$ , is

$$S[\mathcal{P}||\mathcal{P}^0] = - \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] \ln \frac{\mathcal{P}[\mathbf{x}]}{\mathcal{P}^0[\mathbf{x}]}, \quad (8)$$

where  $\mathcal{D}\mathbf{x}$  indicates an integral over all trajectories or paths  $\mathbf{x}$ . The maximum caliber principle states that the optimal distribution  $\mathcal{P}^{MC}[\mathbf{x}]$  is given by

$$\mathcal{P}^{MC}[\mathbf{x}] = \operatorname{argmax}_{\mathcal{P}[\mathbf{x}]} S[\mathcal{P}||\mathcal{P}^0] \quad (9)$$

$$\text{subject to: } \begin{cases} \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] s_i[\mathbf{x}] = \langle s_i[\mathbf{x}] \rangle = s_i^{exp} \\ \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] = 1 \end{cases}$$

that is,  $\mathcal{P}^{MC}[\mathbf{x}]$  maximizes the path entropy or caliber, while obeying the constraints given by external constraint  $s_i^{exp}$ . The observable ensemble average  $\langle s_i[\mathbf{x}] \rangle$  can relate to any measurement either giving rise to static/thermodynamic or dynamic/kinetic information.

Starting with dynamical information, consider an arbitrary time correlation function

$$c(t) = \langle s_i(0) s_j(t) \rangle = \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] s_i(x_0) s_j(x_\tau), \quad (10)$$

where  $\tau = t/\Delta t$  corresponds to the frame index for time  $t$ . As  $i$  and  $j$  can be identical, this definition includes autocorrelations. When one has access to experimental correlation data  $c^{exp}(t)$  it is possible to impose a constraint on the path ensemble distribution, leading to the

Lagrange function

$$\begin{aligned} \mathcal{L} = & - \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] \ln \frac{\mathcal{P}[\mathbf{x}]}{\mathcal{P}^0[\mathbf{x}]} - \nu \left( \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] - 1 \right) \\ & - \sum_{\tau} \mu_{\tau} \left( \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] s_i(0) s_j(t) - c^{exp}(t) \right). \end{aligned} \quad (11)$$

Following the same reasoning as for the MaxEnt approach we optimize the Lagrange function

$$\frac{\delta \mathcal{L}}{\delta \mathcal{P}[\mathbf{x}]} = - \ln \frac{\mathcal{P}[\mathbf{x}]}{\mathcal{P}^0[\mathbf{x}]} - 1 - \sum_{\tau} \mu_{\tau} s_i(x_0) s_j(x_{\tau}) - \nu, \quad (12)$$

giving rise to the posterior

$$\mathcal{P}^{MC}[\mathbf{x}] \propto e^{-\sum_{\tau} \mu_{\tau} s_i(x_0) s_j(x_{\tau})} \mathcal{P}^0[\mathbf{x}]. \quad (13)$$

As an example, suppose that we are interested in a mobility function  $K_{\tau}[\mathbf{x}]$ , measuring, for example, the mean square displacement at a particular time  $\tau$  with respect to time  $\tau = 0$ . As this correlation only has to be constrained at  $\tau$ , the posterior is simply

$$\mathcal{P}^{MC}[\mathbf{x}] \propto e^{-\mu_{\tau} K_{\tau}[\mathbf{x}]} \mathcal{P}^0[\mathbf{x}]. \quad (14)$$

Note that this is identical to the expression for the s-ensemble (with  $\mu = s$ ), which biases path ensembles according to a time correlation function [31] and is usually presented in the context of large deviation theory. The s-ensemble biases all paths with a field  $s$  conjugate to the function  $K$ . In the MaxCal approach the Lagrange multiplier  $\mu$  follows from the constraint imposed. Thus, the s-ensemble might also be interpreted as the field that imposes a certain constraint.

In any case, the posterior MaxCal distribution can be written as

$$\mathcal{P}^{MC}[\mathbf{x}] \propto e^{-\mu f[\mathbf{x}]} \mathcal{P}^0[\mathbf{x}], \quad (15)$$

with  $f[\mathbf{x}]$  a function of the path  $\mathbf{x}$  imposing the constraint. Combining Eq. 15 with the path probability  $\mathcal{P}[\mathbf{x}] = \exp(-\mathcal{S}[\mathbf{x}])$ , in terms of the path action  $\mathcal{S}[\mathbf{x}]$  gives

$$\mathcal{P}^{MC}[\mathbf{x}] \propto \exp(-\mu f[\mathbf{x}]) \exp(-\mathcal{S}^0[\mathbf{x}]), \quad (16)$$

which can be rewritten as

$$S^{MC}[\mathbf{x}] = \mu f[\mathbf{x}] + \mathcal{S}^0[\mathbf{x}], \quad (17)$$

Eq. 17 quantifies the correction of the prior action  $\mathcal{S}^0$  by the experimental constraints.

### C. Thermodynamic constraints

Since equilibrium properties are not time dependent, they can be computed as time averages over path ensembles distributions:

$$\langle s \rangle = \frac{1}{\langle L \rangle} \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] \sum_t s(x_t), \quad (18)$$

with  $\langle L \rangle$  being the average path length, and  $x_t$  the coordinates at each timestep of the path. Constraining an equilibrium property  $s^{exp}$  then leads to a posterior distribution

$$\mathcal{P}^{MC}[\mathbf{x}] \propto e^{-\mu \sum_t s(x_t)} \mathcal{P}^0[\mathbf{x}]. \quad (19)$$

An alternative way of constraining equilibrium properties is to first reduce the path space back to a configurational density  $\rho(x) \equiv P(x)$  by

$$\rho(x) \propto \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] \sum_t \delta(x_t - x). \quad (20)$$

The average then becomes simply

$$\langle s \rangle = \frac{\int dx \rho(x) s(x)}{\int dx \rho(x)}. \quad (21)$$

Indeed, substitution of Eq. 19 and Eq. 20 in Eq. 21 yields the same result as Eq. 18.

### D. Independence of partial path distributions

Up to now we did not specify what the path ensemble distribution refers to. In what follows we focus on systems that show two-state kinetics between two stable states A and B. We assume that there is a separation between the molecular timescale and the reaction time[32], to guarantee that well-defined rate constants exist for the interconversions between A and B. The total distribution  $\mathcal{P}[\mathbf{x}] = \mathcal{P}_A[\mathbf{x}] + \mathcal{P}_B[\mathbf{x}]$  is the sum of the (unnormalised) partial path distributions  $\mathcal{P}_A[\mathbf{x}] \equiv \mathcal{P}[\mathbf{x}] h_A(x_0)$  and  $\mathcal{P}_B[\mathbf{x}] \equiv \mathcal{P}[\mathbf{x}] h_B(x_0)$ , consisting respectively, of all paths that start in A, and paths that start in B. Here  $h_{A,B}(x)$  are the indicator functions, which are unity when the configuration  $x$  is in state  $A(B)$ , and zero otherwise. Note that we restrict all paths to start and end in one of the stable states.

In the next sections we will focus on applying kinetic constraints on each partial path ensemble separately, as they can be treated independent from each other. To show that, we apply two dynamical constraints onto the total distribution, one for each partial ensemble

$$\begin{aligned} \mathcal{L} = & - \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] \ln \frac{\mathcal{P}[\mathbf{x}]}{\mathcal{P}^0[\mathbf{x}]} - \nu \left( \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] - 1 \right) \\ & - \mu_A \left( \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] h_A(x_0) s_A[\mathbf{x}] - s_A^{exp} \right) \end{aligned} \quad (22)$$

$$- \mu_B \left( \int \mathcal{D}\mathbf{x} \mathcal{P}[\mathbf{x}] h_B(x_0) s_B[\mathbf{x}] - s_B^{exp} \right). \quad (23)$$

where we used the definition of the partial ensembles. Maximisation of the caliber yields the posterior

$$\mathcal{P}^{MC}[\mathbf{x}] \propto e^{-\mu_A h_A(x_0) s_A[\mathbf{x}] - \mu_B h_B(x_0) s_B[\mathbf{x}]} \mathcal{P}^0[\mathbf{x}], \quad (24)$$

or, expressing it in partial ensembles

$$\mathcal{P}_A^{MC}[\mathbf{x}] + \mathcal{P}_B^{MC}[\mathbf{x}] \propto e^{-\mu_A h_A(x_0) s_A[\mathbf{x}] - \mu_B h_B(x_0) s_B[\mathbf{x}]} \times (\mathcal{P}_A^0[\mathbf{x}] + \mathcal{P}_B^0[\mathbf{x}]). \quad (25)$$

Clearly, for paths belonging to partial ensemble A  $h_A = 1$  and thus  $h_B = 0$

$$\mathcal{P}_A^{MC}[\mathbf{x}] \propto e^{-\mu_A s_A[\mathbf{x}]} \mathcal{P}_A^0[\mathbf{x}] \quad (26)$$

while for paths from partial ensemble B  $h_A = 0$  and  $h_B = 1$  it holds

$$\mathcal{P}_B^{MC}[\mathbf{x}] \propto e^{-\mu_B s_B[\mathbf{x}]} \mathcal{P}_B^0[\mathbf{x}] \quad (27)$$

Thus, both partial ensembles can be optimised and normalised independently. Indeed, when imposing kinetic constraints, this is what we aim to do.

### E. Constraining rate constants using MaxCal

We now turn to constraining kinetic observables, and in particular rate constants. Suppose we have unbiased simulations that we want to correct in order to match an experimental rate constant,  $s^{exp} \equiv k_{AB}^{exp}$ . First, we need to look at how the rate is defined in the path space as the time derivative of the correlation function  $C(t) = \langle h_A(x_0) h_B(x_L) \rangle / \langle h_A(x_0) \rangle$

$$k_{AB} = \frac{dC(t)}{dt} = \frac{\langle h_A(x_0) \dot{h}_B(x_L) \rangle}{\langle h_A(x_0) \rangle}, \quad (28)$$

where the indicator functions  $h_{A,B}(x)$  are unity when the frame is in state A and B, respectively. In words, this expression computes the flux through entering the state B provided that the trajectories started in A.

