June 9, 2020

Abstract

A recent body of work addresses safety constraints in explore-and-exploit systems. Such constraints arise where, for example, exploration is carried out by individuals whose welfare should be balanced with overall welfare. In this paper, we adopt a model inspired by recent work on a bandit-like setting for recommendations. We contribute to this line of literature by introducing a safety constraint that should be respected in every round and determines that the expected value in each round is above a given threshold. Due to our modeling, the safe explore-and-exploit policy deserves careful planning, or otherwise, it will lead to sub-optimal welfare. We devise an asymptotically optimal algorithm for the setting and analyze its instance-dependent convergence rate.

1 Introduction

Explore-and-exploit tradeoffs are central to Machine Learning (ML) and Artificial Intelligence (AI). They are the core problems in well-studied decision-making problems like Markov Decision Processes [10] and Multi-armed Bandits (MABs) [12]. Such dilemmas refer to environments in which we can *exploit* the knowledge already acquired and get the outcome that we expect, or *explore* other alternatives and reveal potentially better outcomes. Motivated by the extensive use of algorithmic decision making, exploration under system constraints is becoming increasingly popular. Some of these constraints arise due to fairness considerations [18, 21], the need for privacy [28, 29], mitigating strategic behavior [6, 22–24] and safety (see Garcia and Fernández [14] for a recent survey and taxonomy). In this work, we contribute to the literature on learning under safety concerns.

Since safety in this context is ambiguous, it is no surprise that many definitions and approaches exist. In one line of work, the optimization criterion is transformed to address other factors such as variance [17], the worst outcome [11, 16], or the probability of visiting unwanted states [15]. In another line of work, the exploration process itself is constrained to address safety considerations [19, 32]. Further, recent work [3, 30] suggests that safety should be applied in *almost* every action algorithms make, despite that the safe set of actions is initially unknown. Of course, since the safe set of actions is learned throughout the process, safety constraints can only be guaranteed to be satisfied with high probability.

In this paper, we contribute to the latter strand of research. We consider a MAB model under several assumptions, and require what is perhaps the strictest safety constraint that nevertheless allows learning: that the expected reward in every round exceeds some safety threshold, given the Bayesian information available to the algorithm. This safety constraint complements prior work in two important ways. First, safety should hold *invariably*, i.e., in every single round. This is crucial in, e.g., scenarios where a MAB algorithm experiments with one agent per round. Second, the safety constraint relies on the *full Bayesian information* the algorithm has, in sharp contrast to work that leverages information asymmetry (see related work below). Our safety constraint can be used to strengthen existing safety requirements like Bayesian Incentive Compatibility [6, 22–24], or to relax legal responsibilities that allow no learning whatsoever (like fiduciary duty). Our investigation broadens the safety spectrum in MABs, and demonstrates that while learning in the invariable Bayesian safety setting is non-trivial, it can still occur.

1.1 Our Contribution

We consider a MAB setting with a Bayesian prior and static rewards; that is, the reward of each arm is initially unknown, but is realized only once.¹ Some of the arms may be risky, i.e., hide negative rewards, but can also be highly rewarding. Additionally, we assume that there is a *safe arm*, with a known deterministic reward. In every round, the decision maker (henceforth DM) picks a distribution over the arms, which we term a *portfolio*. After committing to a portfolio, DM samples an arm according to the weights of the portfolio and plays it. The utility of DM is the sum of rewards, which she wishes to maximize. Without any further constraints, this is straightforward: try every arm once, and then repeatedly choose the best arm. (Due to our static rewards assumption, one round of exploration is enough to reveal all the rewards.) However, we limit DM to playing only *safe portfolios*; a portfolio is safe if its expected reward is weakly better than that of the safe arm, where this expectation is taken over the Bayesian information and the weights it gives to arms.

We contribute to the existing literature both conceptually and technically. Conceptually, safety is applied in *every* round, and not only with high probability like previous work (see, e.g., Amani et al. [3], Usmanova et al. [30]). Our approach to safety is highly desired in, e.g., situations where DM interacts with agents. We ask that DM provides *every* agent a portfolio that is weakly better than the safe arm in expectation, independently of the other agents. This is in sharp contrast to traditional MABs, in which algorithms intentionally devote some rounds to exploration. Our safety constraint spreads exploration over rounds to distribute its cost, and provides a strong guarantee for agents to use the system (as it is weakly better than the safe arm). Our main conceptual take-away is that systems and decision-makers that are required to ensure safety in its (arguably) most stringent form can still enjoy learning.

On the technical side, the main algorithmic question is to maximize the expected utility subject to safety. Since rewards are realized only once (and remain fixed throughout the execution), planning is crucial: arms with high a priori value extend the set of safe portfolios and enable exploration of a priori inferior arms. Our main technical contribution is an asymptotically optimal algorithm, under a stochastic dominance assumption on the rewards. Our approach is based on a constrained Goal Markov Decision Process (GM DP) [9]. We devise a neat optimal policy for this GM DP, and

¹While this assumption is limiting, it allows us to focus on the novel viewpoint of invariable safety we propose in this paper. Indeed, a similar approach is taken by much other recent work proposing incentive compatibility constraints in MABs [6, 13, 22]. As we will see, even given this assumption, the problem is technically challenging.

harness it to craft an asymptotically optimal algorithm. Finally, we analyze the instance-dependent convergence rate.

1.2 Related Work

As argued above, the notion of safety has many diverse definitions in the ML and AI literature. For example, Moldovan and Abbeel [25] introduce an algorithm that allows safe exploration in Markov Decision Processes in order to avoid fatal absorbing states. Our work takes a different tack, as it constrains the exploration process rather than modifying the objective criterion.

Several lines of work have applied safety constraints to Multi-Arm Bandit problems. One considers a MAB problem with a global budget where the objective is to maximize the total reward before the learner runs out of resources (see, e.g., [1, 4, 5, 31]). Another considers stage-wise safety, ensuring that regret performance stays above a threshold determined by a baseline strategy at every round [19, 32]. Notably, in these lines of work, the constraint applies to the cumulative resource consumption/reward across the entire run of the algorithm. In contrast, Amani et al. [3] consider the application of a reward constraint at each round. In their work, the set of safe decisions is left uncertain, given the inherent uncertainty in the learning system. They therefore have a two-fold objective: to minimize regret while learning the safe decision set.

Our work is motivated by the idea of using a bandit-like setting for recommendations [8, 7, 13, 20]. Under this perception, each round serves a different agent and, therefore, the safety constraint should be applied in each round. This strengthens the approach of Amani et al. [3], as we require the constraint to *always* hold (and not only with high probability). As in Bahar et al. [8, 7], Cohen and Mansour [13], Kremer et al. [20], we assume each arm is associated with a fixed value, which is initially unknown, selected from a known distribution. Given this, our problem becomes the careful planning of safe exploration rather than the more standard explore and exploit subject to constraints, with probabilistic guarantees. Our setting conceptually departs from incentive compatible MABs [7, 13, 20]. In that line of research, optimal solutions rely on *information asymmetry*: each agent has only a priori knowledge while the algorithm witnesses the rewards of all preceding agents; thus, the algorithm can induce agents to explore a priori inferior arms. While this approach might be suitable for some scenarios, it can be highly undesired in cases where, e.g., the system can be held liable to its actions, or cares for long-term engagement. Indeed, this manipulation is what we try to remedy in the present paper.

Another interesting view of safety is to assume the underlying system is safety-critical and to present active learning frameworks that use Gaussian Processes as non-parametric models to learn the safe decision set (e.g., [26, 27]). So, the safe decision set is fixed but is initially unknown, and is learned in the process. Of course, we never know the safe decisions for certain in such settings. This is unlike our work, where we do know the safety constraint at each point. Safety depends on our knowledge, which is perfect in the Bayesian sense.

2 Problem Statement

In this section, we formally define the Invariable Bayesian Safety problem (IBS-P for shorthand). We consider a set A of K arms, $A = \{a_1, \dots, a_K\}$. The reward of arm a_i is a random variable $X(a_i)$, and $(X(a_i))_{i=1}^K$ are mutually independent. The rewards are static, i.e., they are realized only once, but are initially unknown. We denote by $\mu(a_i)$ the expected value of $X(a_i)$, namely $\mu(a_i) \stackrel{\text{def}}{=} \mathbb{E}[X(a_i)]$.

DM knows the Bayesian priors, i.e., distribution $X(a_i)$ for every $a_i \in A$. There are T rounds, where we address rounds as interactions with agents; namely, DM makes a decision for agent t in round t . We augment the set of arms with a *safe arm*, whose reward is always 0,² and which we denote by a_0 for simplicity. In each round, DM can pick the safe arm, or an action from A . We also let $A^+ \stackrel{\text{def}}{=} A \cup \{a_0\}$, and let $\Delta(A^+)$ be the set of distributions over the elements of A^+ .

We denote by \mathcal{I}_t the information DM has at time t —the prior distributions and the reward realizations acquired until round t . Namely, \mathcal{I}_1 encodes the prior information solely, \mathcal{I}_2 encodes both the prior information and the reward of the arm selected at round 1, and so on. If the reward $X(a_i)$ was realized before round t and is hence known to DM, we use $x(a_i)$ to denote its value.

In every round, DM plays a *portfolio* of arms. A portfolio is an element from $\Delta(A^+)$ —it is a distribution over the arms and the safe arm. Put differently, a portfolio is the extension of actions to randomized actions. Whenever DM picks a portfolio $\mathbf{p} \in \Delta(A^+)$, Nature (i.e., a third-party) flips coins according to \mathbf{p} to realize one arm from A^+ . The reward at time t , which we denote by r^t , is defined as the expected value over the coin flips and the randomness of the rewards. Formally, $r^t = \sum_{a_i \in A^+} \mathbf{p}^t(a_i) \mathbb{E}[X(a_i) | \mathcal{I}_t]$, where \mathbf{p}^t is the portfolio DM selects at time t .

In this paper, we limit DM to use *Bayesian-safe portfolios*. A portfolio \mathbf{p}^t is Bayesian-safe (or simply *safe*) at time t if, given the information DM has at time t , its expected reward is greater or equal to zero (which is the reward of the safe arm). Formally,

Definition 1 (Bayesian-Safe Portfolio). *A portfolio \mathbf{p} is safe w.r.t. \mathcal{I} if $\sum_{a_i \in A} \mathbf{p}(a_i) \mathbb{E}[X(a_i) | \mathcal{I}] \geq 0$.*

By restricting DM to play safe portfolios, we assure that every agent (i.e., every round) will receive at least the reward of the safe arm in expectation, independently of the other agents.³ We denote the *utility* achieved by an algorithm ALG by $\mathcal{U}_T(\text{ALG}) = \mathbb{E} \left[\sum_{t=1}^T r^t \right]$. DM wished to maximize her utility—the sum of rewards, subject to selecting safe portfolios in every round.

To conclude, we represent an instance of the IBS-P problem by the tuple $\langle K, A, (X(a_i))_i, (\mu(a_i))_i \rangle$. Notice that the horizon T is not part of the description, as we often discuss a particular instance with varying T . When the instance is known from the context, we denote the highest possible utility of any algorithm by OPT_T , where the subscript emphasizes the dependency on the number of rounds T . As it will become apparent later on, it is convenient to distinguish arms with positive expected rewards and arms with negative expected rewards.⁴ To that end, we let $\text{above}(A) \stackrel{\text{def}}{=} \{a_i \in A : \mu(a_i) > 0\}$. Analogously, $\text{below}(A) \stackrel{\text{def}}{=} \{a_i \in A : \mu(a_i) < 0\}$. The terms *above* and *below* refer to the safe arm—an expected value of 0, which is our benchmark for safety.

Before we go on, we illustrate our setting and notation with an example.

Example 1. Let $K = 4$, and let $X(a_1) \sim N(2, 1)$, $X(a_2) \sim N(1, 1)$, $X(a_3) \sim N(-1, 1)$, and $X(a_4) \sim N(-2, 1)$, where $N(\mu, \sigma^2)$ denotes the normal distribution with a mean μ and a variance σ^2 . Notice that $\text{above}(A) = \{a_1, a_2\}$ and $\text{below}(A) = \{a_3, a_4\}$. In the first round, DM can play, e.g., a portfolio that comprises a_1 w.p. 1. She can also play the portfolio that mixes a_1 w.p. $\frac{1}{2}$ with a_2 w.p. $\frac{1}{2}$, and infinitely many other safe portfolios.

²The selection of zero as the threshold is arbitrary; we can work with any real scalar similarly.

³Notice that DM can explore arms with a negative expected value. However, such arms must be balanced with other arms (with positive rewards). Forbidding DM to explore arms with negative expected value trivializes the problem, as it prevents DM from exploring all arms with negative expectation. Our Bayesian safety is a compromise: it allows learning about a priori “bad” arms, but only when they are mixed with “good” arms.

⁴We assume for simplicity that there are no arms with an expected reward of 0. Our results hold in this case as well with minor modifications.