To link the flux correlation function to the path ensembles and the maximum caliber approach, we will adopt the formalism of Transition Interface Sampling (TIS) [28, 33, 34], which in turn is based on the framework of Transition Path Sampling [35–37]. Introducing a collective variable  $\lambda(x)$  that can parameterise a hypersurface, or interface, in the configuration space, TIS defines a set of  $n + 1$  non-intersecting such interfaces, denoted by the parameters  $\lambda_0 < \lambda_1 < \dots < \lambda_n$ . In this way the rate constant can be written as [28]

$$k_{AB} = \phi_{1,0} P_A(\lambda_B | \lambda_1), \quad (29)$$

where the first term is the effective positive flux through the first interface  $\lambda_0 = \lambda_A$ , and the second term is the crossing probability of interface  $\lambda_B = \lambda_n$  for all trajectories shot from interface 1 that came directly from state A in their backward integration. When evaluating the rate constant using the TIS framework, the first term is accessible through a regular molecular dynamics simulation, and the second term through performing sampling

the interace path ensembles using the TIS algorithm[28], or, as an approximation by the VIE-TPS algorithm. Of course, this term can in principle also be evaluated using a very long MD simulation, although that is naturally not very efficient for rare events. The crossing probability connected to each interface ensemble is expressed as a function of  $\lambda$

$$P_A(\lambda | \lambda_0) = \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda), \quad (30)$$

where  $\mathcal{P}_A[\mathbf{x}]$  is the now normalised (unbiased or reweighted) path ensemble distribution for paths leaving A,  $\theta(x)$  is the Heaviside step function, and  $\lambda_{max}[\mathbf{x}]$  returns the maximum value of  $\lambda$  along the path. Here, we assumed that  $\lambda$  is monotonically increasing with  $i$ .

Imposing the constraint  $k_{AB} = k_{AB}^{exp}$ , now leads to the Lagrange function

$$\mathcal{L} = - \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \ln \frac{\mathcal{P}_A[\mathbf{x}]}{\mathcal{P}_A^0[\mathbf{x}]} - \nu \left( \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] - 1 \right) - \mu_A \left( \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda_B) - k_{AB}^{exp} \right) \quad (31)$$

where we have left out the flux  $\phi_{1,0}$  from the rate constant contribution for notational reasons. Following the same reasoning as before, we can optimize the Lagrange function giving rise to the posterior

$$\mathcal{P}_A^{MC}[\mathbf{x}] \propto e^{\mu_A \theta(\lambda_{max}[\mathbf{x}] - \lambda_B)} \mathcal{P}_A^0[\mathbf{x}], \quad (32)$$

and from the analog of Eq. 6

$$k_{AB}^0 e^{\mu_A} = k_{AB}^{exp}, \quad (33)$$

we obtain the value of the Lagrange multiplier  $\mu_A = \ln(k_{AB}^{exp}/k_{AB}^0)$ . Note that this equation can easily be extended to the analog of Eq. 7

$$k_{AB}^0 e^{\mu_A} = k_{AB}^{exp} + \mu_A \sigma_k^2, \quad (34)$$

where  $\sigma_k$  signifies the level of confidence in the rate constant data. Just as for MaxEnt, one can turn the constraint condition into a restraint condition.

The reweighting procedure can be interpreted as a bias on only the reactive AB paths that make it to the final interface  $\lambda_B$ , such that the total flux of paths is obeying the kinetic rate constraint. However, this means that this reweighting will introduce a discontinuity in the path distribution, as a path that is nearly reaching B, but is recrossing back to A is not reactive, and thus not reweighted. Even though these recrossing paths themselves might be rare, such a discontinuity is undesirable. For an illustration, see Fig. 15 in Appendix C.

### F. Imposing the kinetic constraint for all $\lambda$

We can make progress by realising that the condition that the reweighted rate should be equal to the experimental rate can be generalised to all values of  $\lambda$ . The

constraint of the experimental rate should in fact apply to all values of  $\lambda$ . That is:

$$\mathcal{L} = - \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \ln \frac{\mathcal{P}_A[\mathbf{x}]}{\mathcal{P}_A^0[\mathbf{x}]} - \nu \left( \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] - 1 \right) - \sum_{i=1}^n \mu_i \left( \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda_i) P_A(\lambda_n|\lambda_i) - k_{AB}^{exp} \right)$$

where the sum runs over the  $n$  interfaces. Following the usual minimisation of the Langrange function gives

$$\mathcal{P}_A^{MC}[\mathbf{x}] \propto \exp \left[ - \sum_{i=1}^n \mu_i \theta(\lambda_{max}[\mathbf{x}] - \lambda_i) P_A(\lambda_n|\lambda_i) \right] \mathcal{P}_A^0[\mathbf{x}]. \quad (35)$$

This needs to obey  $n$  constraints, for  $k = 1 \dots n$

$$\begin{aligned} \langle \theta(\lambda_{max}[\mathbf{x}] - \lambda_k) P_A(\lambda_n|\lambda_k) \rangle &\equiv \\ &\equiv \frac{\int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda_k) P_A(\lambda_n|\lambda_k)}{\int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}]} = k_{AB}^{exp}, \end{aligned} \quad (36)$$

or by substitution of  $\mathcal{P}_A^{MC}[\mathbf{x}]$

$$\int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \exp \left[ - \sum_{i=1}^n \mu_i \theta(\lambda_{max}[\mathbf{x}] - \lambda_i) P_A(\lambda_n|\lambda_i) \right] \times \theta(\lambda_{max}[\mathbf{x}] - \lambda_k) P_A(\lambda_n|\lambda_k) = k_{AB}^{exp}, \quad (37)$$

where we for this moment assumed that  $\int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] = 1$ .

We realise that the sum in the exponent is in fact only dependent on  $\lambda_{max}[\mathbf{x}]$  (and of course on  $P(\lambda_n|\lambda)$ ), but for a given system  $P(\lambda_n|\lambda)$  is a function of  $\lambda$ , so the sum can be written as

$$- \sum_{i=1}^n \mu_i \theta(\lambda_{max}[\mathbf{x}] - \lambda_i) P_A(\lambda_n|\lambda_i) \equiv f(\lambda_{max}[\mathbf{x}]), \quad (38)$$

where the  $P_A(\lambda_n|\lambda)$  dependence is implicit in the function  $f$ . The interpretation is that the weight of each path in the posterior path ensemble is entirely dependent on the  $\lambda_{max}[\mathbf{x}]$ . We show that this is indeed correct in Appendix A.

### G. Reweighting paths ensembles using MaxCal

Now the question is whether this biasing function in Eq. 38 leads to the correct behaviour in the reweighted paths ensemble (RPE), which is a way to reweight the interface ensembles into effectively the unbiased path ensemble [38]. We focus again on the (normalized) partial path ensembles  $\mathcal{P}_A[\mathbf{x}]$ ,  $\mathcal{P}_A^0[\mathbf{x}]$ ,  $\mathcal{P}_B[\mathbf{x}]$ ,  $\mathcal{P}_B^0[\mathbf{x}]$ . The projection of the RPE for the crossing probability is then

$$P_A^0(\lambda|\lambda_0) = \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda), \quad (39)$$

and the projection for the configurational density is

$$\rho_A^0(\lambda) \propto \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \sum_{k=0}^L \delta(\lambda(x_k) - \lambda). \quad (40)$$

The result for the partial path ensemble coming from B is similar.

Using the MaxCal path reweighting for the configurational density yields

$$\rho_A^{MC}(\lambda) \propto \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] e^{f(\lambda_{max}[\mathbf{x}])} \sum_{k=0}^L \delta(\lambda(x_k) - \lambda). \quad (41)$$

For the crossing probability the reweighting is a bit more subtle. In Appendix A we show that

$$P_A^{MC}(\lambda|\lambda_0) = \int_{\lambda_n}^{\lambda} R_A^0(\lambda|\lambda_0) e^{f(\lambda)} d\lambda, \quad (42)$$

where  $R_A^0(\lambda|\lambda_0)$  is the 'reaching' histogram of paths that just reach  $\lambda$

$$R_A^0(\lambda|\lambda_0) = \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \delta(\lambda_{max}[\mathbf{x}] - \lambda). \quad (43)$$

This is the proper reweighting of the crossing probabilities. The crossing probability for B is done likewise.

### H. The MaxCal bias function $f(\lambda)$ follows from MaxEnt for the density

Now the problem is to determine the function  $f(\lambda)$ . MaxCal does not give a solution to this problem, as it only concerns the final rate value, which is satisfied as long as the  $f(\lambda_n)$  is set to the proper value. Indeed, a solution to the constraint equation will be correct for all functions  $f$  under the condition the  $f(\lambda_B)$  gives the correct kinetic constraint. This also can be seen by defining the function

$$f(\lambda_i) \equiv F_i = \sum_{j=1}^i \mu_j P(\lambda_n|\lambda_j), \quad (44)$$

where the solution to the Langrange multipliers  $\mu_j$  allow virtually all reasonably shaped functions  $f(\lambda)$ .