To demonstrate the technical difficulty of maximizing utility, assume that $X(a_1), X(a_2) < 0$ while $X(a_3), X(a_4) > 0$ (this information is *not* available to DM). Indeed, this happens with positive non-negligible probability under the distributional assumptions of this example. Consider the case where DM plays the portfolio a_1 w.p. 1 in the first round, and a_2 w.p. 1 in the second round. Notice that these are safe: Given her knowledge in the first round, playing a_1 w.p. 1 is safe, and regardless of $x(a_1)$, playing a_2 w.p. 1 in the second round is also safe. After observing that a_1 and a_2 have negative rewards (since we momentarily assume $X(a_1), X(a_2) < 0$), her only safe portfolio for the subsequent rounds is the safe arm a_0 w.p. 1. However, there are much better ways to act in the first round. Arms with positive expected rewards are essential for exploring arms with negative expected rewards. Consider \mathbf{p}^1 such that $\mathbf{p}^1(a_1) = \frac{1}{3}, \mathbf{p}^1(a_3) = \frac{2}{3}$ and $\mathbf{p}^1(a_2) = \mathbf{p}^1(a_4) = 0$. Notice that \mathbf{p}^1 is safe w.r.t. \mathcal{I}_1 , since $\mathbf{p}^1(a_1)\mu(a_1) + \mathbf{p}^1(a_3)\mu(a_3) = 0$. If DM plays \mathbf{p}^1 in the first round, she would discover the positive reward of arm a_3 already in the first round w.p. $\frac{2}{3}$. It is thus immediate to see that playing \mathbf{p}^1 in the first round results in higher utility than playing a_1 w.p. 1. This example illustrates that DM should use a_1 and a_2 as her “budget”, and leverage their a priori positive rewards to explore the a priori inferior arms a_3 and a_4 .

Stochastic Dominance Our main technical contribution assumes that some of the rewards are stochastically ordered. We say that a random variable X stochastically dominates (or, has first-order stochastic dominance over) a random variable Y if for every $x \in (-\infty, \infty)$, $\Pr(X \geq x) \geq \Pr(Y \geq x)$. Notice that this dominance immediately implies that $\mathbb{E}[X] \geq \mathbb{E}[Y]$.

Assumption 1. *The reward of the arms in $\text{below}(A)$ are stochastically ordered.*

Notice that this assumption applies only to a priori inferior arms, i.e., the arms in $\text{below}(A)$, and not to all arms. There are many natural cases for this assumption: Unit-variance (or any fixed variance) Gaussian like in Example 1, Bernoulli, log-normal and truncated normal, etc. When a formal statement relies on Assumption 1, we mention it explicitly.

3 Our Approach: A Goal Markov Decision Process for the Infinite case

In this section, we assume that T is infinity, that is, we care about $\lim_{T \rightarrow \infty} \mathcal{U}_T$. We develop our main technical contribution, which we outline in Algorithm 1. Algorithm 1 is asymptotically optimal, and can be computed in linearithmic time (sorting $\text{below}(A)$ according to expected values). Achieving asymptotic optimality is non-trivial and requires careful planning of the portfolios we use in every round. Mixing the wrong arms even once can be detrimental, as it may prevent us from exploring more arms or arms with better rewards. Algorithm 1 reveals an interesting insight: as long as Assumption 1 holds, we can follow a neat rule for picking portfolios efficiently in an optimal manner.⁵ In the next section, we leverage our results to derive convergence bounds for the finite case as well.

When there are infinite rounds, the following interesting property occurs.

Observation 1. *Assume that throughout the course of execution we discovered that $X(a_i) > 0$ for some arm $a_i \in A$. Then, we can use a_i to explore all other arms in finite time.*

⁵The proof of Theorem 1 suggests an immediate asymptotically optimal algorithm when Assumption 1 does not hold; however, it runs in exponential time in K . See the proof sketch for more details.

To illustrate, recall Example 1. Assume that we are in the third round, have already explored a_1 and a_2 , and discovered $X(a_1) = x(a_1) > 0$ and that $X(a_2) < 0$. Further, we did not explore a_3 and a_4 yet (one of which can still hide the highest payoff among all arms). Consider the portfolio

$$\mathbf{p}(a) = \begin{cases} \frac{-\mu(a_3)}{x(a_1) - \mu(a_3)} & \text{if } a = a_1 \\ \frac{x(a_1)}{x(a_1) - \mu(a_3)} & \text{if } a = a_3 \\ 0 & \text{otherwise} \end{cases}$$

It can be verified that $\sum_{a_i \in A^+} \mathbf{p}(a_i) \mathbb{E}[X(a_i) | \mathcal{I}_3] = 0$, and thus \mathbf{p} is safe. If we pick this portfolio, Nature flips coins to pick either a_1 and a_3 , where the latter is picked with positive probability. This Bernoulli trial might end up with selecting a_1 , but we can repeat it until Nature picks a_3 . The number of rounds required to explore a_3 follows the Geometric distribution with probability of success of $x(a_1)/x(a_1) - \mu(a_3)$ in each Bernoulli trial. Indeed, by executing Bernoulli trials until the first success, we guarantee exploring a_3 . Zooming out of Example 1 to the general case, Observation 1 suggests that once a positive reward is realized, we can execute sufficiently many Bernoulli trials to explore all the arms in finite time.

Observation 1 calls for a modelling that abstracts the setting once a positive reward is realized. More particularly, we can focus on the case where all unexplored arms are revealed instantly after we realized a positive reward. To that end, we propose a constrained Goal Markov Decision Process (GMDP), which we present in the next subsection. Our goal is to find the optimal policy⁶ for this GMDP, and then translate it to an asymptotically optimal algorithm for the corresponding IBS-P instance.

3.1 An Auxiliary Goal Markov Decision Process

We construct the GMDP as follows:

- Every state is characterized by the set of unobserved arms $s \subseteq A$, and we denote the set of all states by $\mathcal{S} = 2^A$. The initial state is $s_0 = A$.
- In every state s , we can pick any portfolio from the set of safe portfolios w.r.t. the prior information, i.e., from $\text{safe}(s) = \{\mathbf{p} \in \Delta(s) : \sum_{a \in s} \mathbf{p}(a)\mu(a) \geq 0\}$, where $\Delta(s)$ is the set of all distributions over the elements of s .
- Given a portfolio \mathbf{p} , an arm index is sampled. If the realized arm is a , the GMDP transitions to state $s \setminus \{a\}$. If $\text{safe}(s)$ is empty, then we say that s is *terminal*. In particular, we can reach a terminal state if we ran out of arms with a positive expected value, i.e., $\text{above}(s) = \emptyset$, or if we have explored all arms, i.e., $s = \emptyset$.
- Rewards are obtained in terminal states solely. The reward of a terminal state s is

$$R(s) \stackrel{\text{def}}{=} \begin{cases} \max_{a \in A} X(a) & \text{if } X(a') > 0 \text{ for } a' \in A \setminus s \\ 0 & \text{otherwise} \end{cases}.$$

Notice that the reward of a terminal state s depends on the rewards of the arms not in s . If we reached s , then we have explored $A \setminus s$. Following our intuition of Bernoulli trials, if at least one of

⁶We keep the term algorithm for solutions to IBS-P, and use the term policy for solutions of the GMDP.

Policy 1 Optimal GMDP Policy (OGP)

Input: a state $s \subseteq A$.

Output: a portfolio from $(\mathbf{p}_{i,j})_{i,j}$ or \emptyset .

- 1: **if** s is terminal **then**
 - 2: **return** \emptyset .
 - 3: **else**
 - 4: pick any arbitrary $a_i \in \text{above}(s)$.
 - 5: **if** $\text{below}(s) = \emptyset$ **then**
 - 6: **return** $\mathbf{p}_{i,i}$.
 - 7: **else**
 - 8: pick $a_{j^*} \in \arg \max_{a_j \in \text{below}(s)} \mu(a_j)$.
 - 9: **return** \mathbf{p}_{i,j^*} .
-

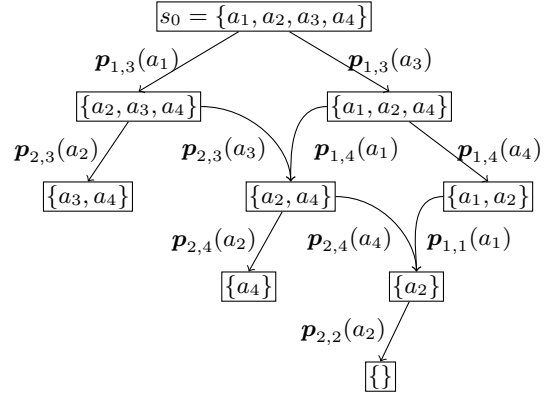

Figure 1: Illustration of OGP for Example 1.

$(X(a))_{a \in A \setminus s}$ is positive, the reward we get is $\max_{a \in A} X(a)$. Notice that the GMDP allows for the realization of each arm only once: in a state s , if a is realized we transition to $s \setminus \{a\}$. This ensures that the profiles in $\text{safe}(s)$ are also safe for an IBS-P algorithm that uses a policy for the GMDP, provided that it did not explore the arms in s .

Let $W(\pi, A)$ be the reward of a policy π starting at the initial state $s_0 = A$. Moreover, let $W^*(A)$ denote the highest possible reward of any policy, i.e., $W^*(A) = \sup_{\pi} W(\pi, A)$. Due to the construction,

Observation 2. For any algorithm ALG, it holds that $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{ALG}) \leq W^*(A)$.

Furthermore, given any policy π for the GMDP, we can construct an algorithm $\text{ALG}(\pi)$ for the corresponding IBS-P instance. At the beginning, $\text{ALG}(\pi)$ picks portfolios according to π and updates the state. Then, once π reaches a terminal state, $\text{ALG}(\pi)$ either executes Bernoulli trials until full exploration as we discussed before (in case a positive reward was realized), or plays the safe arm forever (we further elaborate when introducing Algorithm 1). It is straightforward to see that

Observation 3. for any policy π , there exists an algorithm $\text{ALG}(\pi)$ such that $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{ALG}(\pi)) = W(\pi, A)$.

As an immediate corollary, if π is an optimal policy, namely, $W(\pi, A) = W^*(A)$, then $\text{ALG}(\pi)$ is asymptotically optimal, i.e., $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{ALG}(\pi)) \geq \lim_{T \rightarrow \infty} \text{OPT}_T$. We can thus focus on finding an optimal GMDP policy, and later translate it to an asymptotically optimal algorithm for the IBS-P problem.

3.2 Optimal GMDP Policy

Next, we devise an optimal policy for this GMDP. To that end, we highlight the following family of portfolios that mix at most two arms. Consider a pair of arms, $a_i \in \text{above}(A)$, and $a_j \in \text{below}(A)$. The portfolio

$$\mathbf{p}_{i,j}(a) \stackrel{\text{def}}{=} \begin{cases} \frac{-\mu(a_j)}{\mu(a_i) - \mu(a_j)} & \text{if } a = a_i \\ \frac{\mu(a_i)}{\mu(a_i) - \mu(a_j)} & \text{if } a = a_j \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

mixes a_i and a_j while maximizing the probability of exploring a_j (the a priori inferior arm). The reader can verify that $\mathbf{p}_{i,j}$ is indeed safe, yielding an expected value of precisely zero. For completeness, for every $a_i \in \text{above}(A)$, we also define $\mathbf{p}_{i,i}$ as a deterministic selection of a_i , e.g., $\mathbf{p}_{i,i}(a) = 1$ if $a = a_i$, and zero otherwise.

We are ready to present the optimal GMDP policy (hereinafter OGP for shorthand), which we formalize via Policy 1. Given a state s , OGP(s) operates as follows. If s is terminal, it returns the empty set (Lines 1–2). Otherwise, if s is non-terminal, we enter the “else” clause in Line 3, and pick any arbitrary arm a_i from $\text{above}(s)$. Then, we have two cases. If $\text{below}(s)$ is empty, OGP returns $\mathbf{p}_{i,i}$ (Line 6). Else, it picks the best arm from $\text{below}(s)$ in terms of expected reward, which we denote by a_{j^*} (Line 8), and returns \mathbf{p}_{i,j^*} (Line 9). Overall, OGP returns \emptyset if s is terminal or a portfolio from $(\mathbf{p}_{i,j})_{i,j}$ if s is non-terminal.

Theorem 1. *Fix any arbitrary IBS-P instance satisfying Assumption 1. For OGP prescribed in Policy 1, it holds that $W(\text{OGP}, A) = W^*(A)$.*

Proof Overview of Theorem 1. Proving Theorem 1 is the main technical achievement of this paper. We defer it to Section A and outline it below.

First, using canonical arguments, we show that there exists a *stationary* optimal policy (i.e., a policy that picks a portfolio in the current state independently of the states that led to it). We call a stationary policy that picks portfolios from $(\mathbf{p}_{i,j})_{i,j}$ a \mathcal{P} -valid policy. With a bit more theory work, we show that there exists an optimal policy that is \mathcal{P} -valid. We can find such an optimal policy inefficiently using dynamic programming: in every state s , assume we know the optimal solution for $s' \subset s$. Since s leads to states of the form s/a for $a \in s$, we can compute the expected reward for each portfolio $(\mathbf{p}_{i,j})_{i,j}$, and pick the best one. There are 2^K states and $O(K^2)$ portfolios from $(\mathbf{p}_{i,j})_{i,j}$ we can play in every state, each taking $O(K)$ computations to assess; therefore, this by itself guarantees finding an optimal policy in time $O(2^K K^3)$.

To substantially reduce the computation, we need to understand the crux of the dynamic programming. A crucial ingredient of the procedure is the probability of reaching the empty state, representing the case in which we explored all arms. For every state $s \in \mathcal{S}$ and a policy π , we denote by $Q(\pi, s)$ the probability starting at $s \subseteq A$, following the policy π and reaching the empty state (exploring all arms). We then prove a rather surprising feature of Q : Q is policy independent. Namely, we show that for every two \mathcal{P} -valid policies π, ρ and every state $s \in \mathcal{S}$, it holds that $Q(\pi, s) = Q(\rho, s)$. Interestingly, the arguments we prove until this point (including the existence of an optimal \mathcal{P} -valid policy and the above Q equivalence) do not rely on Assumption 1.

Equipped with these tools, we make the final arguments. We use the recursive structure of Q and the reward function W to prove the optimality of OGP inductively over the sizes of $\text{above}(s)$ and $\text{below}(s)$. This step makes use of further insights about the dynamic programming, like monotonicity in the number of available arms. \square

We exemplify OGP for the induced GMDP of Example 1 in Figure 1. Every node is a state—the root is $s_0 = A$. In s_0 , we play the portfolio $\mathbf{p}_{1,3}$, which mixes $a_1 \in \text{above}(A)$ and $a_3 \in \text{below}(A)$ (we could have equivalently picked $\mathbf{p}_{2,3}$, since Line 4 provides us freedom in picking $a_i \in \text{above}(A)$). The split follows from Nature’s coin flips: left if the realized action is a_1 (w.p. $\mathbf{p}_{1,3}(a_1)$), and right if the action is a_3 (w.p. $\mathbf{p}_{1,3}(a_3)$). The leaves $\{a_3, a_4\}$, $\{a_4\}$, and $\{\}$ are the terminal states.

Notice that Observation 3 and Theorem 1 together suggest an optimal algorithm for IBS-P with an infinite horizon. We denote this algorithm by SEGB for brevity (following the notation of Observation 3, $\text{SEGB} = \text{ALG}(\text{OGP})$). SEGB picks portfolios according to OGP until a positive reward

Algorithm 1 Safe Exploration via GMDP and Bernoulli Trials (SEGB)

```

4:   if  $x_{a_k} > 0$  then
5:     break.
6:    $s \leftarrow s \setminus \{a_k\}$ .
7: if  $x_{a_k} > 0$  for some  $a_k \in A$  then
8:   explore all the remaining arms in  $\text{above}(A)$ .
9:    $a_{k^*} \leftarrow \arg \max_{a_i} x(a_i)$ .
10:  execute Bernoulli trials mixing  $a_{k^*}$  with every other unexplored arm until all are revealed.
11:  play the best arm forever.
12: else, play the safe arm  $a_0$  forever.
```

is realized (Lines 2–6). Then, if SEGB realized a positive reward (Line 7), it explores the remaining arms in $\text{above}(A)$ (Line 8), executes finitely many Bernoulli trials to explore all arms (Line 10), and exploits the best arm (Line 11). Otherwise, it plays the safe arm a_0 forever. As an immediate corollary of Observations 2–3 and Theorem 1:

Corollary 1. *Fix any arbitrary IBS-P instance satisfying Assumption 1. It holds that $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{SEGB}) = \lim_{T \rightarrow \infty} \text{OPT}_T$.*

4 Instance-Dependent Convergence Rate

In this section, we derive convergence rates for SEGB. First, we note that in certain cases, SEGB can be slightly modified to be optimal even for finite T . To illustrate, consider $(X(a_i))_i$ that are supported on $\{-1, +1\}$. Revealing a positive reward, which is 1 due to the $\{-1, +1\}$ support, suggests that we need not explore any further (since the other rewards cannot outperform +1); thus, the Bernoulli trials in Line 10 are redundant. Formalizing this intuition,

Proposition 1. *Fix any arbitrary IBS-P instance such that $(X(a_i))_i \in \{x^-, x^+\}$ w.p. 1, i.e., the rewards take only two possible values almost surely. Let SEGB' be a modified version of SEGB that exploits once a reward of x^+ is realized. Then, there exists T_0 such that whenever $T \geq T_0$, $\mathcal{U}_T(\text{SEGB}') = \text{OPT}_T$.*

However, SEGB is sub-optimal in the general finite case. This sub-optimality comes from various factors. First, the Bernoulli trials in Line 10 might be worthless in expectation. To illustrate, assume that there are a few rounds left, and one unexplored arm from $\text{below}(A)$. In such a case, the one-time cost of exploring this arm can be significantly lower than the value it brings to the remaining rounds. Second, recall that when we get to Line 8, some of the arms in $\text{above}(A)$ might still be explored. Deciding whether to mix such arms in Bernoulli trials or exploit them constitutes another barrier. We leave this technical challenge for future work. Instead, our goal is to derive instance-dependent bounds for Algorithm 1.

Given an IBS-P instance, let $\delta_1 = \min_{a_i \in \text{below}(A): X(a_i) > 0} X(a_i)$. Namely, δ_1 is the lowest positive reward among the arms of $\text{below}(A)$.⁷ In addition, let $\delta_2 = \max_{a_i \in \text{above}(A): X(a_i) > 0} X(a_i)$ denote the highest positive reward among the arms of $\text{above}(A)$. Recall that in Line 10 of Algorithm 1, we execute Bernoulli trials with the best seen arm. The lower bound on the reward of that arm is $\delta = \max\{\delta_1, \delta_2\}$.⁸ Furthermore, let $\gamma = \max_{a_i \in A: \mu(a_i) < 0} |\mu(a_i)|$. Notice that γ quantifies the highest absolute value of an arm in $\text{below}(A)$. The success probability of each Bernoulli trial (which leads to exploring one additional arm) is lower bounded by $\frac{\delta}{\delta + \gamma}$. Consequently, after $K(1 + \frac{\gamma}{\delta})$ Bernoulli trials in expectation, we would explore all arms. We formalize this intuition via Proposition 2 below.

Proposition 2. *Fix any arbitrary IBS-P instance satisfying Assumption 1, and let $\delta > 0$ and γ be the quantities defined above. There exists T_0 such that whenever $T > T_0$, it holds that $\mathcal{U}_T(\text{SEGB}) \geq \left(1 - \frac{K(1 + \frac{\gamma}{\delta})}{T}\right) \text{OPT}_T$.*

For example, assume that $(X(a_i))_i$ are arbitrarily distributed in the discrete set $\{-H, \dots, 0, \dots, H\}$. In such a case, $\frac{\gamma}{\delta} \leq H$; thus, SEGB is optimal up to a multiplicative factor of $\frac{K(H+1)}{T}$ (or an additive factor of $\frac{KH(H+1)}{T}$).

5 Conclusion and Open Problems

We presented a model that is inspired by recent work on safe reinforcement learning. In our model, safety constraints apply to *every* round. Moreover, reaching optimality relies heavily on careful planning, which is one more crucial element of safety-critical systems.

We see considerable scope for future work. On the technical side, one possible follow-up is to relax Assumption 1. Once we relax it, OGP ceases to be optimal due to incorrect planning. We conjecture that a different Gittins index-like policy is optimal; see Proposition 13 in the appendix for more details. A second possible follow-up is to consider stochastic bandits with Bayesian priors. Our Definition 1 is readily extendable to this case as well.

Conceptually, our definition of safety concerns the expected value, yet in many settings other factors should be taken into account, e.g., variance. In such a case, our constraint can be generalized to $\sum_{a_i \in A} \mathbf{p}(a_i) \mathbb{E}[f(X(a_i)) \mid \mathcal{I}] \geq 0$, for some function f . This more general formulation can express risk-aversion or risk-seeking behavior, as well as more complicated quantities that depend on the reward distribution. We note that our results from Section 3 hold for any general f , as long as it agrees with the stochastic order. Finally, our notion of invariable safety could be applied to other explore-exploit models, e.g., to MDPs.

A Proof Outline for Theorem 1

In this section, we outline the proof of Theorem 1. We begin with several notations and definitions we use extensively in the proof.

A.1 Preliminaries

We denote the set of all states by $\mathcal{S} = 2^A$. A *policy* is a mapping from previous states and actions to a randomized action. Formally, let \mathcal{H} be the set of histories, $\mathcal{H} = \cup_{k=0}^K (\mathcal{S} \times \Delta(A))^k$ be a tuple of pairs of states and randomized action taken. A policy π is a function $\pi : \mathcal{H} \times \mathcal{S} \rightarrow \Delta(A)$. We say that a policy is *safe* if for every $h \in \mathcal{H}, s \in \mathcal{S}, \pi(h, s) \in \text{safe}(s)$. From here on, we consider safe policies solely. Given a policy π and a pair (h, s) , we let $W(\pi, h, s)$ denote the expected reward of π when starting from s after witnessing h . Namely,

$$W(\pi, h, s) = \begin{cases} R(s) & \text{if } \text{safe}(s) = \emptyset \\ \sum_{a \in \mathcal{S}} \pi(h, s)(a) W(\pi, h \oplus (s, a), s \setminus \{a\}) & \text{otherwise} \end{cases}. \quad (2)$$

For every state s , let $W^*(s) = \sup_{\pi'} W(\pi', \emptyset, s)$.⁹ While policies may depend on histories, it is often suffice to consider stationary policies.

Definition 2 (Stationary). *A safe policy π is stationary if for every two histories $h, h' \in \mathcal{H}$ and a state $s \in \mathcal{S}, \pi(h, s) = \pi(h', s)$.*

As we show later in Proposition 3, there exists an optimal stationary policy; hence, from here on we address stationary policies solely. When discussing stationary policies, we thus neglect the dependency on h , writing $\pi(s)$. For stationary policies, the definition of W is much more intuitive: Given a stationary policy π and a state s ,

$$W(\pi, s) = \sum_{\substack{s_t \in \mathcal{S}: \\ s_t \text{ is terminal}}} \Pr(s \xrightarrow{\pi} s_t) R(s_t), \quad (3)$$

where $s \xrightarrow{\pi} s_t$ indicates the event that, starting from s and following the actions of π , the GMDP terminates at s_t .

⁹As we show in Proposition 3, there exists a policy that attains this supremum.

An additional useful notation is the following. For every state $s \in \mathcal{S}$, we denote by $Q(\pi, s)$ the probability starting at $s \subseteq A$, following the policy π and exploring all arms. Formally,

$$Q(\pi, s) = \Pr(s \xrightarrow{\pi} \emptyset),$$

Note that Q is defined recursively: Namely, if $\pi(s) = \mathbf{p}_{i,j}$ for a non-terminal state s , then

$$Q(\pi, s) = \mathbf{p}_{i,j}(a_i)Q(\pi, s \setminus \{a_i\}) + \mathbf{p}_{i,j}(a_j)Q(\pi, s \setminus \{a_j\}).$$

It will sometimes be convenient to denote $Q(\pi, \text{above}(s), \text{below}(s))$ for $Q(\pi, s)$, thereby explicitly stating the two distinguished sets of arms.

A.2 Binary Structure

A structural property of the above GMDP is that in every terminal state s_t , $\text{above}(s_t) = \emptyset$, or otherwise we could explore more arms; thus, intuitively, the arms in $\text{above}(A)$ provide us “power” to explore the arms of $\text{below}(A)$. Following this logic, in every state we should aim to explore arms from $\text{below}(A)$ and not those of $\text{above}(A)$, subject to satisfying the safety constraint.

Recall the definition of $\mathbf{p}_{i,j}$ and $\mathbf{p}_{i,i}$ from Equation 1 in Subsection 3.2. Next, we define $\mathcal{P}, \mathcal{P}'$ such that

$$\mathcal{P} \stackrel{\text{def}}{=} \{\mathbf{p}_{i,j} \mid a_i \in \text{above}(A), a_j \in \text{below}(A)\}, \quad \mathcal{P}' \stackrel{\text{def}}{=} \{\mathbf{p}_{i,i} \mid a_i \in \text{above}(A)\}.$$

Notice that $\mathcal{P} \cup \mathcal{P}'$ includes $O(K^2)$ actions, while $\text{safe}(s)$ for a state s is generally a convex polytope with infinitely many actions. Further, in every non-terminate state s , $\text{safe}(s) \cap (\mathcal{P} \cup \mathcal{P}') \neq \emptyset$.