Therefore, it seems that we have not made progress since  $f(\lambda)$  is unknown. Here is where the configurational density comes in. For the configurational density we can also apply the regular MaxEnt approach, which yields

$$\rho^{ME}(x) \propto e^{-\mu g(x)} \rho^0(x), \quad (45)$$

where  $g(x)$  is a function that imposes the constraint. When projecting to the order parameter  $\lambda$  this expression reduces to

$$\rho^{ME}(\lambda) \propto e^{-\mu g(\lambda)} \rho^0(\lambda), \quad (46)$$

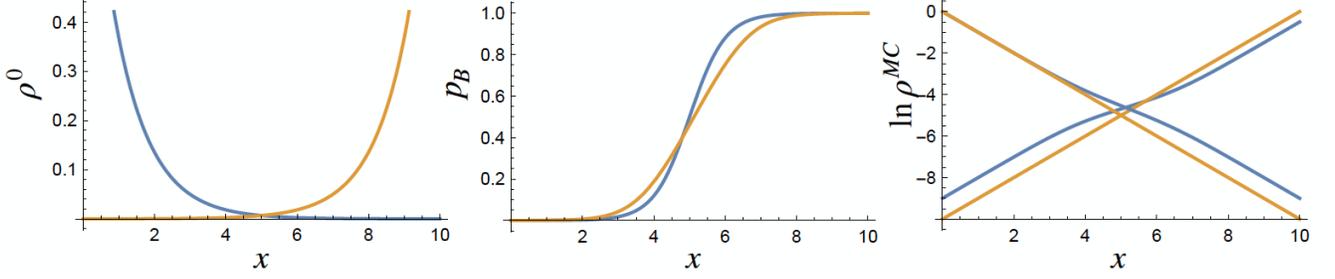

FIG. 1. Left: example initial densities  $\rho_A^0(\lambda)$  (blue) and  $\rho_B^0(\lambda)$  (orange). Middle: initial committor  $p_B^0(\lambda)$  (blue). Solution of the self-consistent equation Eq. 51 (orange). Right: weighted densities (blue) compared to initial densities (orange).

where the constraint imposed is

$$\frac{\int d\lambda g(\lambda)\rho(\lambda)}{\int d\lambda\rho(\lambda)} = g^{exp}. \quad (47)$$

Now what is  $g^{exp}$  if we constrain the rate constants  $k_{AB}$  and  $k_{BA}$ ? The obvious candidate is the ratio  $k_{AB}/k_{BA} \equiv K_{eq}$ , which is equal to the equilibrium constant  $K_{eq} = \pi_B/\pi_A$ . In fact, it turns out better to consider the equilibrium fraction  $K = \pi_B/(\pi_A + \pi_B) = K_{eq}/(1 + K_{eq})$ . (Note that we used  $\pi_{A,B}$  to denote the total equilibrium population in A and B, to avoid confusion with  $\rho_{A,B}(x)$ ). Thus the question is which function  $g(\lambda)$  would obey

$$\frac{\int d\lambda g(\lambda)\rho(\lambda)}{\int d\lambda\rho(\lambda)} = K. \quad (48)$$

In the appendix we show that a natural solution for  $g(\lambda)$  is the committor  $p_B(\lambda)$ , as the points that commit to B are both determining the committor, and the equilibrium fraction  $K$ .

The reweighted MaxEnt densities, given in Eq. 46, then become

$$\rho_A(\lambda) = \rho_A^0(\lambda)e^{\mu_A p_B(\lambda)} \quad (49)$$

$$\rho_B(\lambda) = \rho_B^0(\lambda)e^{-\mu_B p_B(\lambda)}e^{\mu_A}, \quad (50)$$

where the latter equation has a negative exponent and a shift, and we considered two different Lagrange multipliers, one for each direction AB and BA. To solve for  $p_B$  we note that  $p_B(\lambda) = \rho_B(\lambda)/(\rho_A(\lambda) + \rho_B(\lambda))$  and substituting the ME densities gives

$$p_B(\lambda) = \frac{\rho_B^0(\lambda)}{\rho_A^0(\lambda)e^{-\mu_A}e^{(\mu_A+\mu_B)p_B(\lambda)} + \rho_B^0(\lambda)}. \quad (51)$$

This self-consistent equation can be solved numerically, given  $\rho_B^0(\lambda)$ ,  $\rho_A^0(\lambda)$ , and the values of  $\mu_A$  and  $\mu_B$ . These last quantities follow from the MaxCal constraint that the rate constants need to be correct. That is

$$e^{\mu_A} = \frac{k_{AB}^{exp}}{k_{AB}^0} \quad e^{\mu_B} = \frac{k_{BA}^{exp}}{k_{BA}^0} \quad (52)$$

so that the ratio of these equations is

$$e^{\mu_A - \mu_B} = K^{exp}/K^0, \quad (53)$$

which it indeed should be. Note that these last two equations can be extended to account for the experimental error (see Eq. 34). While we use MaxEnt here for clarifying purposes, we note that in principle, we can also add static constraints in the MaxCal formalism

We illustrate this approach for a toy example density. By taking simple exponential forms for the density (see Fig. 1left) we plot the initial committor in Fig. 1middle. We can then apply the self-consistent solution to the committor using  $\mu_A = 1$  and  $\mu_B = 1.5$ , see Fig. 1middle, and reweight the densities (see Fig. 1right).

## I. Obtaining $f(\lambda)$ from $g(\lambda)$

What is the relation between  $g(\lambda) = p_B(\lambda)$  and  $f(\lambda)$ ? They are not identical. However, the MaxCal corrected RPE configurational density and the MaxEnt corrected configurational density should be identical, i.e.

$$\rho_A^{MC}(\lambda) = e^{-\mu g(\lambda)}\rho_A^0(\lambda), \quad (54)$$

or

$$\begin{aligned} \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] e^{f(\lambda_{max}[\mathbf{x}])} \sum_{k=0}^L \delta(\lambda(x_k) - \lambda) &= \\ = e^{-\mu g(\lambda)} \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \sum_{k=0}^L \delta(\lambda(x_k) - \lambda). \end{aligned} \quad (55)$$

In practice, this Volterra equation of the first kind should be solved numerically. For instance, when the configurational density histograms  $\rho_A^0(\lambda, \lambda_m)$  are computed for each interface value  $\lambda_m$ , the maximum value of each path in that ensemble, this equation becomes

$$\int_{\lambda_m=\lambda_n}^{\lambda} \rho_A^0(\lambda, \lambda_m) e^{f(\lambda_m)} = e^{-\mu g(\lambda)} \int_{\lambda_m=\lambda_n}^{\lambda} \rho_A^0(\lambda, \lambda_m), \quad (56)$$

or in a discrete version

$$\sum_{\lambda_m=\lambda_n}^{\lambda} \rho_A^0(\lambda, \lambda_m) e^{f(\lambda_m)} = e^{-\mu g(\lambda)} \sum_{\lambda_m=\lambda_n}^{\lambda} \rho_A^0(\lambda, \lambda_m). \quad (57)$$

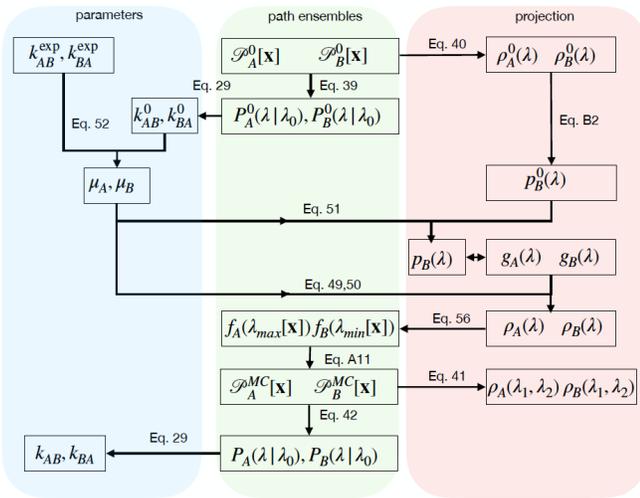

FIG. 2. Scheme relating all important parameters, path ensembles, and projected functions via the key equations. Starting from the top the arrows indicate the direction and order in which the method applies the equations.

This function can be solved numerically starting from the final value  $\lambda_m = \lambda_n$  for which holds

$$\rho_A^0(\lambda, \lambda_n) e^{f(\lambda_n)} = e^{-\mu g(\lambda_n)} \rho_A^0(\lambda, \lambda_n) \quad (58)$$

Iteration by back-substitution leads to the desired weighting function  $f(\lambda)$ . A similar equation needs to be solved for the partial ensemble of paths starting in B.

The entire procedure is summarised as an equation scheme in Fig. 2.

### J. Optimal path distributions by varying the CV

The final perturbed distributions will be dependent on the choice of the CV. In principle, it is possible to vary the CV and maximizing the entropy and caliber as function of the CV. The most optimal CV is then the one that leads to the least perturbed path distribution.