Definition 3 (\mathcal{P} -valid). *A safe policy π is \mathcal{P} -valid if for every non-terminal state $s \in \mathcal{S}$,*

- *if $\text{below}(s) \neq \emptyset$, then $\pi(s) \in \mathcal{P}$;*
- *else, if $\text{below}(s) = \emptyset$, then $\pi(s) \in \mathcal{P}'$.*

Observe that \mathcal{P} is a strict subset of all the safe actions in the state A , which incorporate mixes of at most two arms. However, the set of safe actions $\text{safe}(s)$ for $s \subseteq A$ may include distributions mixing several elements of A . Due to the convexity of $W(\pi, s)$ in $\pi(s)$ (see the elaborated representation of W in Equation (2)), the GMDP exhibits a nice structural property, as captured by the following Proposition 3.

Proposition 3. *There exists an optimal policy which is \mathcal{P} -valid.*

The proof of Proposition 3 appears in Section H. Due to Proposition 3, we shall focus on \mathcal{P} -valid policies. Such policies are easy to visualized using trees, as we exemplify next.¹⁰

Example 2. We reconsider Example 1, but neglect the actual distributions (as we only care about the expected values). Let $A = \{a_1, a_2, a_3, a_4\}$, with $\text{above}(A) = \{a_1, a_2\}$ and $\text{below}(A) = \{a_3, a_4\}$. Consider the tree description in Figure A.2. The root of the tree is the set of all arms. At the root, the policy picks $\mathbf{p}_{1,3}$. The outgoing left edge represents the case the realized action is a_1 , which happens w.p. $\mathbf{p}_{1,3}(a_1)$. In such a case, the new state is $\{a_2, a_3, a_4\}$. With the remaining probability,

¹⁰In Figure 1 we illustrated the optimal policy using a graph that is not a tree. However, a tree structure serves better the presentation of our technical statements.

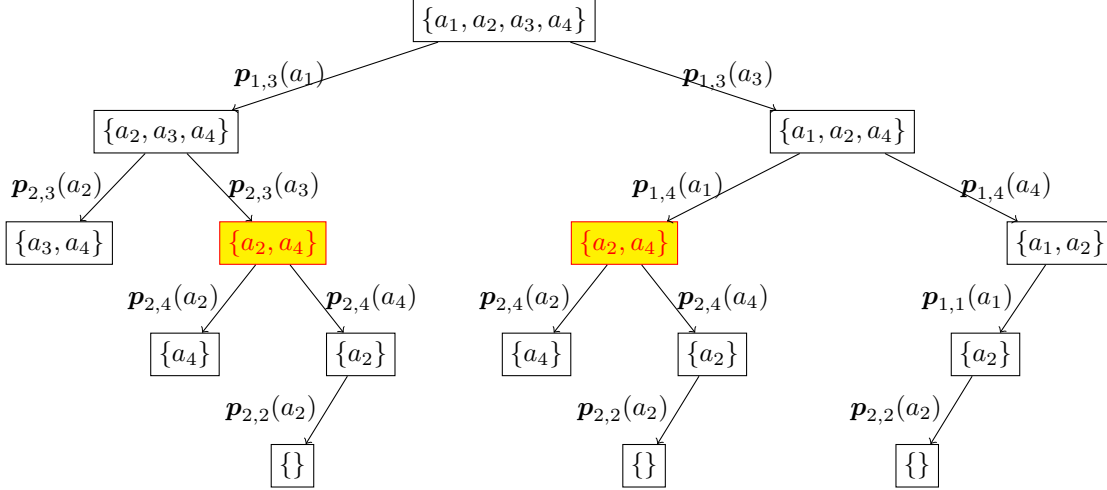

Figure 2: The policy described in Example 2. Every node represents a state (the mapping is onto, but not one-to-one). Outgoing left edges imply coin flips resulted in an arm from above(v), and outgoing right edges imply an arm from below(v). Leaves correspond to terminal states, where no action could be taken.

$\mathbf{p}_{1,3}(a_3)$, the new state will be $\{a_1, a_2, a_4\}$. Leaves of the tree are terminal states, where no further exploration could be done. For instance, in the leftmost leaf, $\{a_3, a_4\}$, the only arms explored are $\{a_1, a_2\}$. The two highlighted nodes represent the same state. Since the presented policy is \mathcal{P} -valid, it is stationary; hence, the policy acts exactly the same in these two nodes and their sub-trees.

Notice that the tree in Figure A.2 represents only the *on-path* states, i.e., states that are reachable with positive probability, while policies are functions from the entire space of states; thus, two different policies can be described using the same tree. Nevertheless, the tree structure is convenient and will be used extensively in our analysis. When we define a policy using a tree, we shall also describe its behavior at *off-path* states.

The policy exemplified in Figure A.2 has an additional combinatorial property: In every state s , it takes an action according to some order of the arms. This property is manifested in the following Definitions 4 and 5.

Definition 4 (Right-ordered policy). *A \mathcal{P} -valid policy π is right-ordered if there exist a bijection $\sigma_\pi^{\text{right}} : \text{below}(A) \rightarrow [|\text{below}(A)|]$ such that in every state s with $\text{below}(s) \neq \emptyset$, $\pi(s) = \mathbf{p}_{i,j^*}$ where $a_i \in \text{above}(s)$ and $a_{j^*} = \arg \min_{a_j \in \text{below}(s)} \sigma_\pi^{\text{right}}(a_j)$.*

Definition 5 (Left-ordered policy). *A \mathcal{P} -valid policy π is left-ordered if there exist a bijection $\sigma_\pi^{\text{left}} : \text{above}(A) \rightarrow [|\text{above}(A)|]$ such that in every state s with $\text{below}(s) \neq \emptyset$, $\pi(s) = \mathbf{p}_{i^*,j}$ where $a_j \in \text{below}(s)$ and $a_{i^*} = \arg \min_{a_i \in \text{above}(s)} \sigma_\pi^{\text{left}}(a_i)$.*

In addition, we say that a policy is *ordered* if it is right-ordered and left-ordered. To illustrate, observe the example in Figure A.2. The tree depicts an ordered policy, with $\sigma^{\text{left}} = (a_1, a_2)$ and $\sigma^{\text{right}} = (a_3, a_4)$. Notice that ordered policies are well-defined for off-path states.

A.3 Stochastic Dominance and Non-triviality

In this subsection, we demonstrate why the problem is still challenging even under Assumption 1. Recall that Proposition 3 ensures that an optimal \mathcal{P} -valid policy exists. One natural candidate for the optimal policy is ordered policy π with with any order σ_π^{left} and $\sigma_\pi^{\text{right}}$ that follow the stochastic order on $\text{below}(A)$. Indeed, as we show formally in Theorem 2, this intuition is appropriate. However, we explain shortly, the optimality of this policy cannot be shown without further work.

Consider a state $s \in \mathcal{S}$, such that $\text{above}(s), \text{below}(s) \geq 2$. Let $a_i = \arg \min_{a_{i'} \in \text{above}(s)} \sigma_\pi^{\text{left}}(a_{i'})$, and $a_j = \arg \min_{a_{j'} \in \text{below}(s)} \sigma_\pi^{\text{right}}(a_{j'})$. In addition, let $a_{\tilde{j}} \in \text{below}(s), a_{\tilde{j}} \neq a_j$. The action $\mathbf{p}_{i,j}$, which mixes the minimal elements according to the stochastic order, is weakly superior to $\mathbf{p}_{i,\tilde{j}}$ if

$$\mathbf{p}_{i,j}(j)W^*(s \setminus \{a_j\}) - \mathbf{p}_{i,\tilde{j}}(\tilde{j})W^*(s \setminus \{a_{\tilde{j}}\}) + (\mathbf{p}_{i,j}(i) - \mathbf{p}_{i,\tilde{j}}(i))W^*(s \setminus \{a_i\}) \geq 0. \quad (4)$$

By our selection of $a_j, a_{\tilde{j}}$, we know that $\mathbf{p}_{i,j}(i) - \mathbf{p}_{i,\tilde{j}}(i) \leq 0$; hence, the third term is non-positive. Moreover, as we show in Claim 5 in Section H, stochastic dominance does not imply that $W^*(s \setminus \{a_j\}) \geq W^*(s \setminus \{a_{\tilde{j}}\})$; thus, it is not even clear that the expression

$$\mathbf{p}_{i,j}(j)W^*(s \setminus \{a_j\}) - \mathbf{p}_{i,\tilde{j}}(\tilde{j})W^*(s \setminus \{a_{\tilde{j}}\})$$

which accounts for the first two terms in Inequality (4), is non-negative. Therefore, we cannot claim for Inequality (4) without revealing the structure of W^* , even when Assumption 1 holds.

A.4 Proof Overview

We are ready to prove Theorem 1. The main tool in our analysis is Lemma 1. Lemma 1 reveals a rather surprising feature of Q : Q is policy independent.

Lemma 1 (Equivalence lemma). *For every two \mathcal{P} -valid policies π, ρ and every state $s \in \mathcal{S}$, it holds that $Q(\pi, s) = Q(\rho, s)$.*

The proof of Lemma 1 appears in Section B. We stress that this lemma holds regardless of Assumption 1. Next, we leverage Lemma 1 to prove the main technical result of the paper.

Theorem 2. *Let π^* be a right-ordered, \mathcal{P} -valid policy with $\sigma_{\pi^*}^{\text{right}}$ ordered in decreasing expected value. Under Assumption 1, for every state $s \in \mathcal{S} = 2^A$, it holds that $W(\pi^*, s) = W^*(s)$.*

In particular, Theorem 2 implies that $W(\text{SEGB}, s_0) = W^*(s_0)$, since SEGB is right-ordered in decreasing expected value. The formal proof of Theorem 2 is relegated to Section E.

B Proof of Lemma 1

Proof of Lemma 1. We prove the lemma by a two-dimensional induction on the number of arms in $\text{above}(s)$ and $\text{below}(s)$. We prove four base cases in Section D:

- $|\text{above}(s)| = 1$ and $|\text{below}(s)| \geq 2$ (Proposition 6).
- $|\text{above}(s)| \geq 2$ and $|\text{below}(s)| = 1$ (Proposition 7).
- $|\text{above}(s)| \geq 2$ and $|\text{below}(s)| = 2$ (Proposition 8).

- $|\text{above}(s)| = 2$ and $|\text{below}(s)| \geq 2$ (Proposition 9).

While the first two cases are almost immediate, the other two are technical and require careful attention. Next, assume the statement holds for all states $s \in \mathcal{S}$ such that $|\text{above}(s)| \leq K_1$, $|\text{below}(s)| \leq K_2$ and $|\text{above}(s)| + |\text{below}(s)| < K_1 + K_2$.

Let $U \in \mathcal{S}$ denote a state with $|\text{above}(U)| = K_1$ and $|\text{below}(U)| = K_2$. For abbreviation, let $U_> \stackrel{\text{def}}{=} \text{above}(U)$, $U_< \stackrel{\text{def}}{=} \text{below}(U)$. Further, define $Q^*(U) = \sup_{\pi} Q(\pi, U)$,¹¹ and for every $a_i \in U_>, a_j \in U_<$ let

$$Q_{i,j}^*(U_>, U_<) \stackrel{\text{def}}{=} \mathbf{p}_{i,j}(a_j)Q^*(U_>, U_< \setminus \{a_j\}) + \mathbf{p}_{i,j}(a_i)Q^*(U_> \setminus \{a_i\}, U_<).$$

Next, let $(a_{i^*}, a_{j^*}) \in \arg \max_{a_i \in U_>, a_j \in U_<} Q_{i,j}^*(U_>, U_<)$, and assume by contradiction that there exists a pair $(a_{\bar{i}}, a_{\bar{j}})$ such that

$$Q_{i^*,j^*}^*(U) > Q_{\bar{i},\bar{j}}^*(U). \quad (5)$$

Step 1 Fix arbitrary $a_{i'}$ and $a_{j'}$ such that $a_{i'} \in U_>$ and $a_{j'} \in U_<$. We will show that

$$Q_{i',j^*}^*(U) = Q_{i',j'}^*(U). \quad (6)$$

We define the ordered policy π such that $\sigma_{\pi}^{\text{right}} = (a_{i'}, \dots)$, i.e., $\sigma_{\pi}^{\text{right}}$ first explores $a_{i'}$ and then the rest of the arms of $U_>$ in some arbitrary order; and, $\sigma_{\pi}^{\text{left}} = (a_{j^*}, a_{j'}, \dots)$. In addition, we define ρ such that $\sigma_{\rho}^{\text{left}} = \sigma_{\pi}^{\text{left}}$, and $\sigma_{\rho}^{\text{right}} = (a_{j'}, a_{j^*}, \dots)$. Due to the inductive assumption, we have

$$\begin{aligned} Q_{i',j^*}^*(U) &= \mathbf{p}_{i',j^*}(a_{j^*})Q^*(U_>, U_< \setminus \{a_{j^*}\}) + \mathbf{p}_{i',j^*}(a_{i'})Q^*(U_> \setminus \{a_{i'}\}, U_<) \\ &= \mathbf{p}_{i',j^*}(a_{j^*})Q(\pi, U_>, U_< \setminus \{a_{j^*}\}) + \mathbf{p}_{i',j^*}(a_{i'})Q(\pi, U_> \setminus \{a_{i'}\}, U_<) \\ &= Q(\pi, U). \end{aligned} \quad (7)$$