Inserting the optimised MaxCal distributions  $\mathcal{P}_A^{MC}[\mathbf{x}] = C_A^{-1} \mathcal{P}_A^0[\mathbf{x}] \exp[f_A(\lambda_{max}[\mathbf{x}])]$  and  $\mathcal{P}_B^{MC}[\mathbf{x}] = C_B^{-1} \mathcal{P}_B^0[\mathbf{x}] \exp[f_B(\lambda_{min}[\mathbf{x}])]$ , with  $C_A, C_B$  appropriate normalisation constants, into the expression for the caliber of the distributions yields

$$S_A[\mathcal{P}_A || \mathcal{P}_A^0] = -\frac{1}{C_A} \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] e^{f_A(\lambda_{max}[\mathbf{x}])} (f_A(\lambda_{max}[\mathbf{x}]) - \ln C_A) \quad (59)$$

and

$$S_B[\mathcal{P}_B || \mathcal{P}_B^0] = -\frac{1}{C_B} \int \mathcal{D}\mathbf{x} \mathcal{P}_B^0[\mathbf{x}] e^{f_B(\lambda_{min}[\mathbf{x}])} (f_B(\lambda_{min}[\mathbf{x}]) - \ln C_B) \quad (60)$$

Using the definition of the 'reaching histograms'  $R_A^0(\lambda|\lambda_0), R_B^0(\lambda|\lambda_n)$  this becomes

$$S[\mathcal{P}_A || \mathcal{P}_A^0] = -\frac{1}{C_A} \int d\lambda R_A^0(\lambda|\lambda_0) e^{f_A(\lambda)} (f_A(\lambda) - \ln C_A)$$

$$S[\mathcal{P}_B || \mathcal{P}_B^0] = -\frac{1}{C_B} \int d\lambda R_B^0(\lambda|\lambda_n) e^{f_B(\lambda)} (f_B(\lambda) - \ln C_B), \quad (61)$$

where the normalisation  $C_A = \int d\lambda R_A^0(\lambda|\lambda_0) e^{f_A(\lambda)}$ , is now also expressed using the reaching histograms. Note that we have assumed all sub-distributions  $\mathcal{P}_A^0, \mathcal{P}_A, \mathcal{P}_B, \mathcal{P}_B^0$  to be normalised. However, when computing the total entropy we need to use the normalised total path distribution. It is possible to express the caliber for the full distributions in terms of  $S[\mathcal{P}_A || \mathcal{P}_A^0]$  and  $S[\mathcal{P}_B || \mathcal{P}_B^0]$  as

$$S[\mathcal{P} || \mathcal{P}^0] = \alpha S[\mathcal{P}_A || \mathcal{P}_A^0] + (1 - \alpha) S[\mathcal{P}_B || \mathcal{P}_B^0]$$

$$+ \alpha \ln \frac{\alpha}{\alpha_0} + (1 - \alpha) \ln \frac{1 - \alpha}{1 - \alpha_0} \quad (62)$$

with  $\alpha = C_A / (C_A + C_B)$ , and  $\alpha_0 = C_A^0 / (C_A^0 + C_B^0)$ . The last two terms provide a kind of penalty for how much the partial ensembles differ in their respective weight. For a symmetric potential, identical sampling and a symmetric bias,  $\alpha = 1/2$  and these terms vanish.

### K. Generalising the approach

When deriving the  $g(\lambda)$  function we use  $\lambda$  as an CV. We can generalize the approach and look for the  $g(x)$  as a function of any configuration  $x$ . In analogy with Eq. 49 and Eq. 50 the reweighted MaxEnt densities are given by:

$$\rho_A(x) = \rho_A^0(x) e^{\mu_A p_B(x)}$$

$$\rho_B(x) = \rho_B^0(x) e^{-\mu_B p_B(x)} e^{\mu_A}. \quad (63)$$

To solve for  $p_B$  we use again the definition  $p_B(x) = \rho_B(x) / (\rho_A(x) + \rho_B(x))$  and substitute the MaxEnt densities,

$$p_B(x) = \frac{\rho_B^0(x)}{\rho_A^0(x) e^{-\mu_A} e^{(\mu_A + \mu_B) p_B(x)} + \rho_B^0(x)}. \quad (64)$$

Again, this self-consistent equation needs to be solved numerically, given  $\rho_A^0(x), \rho_B^0(x)$ , and the values of  $\mu_A$  and  $\mu_B$ .

The  $f(x)$  function then follows from identifying the MaxCal corrected RPE configurational density with the MaxEnt corrected configurational density

$$\rho_A^{MC}(x) = e^{-\mu g(x)} \rho_A^0(x) \quad (65)$$

or, setting  $g(x) = p_B(x)$ ,

$$\begin{aligned} \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] e^{f(p_{B,max}[\mathbf{x}])} \sum_{k=0}^L \delta(x_k - x) &= \\ = e^{-\mu p_B(x)} \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \sum_{k=0}^L \delta(x_k - x) & \quad (66) \end{aligned}$$

where  $p_{B,max}[\mathbf{x}]$  is the maximum value of the committor along the path  $\mathbf{x}$ . In practice this equation should be again solved numerically.

This approach is consistent with the idea that  $p_B(x)$  is the most optimal reaction coordinate (RC).

### L. Interpretation of the method

While the above sections give all the details of our framework, it might be good to take a step back and summarize what is actually done. Simply speaking, the method takes as an input the unbiased ensembles of paths leaving state A and B, and reweights each trajectory in the ensemble according to how far it progresses along a predefined collective variable (see Fig. 3 for a equation scheme and illustration of the reweighting). This includes the paths that cross the barrier and reach the other state, so the rate constants are automatically constrained to the correct value. The more involved part of the framework is to also ensure the thermodynamic properties are correct, in particular the equilibrium constant. This requires a specific bias function based on the committor function, which produces the least perturbed path ensemble, while still obeying the constraints. The interpretation of the reweighting procedure is that trajectories are artificially made more (or less) probable in the path ensembles, analogous of changing the weight of each conformation in the Boltzmann distribution, using the MaxEnt approach. Indeed, the reweighting would then also correspond to altering the underlying force field, leading to both different static and dynamics properties. How the force field needs

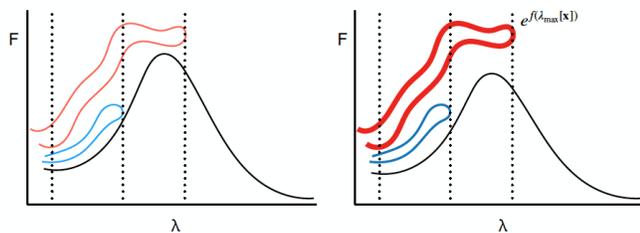

FIG. 3. Illustration of how the method reweights paths. Left: the black curve depicts a free energy barrier. Several paths are shown. Blue path has a high weight, red path a low weight as it has to travel further up the barrier. Maximum  $\lambda$ -values are indicated by dotted vertical lines. Right: after the reweighting the red path is relatively more abundant in the ensemble, indicated by the thicker curve. The resulting free energy barrier is lowered in line with the kinetic constraints.

to be changed to achieve this, is a different question, and might be the subject of future research.

## III. RESULTS AND DISCUSSION

In this section we illustrate the approach on several toy models as well as all atom molecular dynamics simulations of association/dissociation and folding/unfolding reactions.

### A. RPEs for toy models

We first investigate a 2D potential (Fig. 4) which was recently studied using the VIE-TPS method [29]. For details about the potential and the method we refer to Ref. [29]. Setting the (reciprocal) temperature  $\beta = 1/k_B T = 3$ , we performed  $10^7$  trials shots, where paths were generated by Metropolis Monte Carlo, on average roughly 1000 frames long. Applying the VIE-TPS method on this potential gives the two partial path ensembles  $\mathcal{P}_A^0$  and  $\mathcal{P}_B^0$ . We then apply our MaxCal approach, reweighting with  $\mu_A = -1$  and  $\mu_B = 0$ , which corresponds to the lowering of the rate  $k_{AB}$  by a factor  $e$ . The results are shown in Fig. 5. The top left panel shows the committor based on the original data (red curve), as well as the self-consistent solution to the committor (black curve). The top right panel of Fig. 5 gives the solution to Volterra Eq. 55 using the back substitution. The original weight  $e^{-\mu g(\lambda)} = e^{-\mu p_B(\lambda)}$  is shown in black, the back iteration in red. Note that the red curve oscillates, due to numerical inaccuracies.

Next, we show the reweighted densities  $\rho_A$  in the bottom left panel of Fig. 5. The original density is shown in red, the reweighted with the  $e^{-\mu g(\lambda)}$  is shown in green. The RPE-corrected density should be identical and is shown in black (Note that this is not visible as it is in-

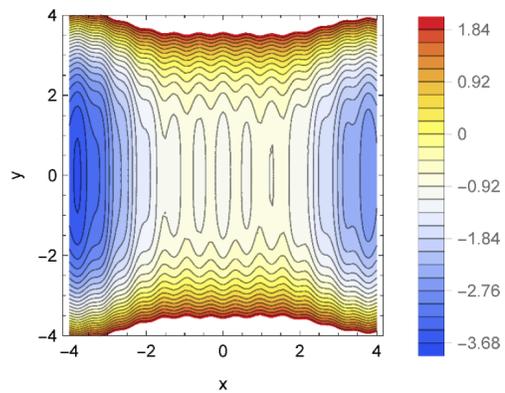

FIG. 4. 2D toy potential from Ref[29]. Energies are in units of  $k_B T$ . The two states A and B are separated by an energy barrier along the x axis. Oscillations are added to show better resolution of the projections.

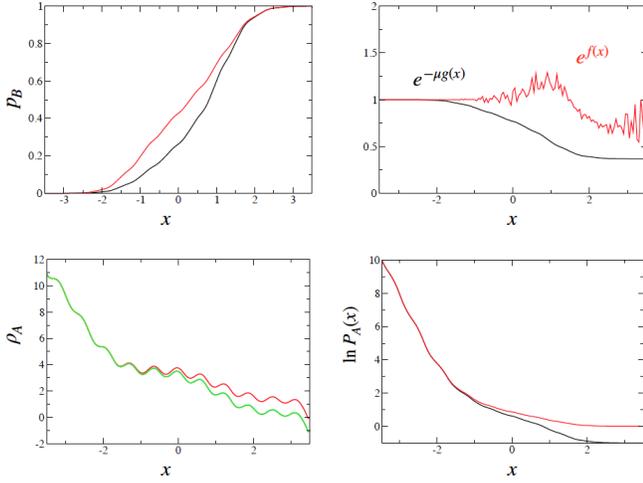

FIG. 5. Analysis of the 2D potential of Fig. 4. Top left: committor  $p_B^0(\lambda)$  function (red) and solution of the self-consistent Eq. 51 (black) for the explicit simulation. Top right: original weight function  $e^{-\mu g(\lambda)}$  (black) and back-iterated function  $e^{f(\lambda)}$  (red). Bottom left: logarithm of the configurational densities with the original in red, the reweighted with the  $g$  function (green) and the RPE-corrected with  $e^{f(\lambda)}$  in black (not visible, behind green). Bottom right: logarithm of the crossing probability with the original in red and the RPE-corrected with  $e^{f(\lambda)}$  in black.

deed exactly the same as the green curve). Finally, we show the logarithm of the crossing probability in the bottom right panel, with the original curve in red, and the RPE-corrected one in black. Indeed the final rate is lowered with 1, as imposed.