Similarly, $Q_{i',j'}^*(U) = Q(\rho, U)$; hence, proving that $Q(\pi, U) = Q(\rho, U)$ entails Equality (6). Next, let $\text{suffix}(\sigma_{\pi}^{\text{left}})$ be the set of all non-empty suffixes of $\sigma_{\pi}^{\text{left}}$. Being left-ordered suggests that on-path¹² terminal states with all arms of $U_<$ explored of π are of the form (Z, \emptyset) , where $Z \in \text{suffix}(\sigma_{\pi}^{\text{left}})$. Next, we factorize $Q(\pi, U)$ recursively as follows: We factorize $Q(\pi, U)$ into two terms, like in Equation (7). Following, for each term obtained, we ask whether the corresponding state excludes $\{a_{j^*}, a_{j'}\}$. If the answer is yes, we stop factorizing it, and move to the other terms. We do this recursively, until we cannot factorize anymore, or we reached a terminal state. Using this factorizing process, we have¹³

$$Q(\pi, U) = \alpha \cdot Q(\pi, \emptyset, U_<) + \beta \cdot Q(\pi, \emptyset, U_< \setminus \{a_{j^*}\}) + \sum_{Z \in \text{suffix}(\sigma_{\pi}^{\text{left}})} c_Z^{\pi} \cdot Q(\pi, Z, U_< \setminus \{a_{j^*}, a_{j'}\}),$$

for $\alpha = \Pr(s \xrightarrow{\pi} (\emptyset, U_<))$ and $\beta = \Pr(s \xrightarrow{\pi} (\emptyset, U_< \setminus \{a_{j^*}\}))$ such that $\alpha + \beta + \sum_{Z \in \text{suffix}(\sigma_{\pi}^{\text{left}})} c_Z^{\pi} = 1$ and $\alpha, \beta, c_Z^{\pi} \in [0, 1]$ for every $Z \in \text{suffix}(\sigma_{\pi}^{\text{left}})$. In this representation, α is the probability of reaching

¹¹This supremum is attained since there are only finitely many \mathcal{P} -valid policies.

¹²These are terminal states that π reaches to with positive probability.

¹³We stop factorizing if both $a_{j^*}, a_{j'}$ were observed; thus, Z will never be the empty set.

the terminal $(\emptyset, U_{<})$, while β is the probability of reaching the terminal state $(\emptyset, U_{<} \setminus \{a_{j^*}\})$. For these two terminal states, we know that $Q^*(\emptyset, U_{<}) = Q^*(\emptyset, U_{<} \setminus \{a_{j^*}\}) = 0$; hence,

$$Q(\pi, U) = \sum_{Z \in \text{suffix}(\sigma_\pi^{\text{left}})} c_Z^\pi \cdot Q(\pi, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}). \quad (8)$$

Following the same factorization process for ρ , we get

$$Q(\rho, U) = \sum_{Z \in \text{suffix}(\sigma_\rho^{\text{left}})} c_Z^\rho \cdot Q(\rho, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}). \quad (9)$$

Next, we want to simplify the coefficients $(c_Z^\pi)_Z$. We remark that c_Z^π is not simply the probability of reaching $(Z, U_{<} \setminus \{a_{j^*}, a_{j'}\})$ from s , i.e., $\Pr(s \xrightarrow{\pi} (Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}))$. To clarify, consider a strict suffix Z , $1 \leq |Z| < |\text{above}(A)|$, and the suffix $Z' = Z \cup \{a_l\}$ for the minimal element $a_l \in U_{>} \setminus Z$ according to σ_π^{left} , i.e., $a_l = \arg \min_{a \in U_{>} \setminus Z} \sigma_\pi^{\text{left}}(a)$. In the factorization process that produced Equation (8), once we got the term $Q(\pi, Z', U_{<} \setminus \{a_{j^*}, a_{j'}\})$, we stopped factorizing any further; thus, c_Z^π does not include the probability of reaching a node associated with $(Z', U_{<} \setminus \{a_{j^*}, a_{j'}\})$ and then following the left edge to $(Z, U_{<} \setminus \{a_{j^*}, a_{j'}\})$. However, this probability is taken into account in $\Pr(s \xrightarrow{\pi} (Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}))$. Rather, c_Z^π is the probability of reaching any node v in the tree induced by π with the following property: v represents the state $(Z, U_{<} \setminus \{a_{j^*}, a_{j'}\})$, while $a_{j'}$ does not belong to the state represented by the parent of v . In the tree interpretation, v should also be a *right child of its parent* (for instance, the left highlighted node in the tree in Figure A.2). The following Proposition 4 describes $(c_Z^\pi)_Z$ in terms of Q .

Proposition 4. *For every $Z \in \text{suffix}(\sigma_\pi^{\text{left}})$, let $a_{i(Z)} = \arg \min_{a_i \in Z} \sigma_\pi^{\text{left}}(a_i)$. It holds that*

$$c_Z^\pi = Q(\pi, U_{>} \setminus Z \cup \{a_{i(Z)}\}, \{a_{j^*}, a_{j'}\}) - Q(\pi, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\}).$$

The proof of Proposition 4 appears at the end of this proof. Notice that for every Z , c_Z^π includes values of Q with less arms than U (besides, perhaps, the case where $|U_{>}| = 2$ and $|Z| = 1$ obtaining $Q(\pi, U_{>}, \{a_{j^*}, a_{j'}\})$, but we cover this case in the bases cases); consequently, due to the inductive step

$$c_Z^\pi = Q(\rho, U_{>} \setminus Z \cup \{a_{i(Z)}\}, \{a_{j^*}, a_{j'}\}) - Q(\rho, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\}) = c_Z^\rho, \quad (10)$$

where the last equality follows from mirroring Proposition 4 for $(c_Z^\rho)_Z$. Ultimately,

$$\begin{aligned} Q(\pi, U) &\stackrel{\text{Eq. (8)}}{=} \sum_{Z \in \text{suffix}(\sigma_\pi^{\text{left}})} c_Z^\pi \cdot Q(\pi, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}) \stackrel{\text{Eq. (10)}}{=} \sum_{Z \in \text{suffix}(\sigma_\pi^{\text{left}})} c_Z^\rho \cdot Q(\pi, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}) \\ &\stackrel{\text{Ind. step}}{=} \sum_{Z \in \text{suffix}(\sigma_\pi^{\text{left}})} c_Z^\rho \cdot Q(\rho, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}) \stackrel{\sigma_\rho^{\text{left}} = \sigma_\pi^{\text{left}}}{=} \sum_{Z \in \text{suffix}(\sigma_\rho^{\text{left}})} c_Z^\rho \cdot Q(\rho, Z, U_{<} \setminus \{a_{j^*}, a_{j'}\}) \\ &\stackrel{\text{Eq. (9)}}{=} Q(\rho, U). \end{aligned}$$

This completes Step 1.

Step 2 Fix arbitrary $a_{i'}$ and $a_{j'}$ such that $a_{i'} \in U_>$ and $a_{j'} \in U_<$. We will show that

$$Q_{i^*,j'}^*(U) = Q_{i',j'}^*(U). \quad (11)$$

We follow the same technique as in the previous step. Let π be an ordered policy such that $\sigma_\pi^{\text{left}} = (a_{i^*}, a_{i'}, \dots)$, i.e., σ_π^{left} ranks a_{i^*} first, $a_{i'}$ second and then follows some arbitrary order on the remaining arms, and $\sigma_\pi^{\text{right}} = (a_{j'}, \dots)$. In addition, we define the ordered policy ρ with $\sigma_\rho^{\text{left}} = (a_{i'}, a_{i^*}, \dots)$, where the dots refer to any arbitrary order on the remaining elements of $U_>$, and $\sigma_\rho^{\text{right}} = \sigma_\pi^{\text{right}} = (a_{j'}, \dots)$. Using the inductive step and the same arguments as in Equation (7), it suffices to show that $Q(\pi, U) = Q(\rho, U)$. We factorize $Q(\pi, U)$ recursively such that

$$Q(\pi, U) = Q(\pi, \{a_{i^*}, a_{i'}\}, U_<) + \sum_{Z \in \text{suffix}(\sigma_\pi^{\text{right}})} d_Z^\pi \cdot Q(\pi, U_> \setminus \{a_{i^*}, a_{i'}\}, Z), \quad (12)$$

and similarly

$$Q(\rho, U) = Q(\rho, \{a_{i^*}, a_{i'}\}, U_<) + \sum_{Z \in \text{suffix}(\sigma_\rho^{\text{right}})} d_Z^\rho \cdot Q(\rho, U_> \setminus \{a_{i^*}, a_{i'}\}, Z). \quad (13)$$

Next, we claim that

Proposition 5. *For every $Z \in \text{suffix}(\sigma_\pi^{\text{right}})$, let $a_{j(Z)} = \arg \min_{a_j \in Z} \sigma_\pi^{\text{right}}(a_j)$. It holds that*

$$d_Z^\pi = Q(\pi, \{a_{i^*}, a_{i'}\}, U_< \setminus Z) - Q(\pi, \{a_{i^*}, a_{i'}\}, U_< \setminus Z \cup \{a_{j(Z)}\}).$$

The proof of Proposition 5 appears at the end of this proof. Notice that for every Z , d_Z^π includes values of Q with less arms than U (besides, perhaps, the case where $|U_<| = 2$ and $|Z| = 1$ obtaining $Q(\pi, \{a_{i^*}, a_{i'}\}, U_<)$), but we cover this case in the bases cases); consequently, due to the inductive step

$$d_Z^\pi = Q(\rho, \{a_{i^*}, a_{i'}\}, U_< \setminus Z) - Q(\rho, \{a_{i^*}, a_{i'}\}, U_< \setminus Z \cup \{a_{j(Z)}\}) = d_Z^\rho, \quad (14)$$

where the last equality follows from mirroring Proposition 5 for $(d_Z^\rho)_Z$. Ultimately, by rearranging Equation (12) and invoking the inductive step, Equation (14) and the fact that $\sigma_\rho^{\text{right}} = \sigma_\pi^{\text{right}}$, we get

$$Q(\pi, U) = Q(\rho, \{a_{i^*}, a_{i'}\}, U_<) + \sum_{Z \in \text{suffix}(\sigma_\rho^{\text{right}})} d_Z^\rho \cdot Q(\rho, U_> \setminus \{a_{i^*}, a_{i'}\}, Z) \stackrel{\text{Eq. (13)}}{=} Q(\pi, U),$$

implying Equation (11) holds.

Step 3 We are ready to prove the lemma. Fix arbitrary $a_{\bar{i}}$ and $a_{\bar{j}}$ such that $a_{\bar{i}} \in U_>$ and $a_{\bar{j}} \in U_<$. By the previous Step 1 and Step 2 we know that

$$Q_{i^*,j^*}^*(U) \stackrel{\text{Step 1}}{=} Q_{i^*,\bar{j}}^*(U) \stackrel{\text{Step 2}}{=} Q_{\bar{i},\bar{j}}^*(U),$$

which contradicts Equation (5); hence, the lemma holds. \square

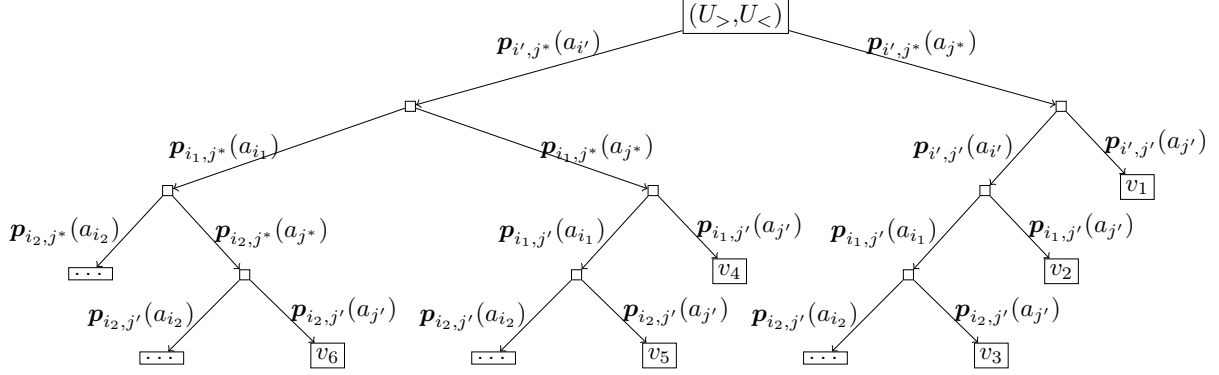

Figure 3: Illustration for Proposition 4. The tree depicts $T(\pi)$. Nodes v_1 to v_6 are nodes whose sub-trees were pruned in the construction of T . Let $Z = U_{>} \setminus \{a_{i'}, a_{i_1}\}$ and $Z^c = \{a_{i'}, a_{i_1}\}$. The minimal element of Z , denoted $a_{i(Z)}$ in the proof, is a_{i_2} . The corresponding c_Z^π is the probability to reach one of $\{v_3, v_5, v_6\}$, namely, $c_Z^\pi = \Pr(\{v_3, v_5, v_6\})$. In the tree T , we ignore sub-trees of nodes v labeled with “...” since these do not contribute to c_Z^π . Observe that the probability of reaching v_i , for $i \in \{1, \dots, 6\}$ is the same in $T(\pi)$ and T . Finally, notice that $Q(\pi, U_{>} \setminus Z \cup \{a_{i(Z)}, \{a_{j^*}, a_{j'}\}\}) = \Pr(\{v_1, v_2, \dots, v_6\})$, and $Q(\pi, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\}) = \Pr(\{v_1, v_2, v_4\})$. Combining, we get that $c_Z^\pi = Q(\pi, U_{>} \setminus Z \cup \{a_{i(Z)}, \{a_{j^*}, a_{j'}\}\}) - Q(\pi, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\}) = \Pr(\{v_3, v_5, v_6\})$ as required.

C Additional Statements for Lemma 1

Proof of Proposition 4. To prove this claim, we focus on the tree induced by π , $T(\pi)$. It is convenient to discuss a modified version $T(\pi)$ obtained by pruning, and this is feasible since even if prune nodes from $T(\pi)$ it still remains Markov chain. We illustrate the proof of this claim in Figure 3.

We factorize $Q(\pi, U)$ recursively (see Equation (8)) until we hit a node associated with a state that excludes $\{a_{j^*}, a_{j'}\}$, or a leaf. This factorization can be illustrated as follows: We traverse $T(\pi)$, from right to left. Every node we visit, we ask whether that node includes $\{a_{j^*}, a_{j'}\}$. If it does not, we prune its sub-tree (i.e., it becomes a leaf) while leaving it intact. Denote the obtained tree by T , and let $V(T)$ be its set of nodes. Observe that

Observation 4. *Every leaf v in $V(T)$ satisfies exactly one property:*

Type 1: $\text{above}(\text{state}(v)) = \emptyset$, or

Type 2: $\text{below}(\text{state}(v)) = U_{<} \setminus \{j^*, j'\}$ with $\text{below}(\text{state}(v)) \subset \text{below}(\text{state}(\text{parent}(v)))$.

Leaves of type 1 are associated with terminal states of the MDP (see Subsection 3.1). Leaves of type 2 are those whose sub-trees were pruned during the traversal. Moreover, $\text{below}(\text{state}(v)) \subset \text{below}(\text{state}(\text{parent}(v)))$ holds in every such a leaf v , since otherwise we would have pruned its parent. Due to Observation 4, every node v with $\text{state}(v) = (Z, U_{<} \setminus \{a_{j^*}, a_{j'}\})$ is of type 2; therefore,

$$c_Z^\pi = \sum_{\substack{v \in V(T): \text{state}(v) = \\ (Z, U_{<} \setminus \{a_{j^*}, a_{j'}\})}} \Pr(\text{root}(T) \rightsquigarrow v). \quad (15)$$

Next, fix an arbitrary non-empty Z , $Z \subseteq U_{>}$, and Ψ be the set of all non empty suffixes of $U_{>} \setminus Z$. Consider T and its root $root(T)$. Notice that $Q(\pi, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\})$ is the probability of reaching a (type 2) leaf v such that $above(v) = \psi \cup Z$ for some $\psi \in \Psi$. This is true since π is ordered, and every path from $root(T)$ to such a leaf v does not include any action from Z ; hence, we can compare the probability of reaching it to off-path behavior of π . Further, $Q(\pi, U_{>} \setminus Z \cup \{a_{i(Z)}\}, \{a_{j^*}, a_{j'}\})$ is the probability of reaching a (type 2) leaf v such that $above(v) = \psi \cup Z$ for some $\psi \in \Psi$ or $above(v) = Z$; hence,

$$Q(\pi, U_{>} \setminus Z \cup \{a_{i(Z)}\}, \{a_{j^*}, a_{j'}\}) - Q(\pi, U_{>} \setminus Z, \{a_{j^*}, a_{j'}\})$$

is precisely the right-hand-side of Equation (15). \square

Proof of Proposition 5. Fix $Z \in \text{suffix}(\sigma_{\pi}^{\text{right}})$, and let $a_{j(Z)} = \arg \min_{a_j \in Z} \sigma_{\pi}^{\text{right}}(a_j)$. Let $T(\pi)$ denote the tree induced by π . Observe that

Observation 5. *The coefficient d_Z^{π} is the probability to get to a node v in $T(\pi)$ such that*

1. $state(v) = (U_{>} \setminus \{a_{i^*}, a_{i'}\}, Z)$, and
2. $state(parent(v)) = (U_{>} \setminus \{a_{i^*}\}, Z)$.

The first condition is immediate, due to the way we factorize Q in Equation (12). To see why the second condition holds, notice that $state(parent(v))$ must be a strict superset of $state(v)$; hence, $state(parent(v))$ could be either $(U_{>} \setminus \{a_{i^*}\}, Z)$ or $(U_{>} \setminus \{a_{i^*}, a_{i'}\}, Z \cup \{a\})$ for $a \in U_{<} \setminus Z$, but then it would contribute to $d_{Z \cup \{a\}}^{\pi}$, namely, to another summand in Equation (12).

Denote by V the set of all nodes that satisfy the conditions of Observation 5. Due to the way we constructed π , the paths from the root of $T(\pi)$ to any node in V consist of actions that involve the arms $\{a_{i^*}, a_{i'}, a_{j(Z)}\} \cup (U_{<} \setminus Z)$ solely; hence, we can focus on the off-path tree whose root is $s'_0 \stackrel{\text{def}}{=} \{a_{i^*}, a_{i'}\} \cup (U_{<} \setminus Z) \cup \{a_{j(Z)}\}$, and the actions are precisely as in the tree induced by π (according to the order of π). Denote this new tree by T' , and let

$$V' \stackrel{\text{def}}{=} \left\{ v \in \text{nodes}(T) \mid state(v) = \{a_{j(Z)}\} \right\}.$$

Due to this construction,

Observation 6. *The coefficient d_Z^{π} is the probability to get to a node that belongs to V' in T' .*

The observation follows from the one-to-one correspondence between the nodes and path in $T(\pi)$ and their counterparts in the off-path tree T' .

In T' , $Q(\pi, s'_0)$ is the probability of starting at s'_0 and reaching the leaf with no arms (terminal state \emptyset), i.e., exploring $U_{<} \setminus Z$ and $a_{j(Z)}$. In contrast, $Q(\pi, \{a_{i^*}, a_{i'}\} \cup (U_{<} \setminus Z))$ is the probability of starting at s'_0 and reaching a node (internal or terminal) v with $state(v) = \cap (U_{<} \setminus Z) = \emptyset$, namely, exploring $U_{<} \setminus Z$. Such a node v leads to a leaf with probability 1; hence, paths from v end in leaves associated with the states \emptyset or $\{a_{j(Z)}\}$ only. Consequently,

$$Q(\pi, \{a_{i^*}, a_{i'}\} \cup (U_{<} \setminus Z)) - Q(\pi, \{a_{i^*}, a_{i'}\} \cup (U_{<} \setminus Z) \cup \{a_{j(Z)}\})$$

is the probability of starting at s'_0 , and reaching a terminal node that belongs to V' . \square

D Base Cases for Lemma 1

Proposition 6. Let $|U_>| = 1$ and $|U_<| \geq 2$. For any pair of policies π, ρ , it holds that $Q(\pi, U_>, U_<) = Q(\rho, U_>, U_<)$.

Proof of Proposition 6. Let $\tilde{\mu}(a) \stackrel{\text{def}}{=} |\mu(a)|$, and denote $U_> = \{a_{i_1}\}$ and $U_< = \{a_{j_1}, \dots, a_{j_k}\}$ for $k = |U_<|$. The probability of reaching the empty terminal state under any \mathcal{P} -valid policy is

$$\prod_{l=1}^k \frac{\tilde{\mu}(a_{j_l})}{\tilde{\mu}(a_{j_l}) + \tilde{\mu}(a_{i_1})},$$

i.e., the probability of successfully exploring $U_<$. Due to multiplication associativity, the above expression is invariant of the way we order its elements. Finally, by definition of Q , this implies that $Q(\pi, U_>, U_<) = Q(\rho, U_>, U_<)$. \square

Proposition 7. Let $|U_>| \geq 2$ and $|U_<| = 1$. For any pair of policies π, ρ , it holds that $Q(\pi, U_>, U_<) = Q(\rho, U_>, U_<)$.

Proof of Proposition 7. Let $\tilde{\mu}(a) \stackrel{\text{def}}{=} |\mu(a)|$, and denote $U_> = \{a_{i_1}, \dots, a_{i_k}\}$ for $k = |U_>|$ and $U_< = \{a_{j_1}\}$. The probability of reaching the terminal state (a_{j_1}) under any \mathcal{P} -valid policy is

$$\prod_{l=1}^k \frac{\tilde{\mu}(a_{i_l})}{\tilde{\mu}(a_{i_l}) + \tilde{\mu}(a_{j_1})},$$

i.e., the probability of failing to explore a_{j_1} . Due to multiplication associativity, the above expression is invariant of the way we order its elements. Finally, by definition of Q , this implies that $1 - Q(\pi, U_>, U_<) = 1 - Q(\rho, U_>, U_<)$; hence, $Q(\pi, U_>, U_<) = Q(\rho, U_>, U_<)$. \square

Proposition 8. Let U be an arbitrary state, such that $U_> \stackrel{\text{def}}{=} \text{above}(U) = 2$ and $U_< \stackrel{\text{def}}{=} \text{below}(U) \geq 2$. For any pair of \mathcal{P} -valid policies π and ρ , it holds that $Q(\pi, U) = Q(\rho, U)$.

Proof of Proposition 8. We prove the claim by induction, with Proposition 7 serving as the base case. Assume the claim holds for $|U_<| = k - 1$. It is enough to show that if $|U_<| = k$, for any $a_i \in U_>, a_j \in U_<$, $Q_{i,j}^*(U) = Q^*(U)$. Assume that $Q_{i_1, j_1}^*(U) = Q^*(U)$, and fix any $a_{i'} \in U_>, a_{j'} \in U_<$.

Remark We do not use Assumption 1 here.

Step 1 Assume that $i' = i_1$ and $j' \neq j_1$. W.l.o.g. $j' = j_2$. We construct two policies, π that ordered $U_<$ as $\sigma_\pi^{\text{right}} = (a_{j_1}, a_{j_2}, \dots, a_{j_k})$, and ρ that orders $U_<$ as $\sigma_\rho^{\text{right}} = (a_{j_2}, a_{j_1}, \dots, a_{j_k})$. Both policies order $U_>$ according to $\sigma_\pi^{\text{left}} = \sigma_\rho^{\text{left}} = (a_{i_1}, a_{i_2})$. Due to the inductive step and our assumption that $Q_{i_1, j_1}^*(U) = Q^*(U)$, we have that $Q(\pi, U) = Q^*(U)$, and

$$Q(\pi, U_>, U_<) = \underbrace{\prod_{l=1}^k p_{i_1, j_l}(a_{j_l})}_{\lambda(\pi)} + \underbrace{\sum_{f=1}^k \left(\prod_{l=1}^{f-1} p_{i_1, j_l}(a_{j_l}) \right) p_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k p_{i_2, j_l}(a_{j_l}) \right)}_{\delta(\pi)}.$$

Notice that $\lambda(\pi) = \lambda(\rho)$. In addition, we have that

$$\begin{aligned}
\delta(\pi) &= \mathbf{p}_{i_1, j_1}(a_{i_1}) \prod_{l=1}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \\
&\quad + \mathbf{p}_{i_1, j_1}(a_{j_1}) \sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right) \\
&= \mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) \mathbf{p}_{i_2, j_2}(a_{j_2}) \prod_{l=3}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \\
&\quad + \mathbf{p}_{i_1, j_1}(a_{j_1}) \left[\mathbf{p}_{i_1, j_2}(a_{i_1}) \mathbf{p}_{i_2, j_2}(a_{j_2}) \prod_{l=3}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right. \\
&\quad \quad \left. + \mathbf{p}_{i_1, j_2}(a_{j_2}) \sum_{f=3}^k \left(\prod_{l=3}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right) \right] \\
&= \mathbf{p}_{i_2, j_2}(a_{j_2}) \left(\mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \right) \prod_{l=3}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \\
&\quad + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{j_2}) \sum_{f=3}^k \left(\prod_{l=3}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right). \tag{16}
\end{aligned}$$