For positive bias  $\mu_A > 0$  this treatment is also possible, but can result in some negative weights  $e^{f(\lambda)}$  for  $\lambda$  just below  $\lambda_n$ . We ameliorate this by putting the weights to zero for these cases, which precludes an precise solution for these cases. Still, the reweighted densities are almost correct. In any case, the values of  $f(\lambda)$  do not affect the densities strongly at these values.

In Fig. 6 the bias is increased to  $\mu_A = -3$  and  $\mu_B = 3$  and the crossing probabilities now shows a dramatic

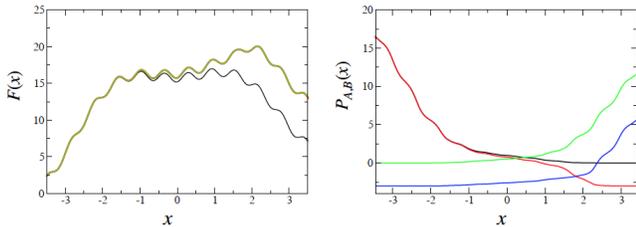

FIG. 6. Analysis of the 2D potential of Fig. 4 by increasing the bias. Left: the free energy for a tilt with  $\mu_A = -3$ ,  $\mu_B = 3$ : original (black), reweighted with  $g$  function (green), RPE-corrected with  $e^{f(\lambda)}$  (red) (not visible, behind green). Right: log of the crossing probability: original in black/green, RPE-corrected with  $e^{f(\lambda)}$  in red/blue.

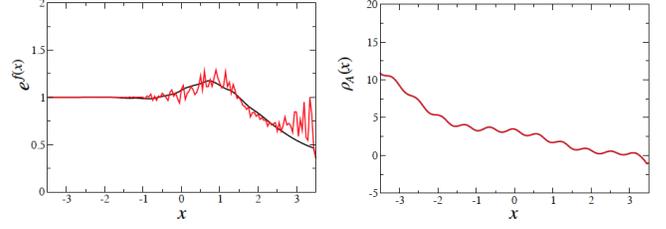

FIG. 7. Analysis of the 2D potential of Fig. 4 by parametrizing  $e^{f(\lambda)}$  with a functional form. Left: back-iterated function  $f(\lambda)$  (red), and the fit (black curve). Right: the corresponding densities are identical.

change. Both forward (AB) and backward (BA) curves are shown. The crossing probability curves are shifted to match the minimum values. Note that the BA curve (blue) is thus shifted by  $6k_B T$ . The free energy (left) is also shown, showing a strong shift of the transition state toward the final state.

The oscillations occurring in Fig. 5b are related to numerical inaccuracies during the backward substitution solution for  $f(\lambda)$ . These oscillations indeed decrease with the amount of path ensemble data that is available. In the limit of infinite amounts of data this curves should be smooth. It should be therefore possible to parametrize  $f(\lambda)$  with a functional form, e.g. with

$$f(\lambda) = g(\lambda) + \sum_i^{n_p} a_{i,0} \exp(-a_{i,1}(x - a_{i,2})^2),$$

with  $n_p$  the number of Gaussian functions, and optimized the  $a_{i,j}$  coefficients in order to optimally accommodate Eq. 58. The result for  $n_p = 1$  is shown in Fig. 7. This opens up the possibility to optimize parameterisations of  $f(\lambda)$  using advanced regression procedures, and even machine learning approaches.

## B. Influence of the choice of CV

In this section we explore the influence of the choice of CV on the optimisation. We examine two different 2D potentials which are shown in Fig. 8 employing standard replica exchange transition interface sampling (RETIS). These potentials are of the form

$$\begin{aligned} v(x, y) = & 10e^{-a((x+b)^2+(y-b)^2)} \\ & - 3e^{-0.3(x-y)^2-0.3(x+y-8)^2} - 3e^{-0.3(x-y)^2-0.3(x+y+8)^2} \\ & + \frac{32}{1800} (0.00625(x+y)^4 + 10(x-y)^2). \end{aligned} \quad (67)$$

The left potential is obtained by setting  $a = 0.1$ , and  $b = 2$ , while the right potential is defined by  $a = 0.5$ , and  $b = 0$ .

For the first potential (Fig. 8a) we run a path sampling simulation with RETIS using the  $x$  coordinate to

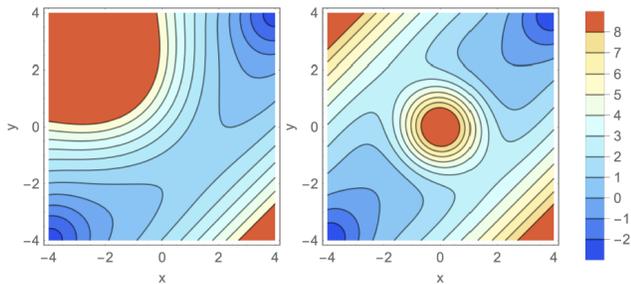

FIG. 8. 2D toy potentials to study the influence of the order parameter.

define the interfaces. Here, we have set 29 interfaces, at respectively,  $x$  values of  $\{-3.7, -3.55, -3.4, -3.2, -2.9, -2.6, -2.2, -1.8, -1.5, -1.2, -1.0, -0.8, -0.5, 0, 0.5, 0.8, 1.0, 1.2, 1.5, 1.8, 2.2, 2.6, 2.9, 3.2, 3.4, 3.55, 3.7\}$ . The reciprocal temperature was set  $\beta = 1.5$ . We performed  $10^5$  trials shots per interface, and included replica exchanges and path reversals. Just as before we obtained the densities, which reproduced the potentials (not shown). The reciprocal temperature was set  $\beta = 1.5$

Next, we apply the MaxCal approach with a strong kinetic constraint of  $\mu_A = -3$  and  $\mu_B = 3$ ; the reconstructed RPE free energy is shown in Fig. 9. Then we run a path sampling simulation with RETIS using the  $y$  coordinate to define the interfaces; the corresponding

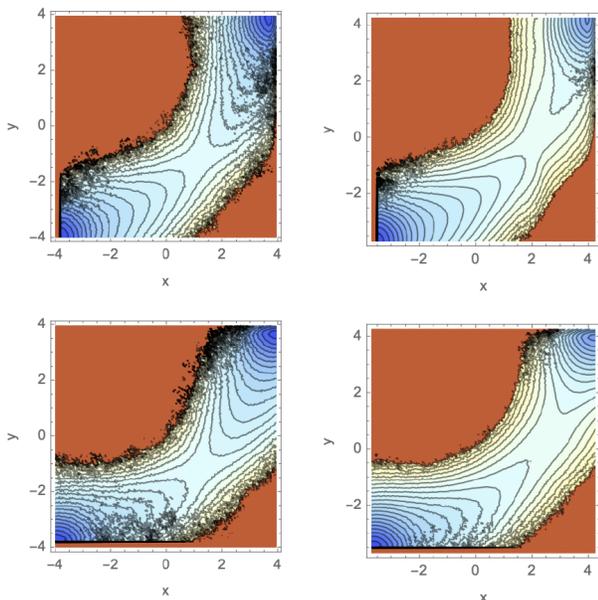

FIG. 9. Analysis of the influence of the choice of the order parameter on the RPEs for a curved potential (Fig. 8a). Free energy landscapes from the RPE for the curved potential. Left is the original sampling, with the  $x$  coordinate (top) and the  $y$  coordinate (bottom) to place interfaces. The right column shows the free energy landscape from the MaxCal posterior RPEs.

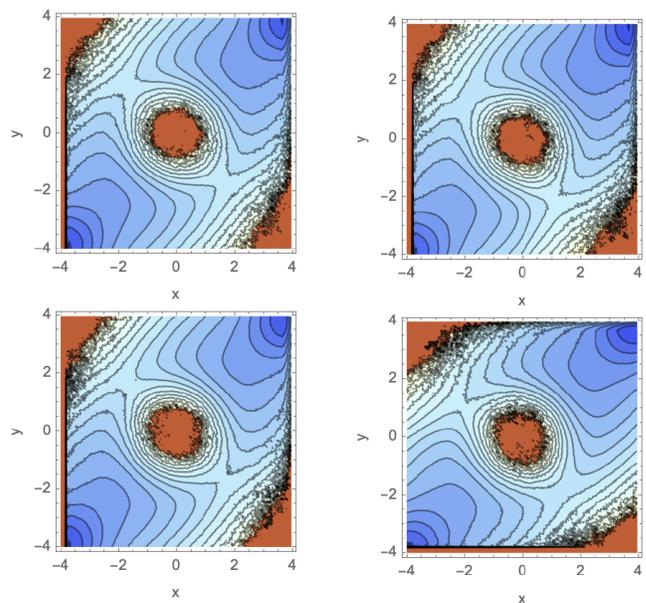

FIG. 10. Analysis for the influence of choice of order parameter on the RPEs for a potential with two channels Fig. 8b. Free energy landscapes from the RPEs for the curved potential. Left is the original sampling, with the  $x$  coordinate (top) and  $y$  coordinate (bottom) to place interfaces. The right column shows the free energy landscapes from the MaxCal posterior RPEs.

RPE free energy landscape is also shown in Fig. 9bottom. The free energy landscape is clearly shifted, and behaves rather independent from the choice of collective variable as order parameter for the RETIS.