We show that

Claim 1. *It holds that*

$$\begin{aligned}
&\mathbf{p}_{i_2, j_2}(a_{j_2}) \left(\mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \right) \\
&= \mathbf{p}_{i_2, j_1}(a_{j_1}) \left(\mathbf{p}_{i_1, j_2}(a_{i_1}) \mathbf{p}_{i_2, j_2}(a_{j_2}) + \mathbf{p}_{i_1, j_2}(a_{j_2}) \mathbf{p}_{i_1, j_1}(a_{i_1}) \right).
\end{aligned}$$

Now, set $\sigma : \mathbb{N} \rightarrow \mathbb{N}$ such that $\sigma(1) = 2$, $\sigma(2) = 1$, and $\sigma(i) = i$ for $i \geq 3$; hence, using Claim 1,

$$\begin{aligned}
\text{Eq. (16)} &= \mathbf{p}_{i_1, j_2}(a_{i_1}) \mathbf{p}_{i_2, j_2}(a_{j_2}) \mathbf{p}_{i_2, j_1}(a_{j_1}) \prod_{l=3}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \\
&\quad + \mathbf{p}_{i_1, j_2}(a_{j_2}) \left[\mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) \prod_{l=3}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right. \\
&\quad \quad \left. + \mathbf{p}_{i_1, j_1}(a_{j_1}) \sum_{f=3}^k \left(\prod_{l=3}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right) \right] \\
&= \sum_{f=1}^k \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \mathbf{p}_{i_1, j_{\sigma(f)}}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \\
&= \delta(\rho) \tag{17}
\end{aligned}$$

Step 2 Assume that $i' = i_2 \neq i_1$ and $j' = j_1$. We construct two policies, π that orders $U_{>}$ as $\sigma_{\pi}^{\text{left}} = (a_{i_1}, a_{i_2})$, and ρ that orders $U_{>}$ as $\sigma_{\rho}^{\text{left}} = (a_{i_2}, a_{i_1})$. Both policies order $U_{<}$ by

$\sigma_\pi^{\text{right}} = \sigma_\rho^{\text{right}} = (a_{j_1}, a_{j_2}, \dots, a_{j_k})$. In addition, we introduce a third policy, $\tilde{\rho}$, that has the same order as ρ on $U_>$, namely $\sigma_{\tilde{\rho}}^{\text{left}} = \sigma_\rho^{\text{left}} = (a_{i_2}, a_{i_1})$, and orders $U_<$ by $\sigma_{\tilde{\rho}}^{\text{right}} = (a_{j_k}, a_{j_2}, \dots, a_{j_{k-1}}, a_{j_1})$. It holds that

$$\begin{aligned}
Q(\pi, U_>, U_<) &= \prod_{l=1}^k \mathbf{p}_{i_1, j_l}(a_{j_l}) + \sum_{f=1}^k \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_2, j_l}(a_{j_l}) \right) \\
&= \underbrace{\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \prod_{l=2}^{k-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) + \mathbf{p}_{i_2, j_k}(a_{j_k})}_{I_1} \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{i_1}) \underbrace{\prod_{l=2}^{k-1} \mathbf{p}_{i_1, j_l}(a_{j_l})}_{I_1} \right. \\
&\quad \left. + \sum_{f=1}^{k-1} \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^{k-1} \mathbf{p}_{i_2, j_l}(a_{j_l}) \right) \right] \\
&= \underbrace{\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \mathbf{p}_{i_2, j_k}(a_{j_k})}_{I_2} I_1 + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \mathbf{p}_{i_2, j_k}(a_{i_2}) I_1 \\
&\quad + \mathbf{p}_{i_2, j_k}(a_{j_k}) \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{i_1}) I_1 + I_2 \right] \\
&= \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \mathbf{p}_{i_2, j_k}(a_{i_2}) I_1 \\
&\quad + \mathbf{p}_{i_2, j_k}(a_{j_k}) \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) I_1 + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{i_1}) I_1 + I_2 \right] \\
&= \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \mathbf{p}_{i_2, j_k}(a_{i_2}) I_1 + \mathbf{p}_{i_2, j_k}(a_{j_k}) \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) I_1 + I_2 \right]. \tag{18}
\end{aligned}$$

Next, observe that

$$\left[\mathbf{p}_{i_1, j_1}(a_{j_1}) I_1 + I_2 \right] = \prod_{l=1}^{k-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) + \sum_{f=1}^{k-1} \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_1, j_l}(a_{j_l}) \right) \mathbf{p}_{i_1, j_f}(a_{i_1}) \left(\prod_{l=f}^{k-1} \mathbf{p}_{i_2, j_l}(a_{j_l}) \right). \tag{19}$$

Notice that the latter is precisely $Q(\pi, \{a_{i_1}, a_{i_2}, a_{j_1}, \dots, a_{j_{k-1}}\})$; thus, the inductive step implies that it is order invariant. Let $\sigma : \mathbb{N} \rightarrow \mathbb{N}$ such that $\sigma(1) = k, \sigma(k) = 1$, and $\sigma(i) = i$ for $1 < i < k$. Since $Q(\pi, \{a_{i_1}, a_{i_2}, a_{j_1}, \dots, a_{j_{k-1}}\}) = Q(\tilde{\rho}, \{a_{i_1}, a_{i_2}, a_{j_1}, \dots, a_{j_{k-1}}\})$, we conclude that the expression in Equation (19) equals

$$\prod_{l=2}^k \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) + \sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \mathbf{p}_{i_2, j_{\sigma(f)}}(a_{i_2}) \left(\prod_{l=f}^k \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right).$$

Combining this with Equation (18),

$$\begin{aligned}
\text{Eq. (18)} &= \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_k}(a_{j_k}) \mathbf{p}_{i_2, j_k}(a_{i_2}) \prod_{l=2}^{k-1} \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \\
&\quad + \mathbf{p}_{i_2, j_k}(a_{j_k}) \left[\prod_{l=2}^k \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) + \sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \mathbf{p}_{i_2, j_{\sigma(f)}}(a_{i_2}) \left(\prod_{l=f}^k \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \right] \\
&= \mathbf{p}_{i_2, j_k}(a_{i_2}) \prod_{l=1}^k \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) + \mathbf{p}_{i_2, j_k}(a_{j_k}) \prod_{l=2}^k \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \\
&\quad + \mathbf{p}_{i_2, j_k}(a_{j_k}) \left[\sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \mathbf{p}_{i_2, j_{\sigma(f)}}(a_{i_2}) \left(\prod_{l=f}^k \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \right] \\
&= \prod_{l=1}^k \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) + \sum_{f=1}^k \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_2, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \mathbf{p}_{i_2, j_{\sigma(f)}}(a_{i_2}) \left(\prod_{l=f}^k \mathbf{p}_{i_1, j_{\sigma(l)}}(a_{j_{\sigma(l)}}) \right) \\
&= Q(\tilde{\rho}, U), \tag{20}
\end{aligned}$$

where the last equality follows from the definition of $\tilde{\rho}$ (orders the arms precisely so). Finally, $Q(\tilde{\rho}, U) = Q(\rho, U)$ follows from the previous Step 1.

Step 3 The two previous steps imply that for any $a_{i'} \in U_>, a_{j'} \in U_<$, it holds that

$$Q_{i', j'}(U) = Q_{i', j_1}(U) = Q_{i_1, j_1}(U).$$

This completes the proof of Proposition 8. \square

Proof of Claim 1. To ease readability, let $\tilde{\mu}_i \stackrel{\text{def}}{=} |\mu(a_i)|$ for every $a_i \in A$. It holds that

$$\begin{aligned}
&\mathbf{p}_{i_2, j_2}(j_2) \left(\mathbf{p}_{i_1, j_1}(i_1) \mathbf{p}_{i_2, j_1}(j_1) + \mathbf{p}_{i_1, j_1}(j_1) \mathbf{p}_{i_1, j_2}(i_1) \right) \\
&= \frac{\tilde{\mu}_{i_2}}{\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2}} \left(\frac{\tilde{\mu}_{j_1}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}} \frac{\tilde{\mu}_{i_2}}{\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}} + \frac{\tilde{\mu}_{i_1}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}} \frac{\tilde{\mu}_{j_2}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}} \right) \\
&= \frac{\tilde{\mu}_{i_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) + \tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1})}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
&= \frac{\overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{i_1}}^I + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{j_2}}^{II} + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2}}^{III} + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{j_1}}^{IV}}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
&= \frac{\overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2} \tilde{\mu}_{i_1}}^{III} + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2} \tilde{\mu}_{j_1}}^{II} + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2}}^I + \overbrace{\tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_1} \tilde{\mu}_{j_2}}^{IV}}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
&= \frac{\tilde{\mu}_{i_2} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2} (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) + \tilde{\mu}_{i_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_1} (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
&= \mathbf{p}_{i_2, j_1}(j_1) \left(\mathbf{p}_{i_1, j_2}(i_1) \mathbf{p}_{i_2, j_2}(j_2) + \mathbf{p}_{i_1, j_2}(j_2) \mathbf{p}_{i_1, j_1}(i_1) \right)
\end{aligned}$$

\square

Proposition 9. Let U be an arbitrary state, such that $U_{>} \stackrel{\text{def}}{=} \text{above}(U) \geq 2$ and $U_{<} \stackrel{\text{def}}{=} \text{below}(U) = 2$. For any pair of \mathcal{P} -valid policies π and ρ , it holds that $Q(\pi, U) = Q(\rho, U)$.

Proof of Proposition 9. The proof of this proposition goes along the lines of the proof of Proposition 8, but we provide the details here for completeness. For simplicity, we let $\bar{Q} = 1 - Q$, and prove that for any two policies π, ρ it holds that $\bar{Q}(\pi, U) = \bar{Q}(\rho, U)$.

We prove the claim by induction, with Proposition 6 serving as the base case. Assume the claim holds for $|U_{>}| = k - 1$. It is enough to show that if $|U_{>}| = k$, for any $a_i \in U_{>}, a_j \in U_{<}$, $Q_{i,j}^*(U) = Q^*(U)$. Assume that $Q_{i_1, j_1}^*(U) = Q^*(U)$, and define a policy π such that $\sigma_{\pi}^{\text{right}} = (a_{j_1}, a_{j_2})$ and $\sigma_{\pi}^{\text{left}} = (a_{i_1}, a_{i_2}, \dots, a_{i_k})$. Next, fix any $a_{i'} \in U_{>}, a_{j'} \in U_{<}$.

Remark We do not use Assumption 1 here.

Step 1 Assume that $i' \neq i_1$ and $j' = j_1$. W.l.o.g. $i' = i_2$. We construct the ordered policy ρ that orders $U_{<}$ by $\sigma_{\rho}^{\text{right}} = \sigma_{\pi}^{\text{right}} = (a_{j_1}, a_{j_2})$ and $U_{>}$ by $\sigma_{\rho}^{\text{left}} = (a_{i_2}, a_{i_1}, \dots, a_{i_k})$. Due to the inductive step and our assumption that $Q_{i_1, j_1}^*(U) = Q^*(U)$, we have that $\bar{Q}(\pi, U) = \bar{Q}^*(U)$. For brevity, we introduce the following notations. For $r \in \{1, 2, 3\}$, let

$$\lambda_{j_1}^r = \prod_{l=r}^k \mathbf{p}_{i_l, j_1}(a_{i_l}), \lambda_{j_2}^r = \prod_{l=r}^k \mathbf{p}_{i_l, j_2}(a_{i_l}), \delta^r = \sum_{f=r}^k \left(\prod_{l=r}^{f-1} \mathbf{p}_{i_l, j_1}(a_{i_l}) \right) \mathbf{p}_{i_f, j_1}(a_{j_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_l, j_2}(a_{i_l}) \right).$$

Observe that

$$\begin{aligned} \bar{Q}(\pi, U) &= \lambda_{j_1}^1 + \delta^1 = \lambda_{j_1}^1 + \mathbf{p}_{i_1, j_1}(a_{j_1}) \lambda_{j_2}^1 + \mathbf{p}_{i_1, j_1}(a_{i_1}) \delta^2 \\ &= \lambda_{j_1}^1 + \mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \mathbf{p}_{i_2, j_2}(a_{i_2}) \lambda_{j_2}^3 \\ &\quad + \mathbf{p}_{i_1, j_1}(a_{i_1}) \left[\mathbf{p}_{i_2, j_1}(a_{j_1}) \mathbf{p}_{i_2, j_2}(a_{i_2}) \lambda_{j_2}^3 + \mathbf{p}_{i_2, j_1}(a_{i_2}) \delta^3 \right]. \end{aligned} \quad (21)$$

Next, we show that

Claim 2. It holds that

$$\begin{aligned} &\mathbf{p}_{i_2, j_2}(a_{i_2}) \left(\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) + \mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) \right) \\ &= \mathbf{p}_{i_1, j_2}(a_{i_1}) \left(\mathbf{p}_{i_2, j_1}(a_{j_1}) \mathbf{p}_{i_2, j_2}(a_{i_2}) + \mathbf{p}_{i_2, j_1}(a_{i_2}) \mathbf{p}_{i_1, j_1}(a_{j_1}) \right). \end{aligned}$$