For the other potential with two channels we do exactly the same, albeit with a milder constraint  $\mu_A = -1$  and  $\mu_B = 0$ , and show the results in Fig. 10b. Note that here the unbiased RPEs are the same, so it does not matter whether  $x$  or  $y$  is used as an order parameter to define interfaces. However, in the posterior FE landscapes, there are differences, depending on which CV is used as an order parameter (OP). The upper channel is biased more when using  $y$  as an OP while the lower one is biased more when using  $x$  as an OP. This leads to a higher free energy for the upper or lower channels respectively. This discrepancy can most likely be resolved by using the generalised approach. We leave this for a future study.

As described in section IIJ, it is possible to compute the MaxCal entropy or equivalently the KL divergence for the MaxCal optimised distributions, and identify which CV perturbs the distribution the least. Here, care needs to be taken how to add the different AB and BA sub-distributions. Since the potential is symmetric along the diagonal, there is no difference between the  $x$  and  $y$  CV, and both give an identical entropy or KL divergence. Therefore we compare in Table I of Appendix D the entropy of the  $x$ -axis with an order parameter chosen along the diagonal. Since the diagonal is much more aligned

with the reaction coordinate, we expect the diagonal CV to give better KL divergences. And indeed, for instance for the bias  $\mu_A = -1$  and  $\mu_B = 0$ , the KL divergence for the AB path distribution is a factor of two lower for the diagonal. When the BA ensemble is also perturbed, care needs to be taken to weight the contributions of the perturbations in the right way, as given in Eq. 62. For instance, for  $\mu_A = -1$  and  $\mu_B = 1$ , the BA path distribution KL divergence is at least four times smaller for the diagonal CV, as for the x-axis CV. However, since the path distributions contribute in different proportions the total entropy for the diagonal is only twice as improved. Nevertheless, the analysis can show how the choice of the CV influences the optimisation, and how one can use this to optimize the order parameter progress variable along which the MaxCal is performed.

### C. Association and dissociation of two diphenylalanine dipeptides

Next, we illustrate the method to characterise the association and dissociation transition of two diphenylalanine dipeptides (FFs), as studied in Refs. [29, 39]. In this system A and B refer to the bound and unbound states respectively. Here, we focus on trajectories coming from state A. We obtain the kinetic ensemble, by using minimum distance between the peptides,  $d_{min}$  as a forward model order parameter  $\lambda$ . As shown in Fig. 11 we first reweight with  $\mu_A = -1$  and  $\mu_B = 0$ . Notably, as shown in Fig. 11a, the self-consistent solution to the committor

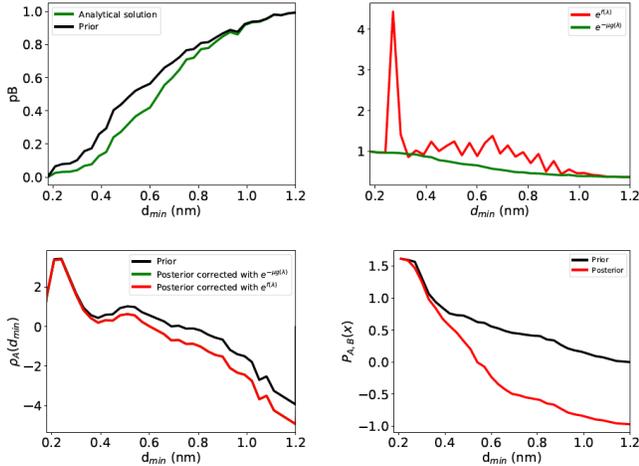

FIG. 11. Dissociation of two diphenylalanine dipeptides. is shown to exhibit a shift with respect to the prior  $p_B$ , and the position of the isocommittor point  $p_B(\lambda) = 0.5$  shifts to larger values of the minimum distance between the peptides. The fact that we constrain  $k_{AB}$  to a value of  $k_{AB}^0 \exp(-1)$  is reflected by the steeper posterior  $p_B(\lambda)$ , signifying a steeper barrier and thereby slower kinetics, as expected.

Fig. 11b illustrates the numerical solution of the Volterra equation Eq. 55 using back substitution. The original weight  $e^{-\mu g(\lambda)} = e^{-\mu p_B(\lambda)}$  is shown in green, the back iterated solution  $e^{-\mu f(\lambda)}$  in red. As for the toy models described above, the weighting function is non-linear (red curve) and oscillates due to numerical errors. Fig. 11c illustrates the original and reweighted densities  $\rho_A$ . The reweighted densities with the  $e^{-\mu g(\lambda)}$  are equal to the RPE weighted ones, as expected by construction. Note the smaller probability density at values of minimum distance larger than 0.4 nm. This is exactly the effect of a smaller transition rate constant which steepens the free energy barriers. Finally, Fig. 11d shows the effect of the kinetic constraint to the crossing probabilities. The original crossing probability is shown in red, and the RPE-corrected in black. Indeed, the crossing probability value at interface B is lowered by a factor of  $1/e$ , as imposed. In Fig. 12 we restrain both the forward and the backward rate by  $\mu_A = -1$  and  $\mu_B = -1$  and the log crossing probabilities now change on both sides by a factor (-1). The reweighted densities with the  $e^{-\mu g(\lambda)}$  are equal to the RPE-weighted ones, as expected by construction. Interestingly, making the rate  $\exp(-1)$  times slower increases both the dissociation barrier ( $d \approx 0.4$  nm) as well as the association barrier ( $d \approx 0.5$  nm). The latter is done by disfavoring the stability of a secondary state A' at  $d \approx 0.5$  nm, where one water-hydration layer is mediating peptide contacts. This water-mediated peptide-

contact state  $A'$  now becomes a transition state region configuration, also found in a previous study in the context of protein-protein association/dissociation [40].

#### D. Folding and unfolding of chignolin

The kinetics of fast folding  $\beta$ -hairpins have been studied by temperature-jump spectroscopy [41], reporting  $\mu$ s timescale folding. Chignolin is a two-state,  $\beta$ -hairpin, mini-protein that folds in the  $\mu$ s timescale [42]. Despite its simple fold (PDB cln025), molecular simulation fails to capture the experimentally-determined melting temperature of 341 K [42–44]. Here we perform our kinetic analysis on an equilibrium molecular dynamics trajectory of chignolin at 341 K [42]. While at this temperature experiments suggest that the folding and unfolding rates should be the same, simulations report a folding rate of  $k_f = 1.667\mu s^{-1}$  and an unfolding rate of  $k_u = 0.455\mu s^{-1}$  respectively. The corresponding enhanced stability of the folded state is likely to arise from inaccuracies in the forcefield used in the molecular dynamics simulations. In the absence of an experimental folding rate for chignolin, but in light of: (a) knowledge that the barrier heights should not exceed  $4.5k_B T$  [42], and (b) that folding and unfolding rates should be the same at the melting temperature, we perform our kinetic analysis by constraining only the folding rate  $k_f^{exp} = 0.455\mu s^{-1}$ . This leads to posterior kinetic ensemble of (un)folding pathways exhibiting new kinetics and thermodynamics, as shown in Fig. 13. We use the fraction of native con-

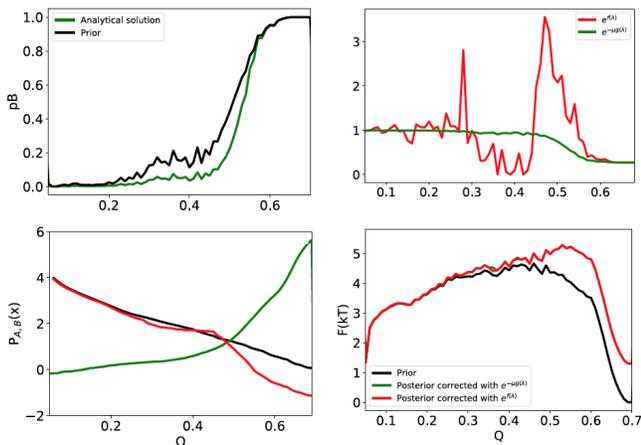

FIG. 13. Simulations of folding and unfolding of chignolin. (a) Committor  $p_B^0(\lambda)$  function (black) and solution of the self-consistent Eq. 51 (green) for the explicit simulation using  $\mu_A = -1.3$ . (b) Original weight function  $e^{-\mu g(\lambda)}$  (green) and back-iterated function  $e^{f(\lambda)}$  (red). (c) Logarithm of the crossing probability histogram of the original (black) and RPE-corrected with  $e^{f(\lambda)}$  (red). (d) Free energies as a function of the fraction of native contacts  $Q$ , original (black), reweighted with  $g$  function (green), RPE-corrected with  $e^{f(\lambda)}$  (red) (green not visible, behind red).

tacts  $Q$  as the collective variable for the order parameter  $\lambda$ . In the remainder of this section states A and B refer to the unfolded ( $Q < 0.05$ ) and folded state ( $Q > 0.7$ ), respectively.

The posterior committor distribution becomes steeper and gets shifted to higher  $Q$  values (see Fig. 13a). In particular the isocommittor surfaces  $p_B = 0.5$  shifts by 10%, from  $Q = 0.5$  to  $Q = 0.55$ . This is in agreement with an effect of lowering the temperature to the increase of the nativeness of the transition state [45], as well as the knowledge of native-like transition states in protein zippers [41]. Fig. 13b illustrates the solution to the Volterra equation Eq. 55 by back substitution. The original weight  $e^{-\mu g(\lambda)} = e^{-\mu p_B(\lambda)}$  is shown in green, the back iteration gives the MaxCal bias on the path weights  $e^{f(\lambda)}$ . Applying this bias to reweight the path ensemble results in posterior crossing probabilities (see Fig. 13c), where the folding conditional probability becomes steeper, indicating slower folding kinetics. At the same time the final shift in the folding crossing probabilities is  $\exp(-1.3)$ , giving indeed rise to the imposed folding rate of  $k_f^{exp} = 0.455\mu s^{-1}$ . Finally, Fig. 13d illustrates the effect of the kinetic constraint on the free energy. The free energy difference between folded and unfolded state becomes zero, as expected by the constraint, and amends the current force field’s inaccuracy in predicting the simulated temperature (341 K) as the melting temperature. Moreover the free energy barrier becomes more asymmetric, shifting towards a more native-like conformations, as indicated also in Fig. 13a.

In Fig. 14 we assess how the kinetic correction alters the free energy and committor landscapes as a function of fraction of native contacts and solvent accessible surface. The kinetic constraint increases the population of the misfolded configurations ( $0.05 < Q < 0.4$ ) state (see Fig. 14b), as well widens the distribution of solvent accessible area of the protein. Moreover Fig. 14c,d show that the kinetic constraint shifts the transition state, i.e. the 0.5 isocommittor surface, to a higher fraction of native contacts  $Q \approx 0.55$  and a slightly lower SASA of  $12.2 \text{ nm}^2$ , indicating a more packed structure. As illustrated in Fig. 14, the prior transition state configuration TS forms one backbone hydrogen bond and has the residues Y2 and W9, crucial for hydrophobic collapse, facing away from each other. On the contrary, the posterior transition state configuration TS’ is more native-like and shows to form more native backbone hydrogen bonds while forming contacts at the key hydrophobic collapse residues Y2 and W9.

## IV. CONCLUSIONS

Nearly 60 years after the first X-ray determination of the structure of a globular protein, molecular simulations can accurately address structural ensembles and their corresponding thermodynamics [5]. Yet, while the functions of proteins depend often on the transition rates

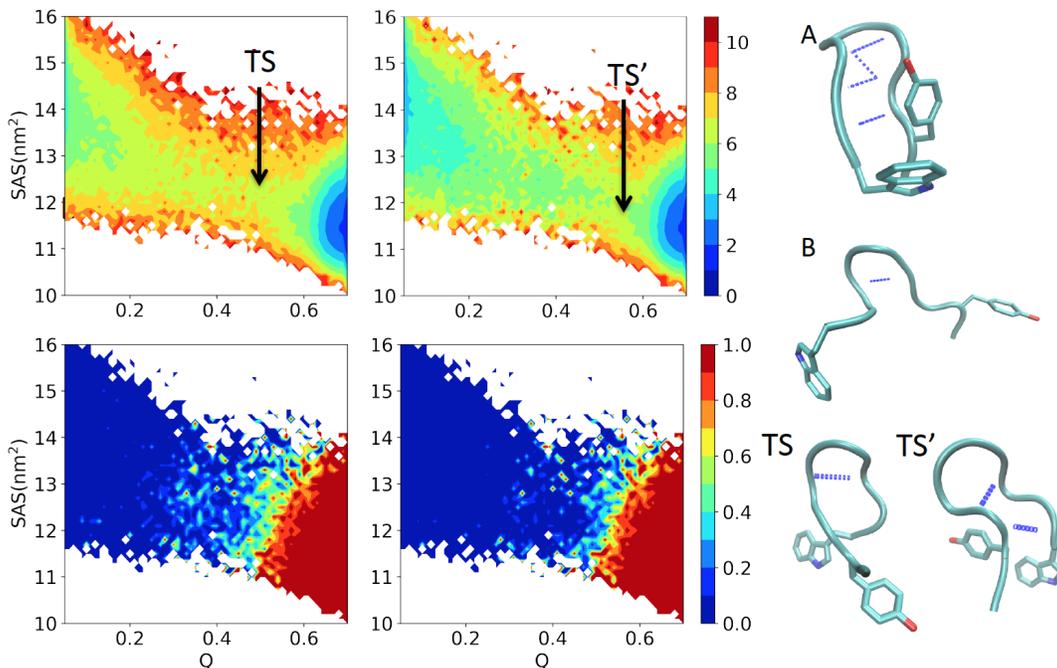

FIG. 14. Free energy surface as a function of the fraction of native contacts,  $Q$ , and the solvent accessible surface, SAS, of the prior (a) and the posterior (b). In the bottom we highlight the respective committor landscapes of the prior (c) and the posterior (d). The right structure panel refers to the folded (A), unfolded (B), prior transition state (TS) and posterior transition state (TS').

between their different states, there is still a need for developing accurate methods for characterizing them.

To address this challenge, in this work we have developed a framework to determine kinetic ensembles from experimental information. This framework combines maximum caliber and maximum entropy concepts in order to match experimentally-determined kinetic rate constants with molecular dynamics simulations. The matching is done by biasing the paths in the unbiased reweighted path ensemble based on how far they are progressing along a chosen collective variable. In this reweighting both the rate constant as well as the equilibrium free energy are constrained. In doing so we are able to ameliorate dynamical profiles such as conditional probabilities, committor functions and transition states, as well as the long time kinetics and the equilibrium thermodynamics. In addition, the method can impose restraints rather than constraints, by accounting for the uncertainty in the data.

To illustrate possible applications of this method we showed that matching the rate constants of protein folding of chignolin to a simulated structural ensemble yields accurate melting temperature and a more native-like transition state ensemble.

We anticipate that this method will extend the applicability of atomistic and coarse-grained molecular simulations as a kinetic tool in structural biology, e.g. for accurate mechanistic and reaction coordinate analysis. Furthermore, the approach can be extended to amend

imperfections in current atomistic force fields to reproduce the kinetics and thermodynamic observables. Such a possible method would require computing the derivative of the kinetic rate constant in path ensembles. We leave this for future research.

We finally note that in principle the method is general and could be applied to a wide range of problems amenable to molecular simulations.

## Appendix A: Constraint function

To solve the constraint equation Eq. 37 we make use of the fact that the integral over the paths can be split into the intervals between the interfaces. For each path with  $\lambda_{max}$  between  $i$  and  $i + 1$ , the situation is then identical. For each interval the situation is different. For instance, for  $k = n$  it holds that only paths beyond  $\lambda_n$  will contribute.

$$D_n e^{F_n} P_A(\lambda_n | \lambda_n) = k_{AB}^{exp}, \quad (\text{A1})$$

where  $D_n$  is the path fraction for paths beyond  $\lambda_n$ , so  $D_n = P_A^0(\lambda_n)$ , and we have defined the sum  $F_n \equiv \sum_{i=1}^n \mu_i P_A(\lambda_n|\lambda_i)$ . Since  $P_A(\lambda_n|\lambda_n) = 1$  by definition this changes into

$$e^{F_n} = k_{AB}^{exp}/D_n = k_{AB}^{exp}/P_A^0(\lambda_n|\lambda_1) = \frac{P_A(\lambda_n|\lambda_0)}{P_A^0(\lambda_n|\lambda_0)} \equiv e^{\mu f(\lambda_n)} \quad (\text{A2})$$

Indeed this is the correct reweighting that is needed. For the case of  $k = n - 1$

$$(D_{n-1}e^{F_{n-1}} + D_n e^{F_n}) P_A(\lambda_n|\lambda_{n-1}) = k_{AB}^{exp} \quad (\text{A3})$$

Now  $D_{n-1} = P_A^0(\lambda_{n-1}|\lambda_0) - P_A^0(\lambda_n|\lambda_0)$ , and

$$P_A(\lambda_n|\lambda_{n-1}) = P_A(\lambda_n|\lambda_0)/P_A(\lambda_{n-1}|\lambda_0) \quad (\text{A4})$$

This will give

$$D_{n-1}e^{F_{n-1}} + D_n e^{F_n} = k_{AB}^{exp} \frac{P_A(\lambda_{n-1}|\lambda_0)}{P_A(\lambda_n|\lambda_0)} \quad (\text{A5})$$

or

$$D_{n-1}e^{F_{n-1}} + k_{AB}^{exp} = k_{AB}^{exp} \frac{P_A(\lambda_{n-1}|\lambda_0)}{P_A(\lambda_n|\lambda_0)}, \quad (\text{A6})$$

which is

$$D_{n-1}e^{F_{n-1}} = \frac{k_{AB}^{exp}}{P_A(\lambda_n|\lambda_0)} (P_A(\lambda_{n-1}|\lambda_0) - P_A(\lambda_n|\lambda_0)), \quad (\text{A7})$$

or, since  $k_{AB}^{exp} = P_A(\lambda_n|\lambda_0)$  by definition, the weight for paths in the  $k = n - 1$  slot becomes

$$e^{F_{n-1}} = \frac{P_A(\lambda_{n-1}|\lambda_0) - P_A(\lambda_n|\lambda_0)}{P_A^0(\lambda_{n-1}|\lambda_0) - P_A^0(\lambda_n|\lambda_0)}. \quad (\text{A8})$$

This gives a regular pattern, and for  $k = i$  it holds that for paths in this slot the weight is as follows

$$e^{F_i} = \frac{P_A(\lambda_i|\lambda_0) - P_A(\lambda_{i+1}|\lambda_0)}{P_A^0(\lambda_i|\lambda_0) - P_A^0(\lambda_{i+1}|\lambda_0)} \quad (\text{A9})$$

The next question is what the function  $F_i$  is. This function can be expressed as a function of  $\lambda$  by noticing that all the paths fall in a slot  $i$  and  $i + 1$ , which are determined by  $\lambda_{max}[\mathbf{x}]$ . This means that for paths in this slot

$$F_i = f(\lambda_{max}[\mathbf{x}]) \quad (\text{A10})$$

This would mean that each path should be reweighted using

$$\mathcal{P}_A^{MC}[\mathbf{x}] \propto \exp(f(\lambda_{max}[\mathbf{x}])) \mathcal{P}_A^0[\mathbf{x}] \quad (\text{A11})$$

where the function  $f(\lambda)$  should be the biasing function.

Now we should still check whether  $\int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] = 1$ . To do so we expand the integral in intervals, as before, to get

$$\begin{aligned} \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] &= \sum_i^n D_i \exp \left[ \sum_{j=1}^n \mu_j \theta(\lambda_{max}[\mathbf{x}] - \lambda_j) P_A(\lambda_n|\lambda_j) \right] \\ &= \sum_i^n P_A(\lambda_i|\lambda_0) - P_A(\lambda_{i+1}|\lambda_0) = 1 \end{aligned} \quad (\text{A12})$$

where we used the fact that  $P_A(\lambda_0|\lambda_0) = 1$ . So indeed the normalisation is guaranteed.

At first sight it seems that, when the path histograms, e.g. the crossing probabilities  $P_A(\lambda|\lambda_0)$ , are reweighted with a function  $f(\lambda)$ , we can simply replace

$$P_A^{MC}(\lambda|\lambda_0) = C \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \theta(\lambda_{max}[\mathbf{x}] - \lambda) e^{f(\lambda_{max}[\mathbf{x}])} \quad (\text{A13})$$

by  $P_A^0(\lambda|\lambda_0) e^{f(\lambda_{max}[\mathbf{x}])}$ . But this would be wrong. The  $\theta$ -function in the integral means we have to sum over ensemble of paths for a certain  $\lambda_{max}[\mathbf{x}]$ . To see this we should look at the 'reaching' histogram :

$$R_A^0(\lambda|\lambda_0) = C \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] \delta(\lambda_{max}[\mathbf{x}] - \lambda), \quad (\text{A14})$$

where  $C$  is a normalisation constant. This histogram counts the paths that 'just reached'  $\lambda$ . The crossing probability can be simply obtained from this by integration:

$$P_A^0(\lambda|\lambda_0) = C \int_{\lambda_n}^{\lambda} R_A^0(\lambda|\lambda_0) d\lambda. \quad (\text{A15})$$

This can be easily seen by realising  $\theta(\lambda_{max}[\mathbf{x}] - \lambda) = \int_{\lambda_n}^{\lambda} \delta(\lambda_{max}[\mathbf{x}] - \lambda) d\lambda$ . For  $\lambda = \lambda_n$ , all paths that cross  $\lambda_n$  should be included. Effectively this could be achieved by taking  $\lambda_n \rightarrow \infty$

When the paths are reweighted with  $e^{f(\lambda_{max}[\mathbf{x}])}$  this should be done on  $R_A^0(\lambda|\lambda_0)$ , and not directly on  $P_A^0(\lambda|\lambda_0)$ . Thus

$$\begin{aligned} R_A^{MC}(\lambda|\lambda_0) &= C \int \mathcal{D}\mathbf{x} \mathcal{P}_A[\mathbf{x}] \delta(\lambda_{max}[\mathbf{x}] - \lambda) \\ &= C \int \mathcal{D}\mathbf{x} \mathcal{P}_A^0[\mathbf{x}] e^{f(\lambda_{max}[\mathbf{x}])} \delta(\lambda_{max}[\mathbf{x}] - \lambda) \\ &= R_A^0(\lambda|\lambda_0) e^{f(\lambda)}. \end{aligned} \quad (\text{A16})$$

Substitution in the crossing probability yield

$$P_A^{MC}(\lambda|\lambda_0) = C \int_{\lambda_n}^{\lambda} R_A^0(\lambda|\lambda_0) e^{f(\lambda)} d\lambda \quad (\text{A17})$$

This is the proper reweighting of the crossing probabilities.

We are now in the position to check whether the reweighting assumption Eq. A11 is correct, by using Eq. A9 and substitute Eq. A17.

$$\begin{aligned} e^{F_i} &= \frac{P(\lambda_i|\lambda_0) - P(\lambda_{i+1}|\lambda_0)}{P^0(\lambda_i|\lambda_0) - P^0(\lambda_{i+1}|\lambda_0)} \\ &= \frac{\int_{\lambda_n}^{\lambda_i} R_A^0(\lambda|\lambda_0) e^{f(\lambda)} d\lambda - \int_{\lambda_n}^{\lambda_{i+1}} R_A^0(\lambda|\lambda_0) e^{f(\lambda)} d\lambda}{\int_{\lambda_n}^{\lambda_i} R_A^0(\lambda|\lambda_0) d\lambda - \int_{\lambda_n}^{\lambda_{i+1}} R_A^0(\lambda|\lambda_0) d\lambda} \\ &= \frac{\int_{\lambda_{i+1}}^{\lambda_i} R_A^0(\lambda|\lambda_0) e^{f(\lambda)} d\lambda}{\int_{\lambda_{i+1}}^{\lambda_i} R_A^0(\lambda|\lambda_0) d\lambda} = e^{f(\lambda_i)}, \end{aligned} \quad (\text{A18})$$

where the latter equality follows from the fact that all paths between  $\lambda_i$  and  $\lambda_{i+1}$  get the same weight.

### Appendix B: The committor is a solution for $g(\lambda)$

The natural solution of the equation

$$\frac{\int d\lambda g(\lambda)\rho(\lambda)}{\int d\lambda\rho(\lambda)} = K \quad (\text{B1})$$

is that  $g(\lambda)$  is equal to the committor  $p_B(\lambda)$ . This can be seen as follows. The definition of the committor is the fraction of all paths that lead to  $B$

$$p_B(\lambda) = \frac{\rho_{BB}(\lambda) + \rho_{AB}(\lambda)}{\rho(\lambda)} = \frac{\rho_B(\lambda)}{\rho(\lambda)} \quad (\text{B2})$$

where  $\rho_B = \rho_{BB} + \rho_{AB}$  is the density of points that commit to B. As the total density  $\rho(\lambda) = \rho_A(\lambda) + \rho_B(\lambda)$ . Substituting  $g(\lambda)$  by  $p_B(\lambda)$  gives

$$\frac{\int d\lambda p_B(\lambda)\rho(\lambda)}{\int d\lambda\rho(\lambda)} = \frac{\int d\lambda\rho_B(\lambda)}{\int d\lambda\rho(\lambda)}, \quad (\text{B3})$$

which is indeed the fraction of points committed to B, thus by definition equal to  $K^{exp}$ .

So the task is now to find the function  $p_B(\lambda)$  that solves

$$\frac{\int d\lambda p_B(\lambda)}{\int d\lambda\rho(\lambda)} = K^{exp} \quad (\text{B4})$$

given that original distributions obey

$$\frac{\int d\lambda\rho_B^0(\lambda)}{\int d\lambda\rho^0(\lambda)} = K^0 \quad (\text{B5})$$

Indeed, using the ME reweighted densities this leads to the self consistent relation for the committor Eq. 51.

### Appendix C: Restraining only the final interface $\lambda_B$

Here, we demonstrate how reweighting only pathways that cross the interface of state B leads to and a discontinuity and sudden increase in the otherwise monotonically decreasing crossing probability histogram, (see Fig. 15a) as well as a sudden discontinuity in the configurational density ( Fig. 15b).

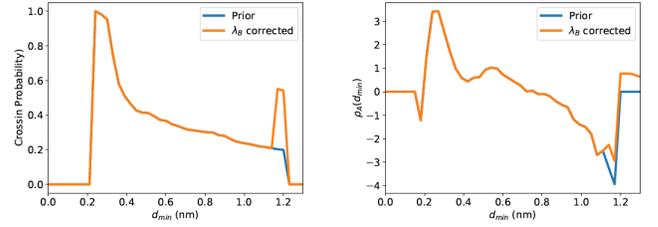

FIG. 15. a) Crossing probability out of state A and b) the respective configurational density.

### Appendix D: The MaxCal entropy for different CVs in the 2D potential

In section II J we introduced Eq. 62 to compute the MaxCal entropy for the optimised path distributions. Using this equation we can compute the entropy or equivalently the KL divergence for the 2D potentials using different bias settings for two different CVs:  $\lambda = x$  along the x axis (or equivalently the y axis), and along the diagonal  $\lambda = x + y$ . In Table I we report the values for the individual path distributions  $S_A, S_B$ , as well as the total  $S_A + S_B$ , using Eq. 59. In addition, we compute the correction based on the  $\alpha$  parameter due to the normalisation, from Eq. 62. The last three columns report the  $\alpha$  weighted entropies (KL divergence), as well as the corrected value of  $S$ . Note that we report the negative entropy, or KL divergence, in order to keep all numbers positive. Also, here we can set  $\alpha_0 = 0.5$  due to the symmetry of the potential.

Note that the diagonal CV is always performing better for the total path distributions ( $S_A + S_B$ ). This is to be expected, as the diagonal is more aligned to the reaction coordinate, and thus the distribution are expected to be less perturbed. However, for the individual AB and BA path distribution a strong bias (e.g.  $\mu_A = -2$ ) will make the diagonal CV for the AB distribution seem worse (4th column), indicating that diagonal AB distribution is perturbed more than the AB distribution for  $\lambda = x$ . This is

possibly caused by difficulties in the numerical solution of the Volterra equation. We stress that the MaxCal approach should focus on the total distribution, to make a proper comparison, and indeed, both the sum  $S_A + S_B$  and the alpha weighted, and total corrected entropy all show improvements for the diagonal.

Note also that the final KL divergence reported in the last column, including the correction, is steadily increasing when the bias becomes more asymmetric. In fact it is largely dominated by the correction term, due to this

asymmetry. This reflects the fact that due to the asymmetry the BA and AB distributions are biased in different directions. However, when just the individual distribution are considered, the normalisation reduces the individual entropies. When the distributions are taken together, the larger difference in weighting (the value of  $\alpha$ ) is causing a much larger KL divergence. It is thus the asymmetry, reflecting a change in the thermodynamic equilibrium constant that dominates the MaxCal entropy. Note that for symmetric bias the correction vanishes.