Combining Equation (21) and Claim 2, we get

$$\begin{aligned} \text{Eq. (21)} &= \lambda_{j_1}^1 + \mathbf{p}_{i_2, j_1}(a_{j_1}) \mathbf{p}_{i_2, j_2}(a_{i_2}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \lambda_{j_2}^3 \\ &\quad + \mathbf{p}_{i_2, j_1}(a_{i_2}) \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \lambda_{j_2}^3 + \mathbf{p}_{i_1, j_1}(a_{i_1}) \delta^3 \right] \\ &= \lambda_{j_1}^1 + \mathbf{p}_{i_2, j_1}(a_{j_1}) \lambda_{j_2}^1 + \mathbf{p}_{i_2, j_1}(a_{i_2}) \left[\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) \lambda_{j_2}^3 + \mathbf{p}_{i_1, j_1}(a_{i_1}) \delta^3 \right] \end{aligned} \quad (22)$$

Now, set $\sigma : \mathbb{N} \rightarrow \mathbb{N}$ such that $\sigma(1) = 2, \sigma(2) = 1$, and $\sigma(i) = i$ for $i \geq 3$; hence,

$$\begin{aligned}
\text{Eq. (22)} &= \lambda_{j_1}^1 + \mathbf{p}_{i_2, j_1}(a_{j_1}) \lambda_{j_2}^1 \\
&\quad + \mathbf{p}_{i_2, j_1}(a_{i_2}) \left[\sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{i_{\sigma(l)}, j_1}(a_{i_{\sigma(l)}}) \right) \mathbf{p}_{i_{\sigma(f)}, j_1}(a_{j_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_{\sigma(l)}, j_2}(a_{i_{\sigma(l)}}) \right) \right] \\
&= \lambda_{j_1}^1 + \sum_{f=1}^k \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_{\sigma(l)}, j_1}(a_{i_{\sigma(l)}}) \right) \mathbf{p}_{i_{\sigma(f)}, j_1}(a_{j_1}) \left(\prod_{l=f}^k \mathbf{p}_{i_{\sigma(l)}, j_2}(a_{i_{\sigma(l)}}) \right) \\
&= \overline{Q}(\rho, U).
\end{aligned}$$

This concludes Step 1.

Step 2 Assume that $i' = i_1$ and $j' = j_2 \neq j_1$. We construct two ordered policies, ρ and $\tilde{\rho}$ such that $\sigma_\rho^{\text{right}} = \sigma_{\tilde{\rho}}^{\text{right}} = (a_{j_2}, a_{j_1})$ and $\sigma_\rho^{\text{left}} = (a_{i_1}, a_{i_2}, \dots, a_{i_k}), \sigma_{\tilde{\rho}}^{\text{left}} = (a_{i_k}, a_{i_2}, \dots, a_{i_{k-1}}, a_{i_1})$. The previous Step 1 implies that $\overline{Q}(\rho, U) = \overline{Q}(\tilde{\rho}, U)$; thus, it suffices to show that $\overline{Q}(\pi, U) = \overline{Q}(\tilde{\rho}, U)$. Notice that

$$\begin{aligned}
\overline{Q}(\pi, U) &= \mathbf{p}_{i_k, j_1}(a_{i_k}) \overbrace{\prod_{l=1}^{k-1} \mathbf{p}_{i_l, j_1}(a_{i_l})}^{I_1} \\
&\quad + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\underbrace{\mathbf{p}_{i_k, j_1}(a_{j_1}) \prod_{l=1}^{k-1} \mathbf{p}_{i_l, j_1}(a_{i_l})}_{I_1} + \underbrace{\sum_{f=1}^{k-1} \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_l, j_1}(a_{i_l}) \right) \mathbf{p}_{i_f, j_1}(a_{j_1}) \left(\prod_{l=f}^{k-1} \mathbf{p}_{i_l, j_2}(a_{i_l}) \right)}_{I_2} \right] \quad (23)
\end{aligned}$$

Rearranging,

$$\begin{aligned}
\text{Eq. (23)} &= \mathbf{p}_{i_k, j_1}(a_{i_k}) I_1 + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\mathbf{p}_{i_k, j_1}(a_{j_1}) I_1 + I_2 \right] \\
&= \mathbf{p}_{i_k, j_1}(a_{i_k}) \left(\mathbf{p}_{i_k, j_2}(a_{i_k}) + \mathbf{p}_{i_k, j_2}(a_{j_2}) \right) I_1 + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\mathbf{p}_{i_k, j_1}(a_{j_1}) I_1 + I_2 \right] \\
&= \mathbf{p}_{i_k, j_1}(a_{i_k}) \mathbf{p}_{i_k, j_2}(a_{j_2}) I_1 + \mathbf{p}_{i_k, j_2}(a_{i_k}) [I_1 + I_2]. \quad (24)
\end{aligned}$$

Recall that

$$I_1 + I_2 = \prod_{l=1}^{k-1} \mathbf{p}_{i_l, j_1}(a_{i_l}) + \sum_{f=1}^{k-1} \left(\prod_{l=1}^{f-1} \mathbf{p}_{i_l, j_1}(a_{i_l}) \right) \mathbf{p}_{i_f, j_1}(a_{j_1}) \left(\prod_{l=f}^{k-1} \mathbf{p}_{i_l, j_2}(a_{i_l}) \right), \quad (25)$$

which is precisely $\overline{Q}(\pi, \{a_{i_1}, \dots, a_{i_{k-1}}, a_{j_1}, a_{j_2}\})$; thus, the inductive step implies that it is order invariant. Let $\sigma : \mathbb{N} \rightarrow \mathbb{N}$ such that $\sigma(1) = k, \sigma(k) = 1$, and $\sigma(i) = i$ for $1 < i < k$. Since $\overline{Q}(\pi, \{a_{i_1}, \dots, a_{i_{k-1}}, a_{j_1}, a_{j_2}\}) = \overline{Q}(\tilde{\rho}, \{a_{i_1}, \dots, a_{i_{k-1}}, a_{j_1}, a_{j_2}\})$, we conclude that the expression in Equation (25) equals

$$\prod_{l=2}^k \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) + \sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \right) \mathbf{p}_{\sigma(i_f), j_2}(a_{j_2}) \left(\prod_{l=f}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) \right).$$

Notice that in the above expression, we first try to explore a_{j_2} , and only then a_{j_1} . Combining this with Equation (24),

$$\begin{aligned}
& \text{Eq. (24)} = \mathbf{p}_{i_k, j_1}(a_{i_k}) \mathbf{p}_{i_k, j_2}(a_{j_2}) I_1 \\
& + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\prod_{l=2}^k \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) + \sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \right) \mathbf{p}_{\sigma(i_f), j_2}(a_{j_2}) \left(\prod_{l=f}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) \right) \right]. \\
& = \mathbf{p}_{i_k, j_1}(a_{i_k}) \mathbf{p}_{i_k, j_2}(a_{j_2}) \prod_{l=1}^{k-1} \mathbf{p}_{i_l, j_1}(a_{i_l}) + \mathbf{p}_{i_k, j_2}(a_{i_k}) \prod_{l=2}^k \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \\
& + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \right) \mathbf{p}_{\sigma(i_f), j_2}(a_{j_2}) \left(\prod_{l=f}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) \right) \right] \\
& = \mathbf{p}_{i_k, j_2}(a_{j_2}) \prod_{l=1}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) + \prod_{l=1}^k \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \\
& + \mathbf{p}_{i_k, j_2}(a_{i_k}) \left[\sum_{f=2}^k \left(\prod_{l=2}^{f-1} \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \right) \mathbf{p}_{\sigma(i_f), j_2}(a_{j_2}) \left(\prod_{l=f}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) \right) \right] \\
& = \prod_{l=1}^k \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) + \sum_{f=1}^k \left(\prod_{l=1}^{f-1} \mathbf{p}_{\sigma(i_l), j_2}(a_{\sigma(i_l)}) \right) \mathbf{p}_{\sigma(i_f), j_2}(a_{j_2}) \left(\prod_{l=f}^k \mathbf{p}_{\sigma(i_l), j_1}(a_{\sigma(i_l)}) \right),
\end{aligned}$$

and the latter is precisely $\overline{Q}(\tilde{\rho}, U)$.

Step 3 The two previous steps imply that for any $a_{i'} \in U_>, a_{j'} \in U_<$, it holds that

$$\overline{Q}_{i', j'}(U) = \overline{Q}_{i', j_1}(U) = \overline{Q}_{i_1, j_1}(U).$$

This completes the proof of Proposition 9. □

Proof of Claim 2. To ease readability, let $\tilde{\mu}_i \stackrel{\text{def}}{=} |\mu(a_i)|$ for every $a_i \in A$. It holds that

$$\begin{aligned}
& \mathbf{p}_{i_2, j_2}(a_{i_2}) \left(\mathbf{p}_{i_1, j_1}(a_{j_1}) \mathbf{p}_{i_1, j_2}(a_{i_1}) + \mathbf{p}_{i_1, j_1}(a_{i_1}) \mathbf{p}_{i_2, j_1}(a_{j_1}) \right) \\
& = \frac{\tilde{\mu}_{j_2}}{\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2}} \left(\frac{\tilde{\mu}_{i_1}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}} \frac{\tilde{\mu}_{j_2}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}} + \frac{\tilde{\mu}_{j_1}}{\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}} \frac{\tilde{\mu}_{i_2}}{\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2}} \right) \\
& = \frac{\tilde{\mu}_{j_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) + \tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2})}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
& = \frac{\overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2}}^I + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{j_1}}^{II} + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{i_1}}^{III} + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{j_2}}^{IV}}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
& = \frac{\overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{i_2}}^I + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{j_2}}^{IV} + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_2} \tilde{\mu}_{i_1}}^{III} + \overbrace{\tilde{\mu}_{j_2} \tilde{\mu}_{i_1} \tilde{\mu}_{j_2} \tilde{\mu}_{j_1}}^{II}}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
& = \frac{\tilde{\mu}_{j_2} \tilde{\mu}_{i_2} \tilde{\mu}_{j_2} (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) + \tilde{\mu}_{j_2} \tilde{\mu}_{j_1} \tilde{\mu}_{i_1} (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})}{(\tilde{\mu}_{i_1} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_1} + \tilde{\mu}_{j_2}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_1}) (\tilde{\mu}_{i_2} + \tilde{\mu}_{j_2})} \\
& = \mathbf{p}_{i_1, j_2}(a_{i_1}) \left(\mathbf{p}_{i_2, j_1}(a_{j_1}) \mathbf{p}_{i_2, j_2}(a_{i_2}) + \mathbf{p}_{i_2, j_1}(a_{i_2}) \mathbf{p}_{i_1, j_1}(a_{j_1}) \right).
\end{aligned}$$

□

E Proof of Theorem 2

Proof of Theorem 2. Fix an arbitrary instance. We prove the claim by a two-dimensional induction on the size of $\text{above}(s)$, $\text{below}(s)$, for states $s \in \mathcal{S}$. The base cases are

- $|\text{above}(s)| \geq 2$ and $|\text{below}(s)| = 1$ (Proposition 11), and
- $|\text{above}(s)| = 1$ and $|\text{below}(s)| \geq 2$ (Proposition 12),

which we relegate to Section F. Next, assume the statement holds for all $s \in \mathcal{S}$ such that $|\text{above}(s)| \leq K_1$, $|\text{below}(s)| \leq K_2$ and $|\text{above}(s)| + |\text{below}(s)| < K_1 + K_2$. Let $U \in \mathcal{S}$ denote a state with $|\text{above}(U)| = K_1$ and $|\text{below}(U)| = K_2$. For abbreviation, let $U_> \stackrel{\text{def}}{=} \text{above}(U) = \{a_{i_1}, a_{i_2}, \dots, a_{i_{K_1}}\}$ and $U_< \stackrel{\text{def}}{=} \text{below}(U) = \{a_{j_1}, a_{j_2}, \dots, a_{j_{K_2}}\}$, and assume the indices follow the stochastic order. Further, for every $a_i \in U_>, a_j \in U_<$ let

$$W_{i,j}^*(U_>, U_<) \stackrel{\text{def}}{=} \mathbf{p}_{i,j}(a_j)W^*(U_>, U_< \setminus \{a_j\}) + \mathbf{p}_{i,j}(a_i)W^*(U_> \setminus \{a_i\}, U_<).$$

We need to prove that $W_{i_1, j_1}^*(s) = W^*(s)$.

Remarks Notice that if $X_{a_{i'}} > 0$ for $a_{i'} \in \text{above}(A)$, any \mathcal{P} -valid policy gets $W^*(s)$. To see this, recall that \mathcal{P} -valid policies reach terminate states only after exploring all arms in $\text{above}(A)$. Consequently, we assume for the rest of the proof that $X_{a_{i'}} \leq 0$ for $a_{i'} \in \text{above}(A)$.

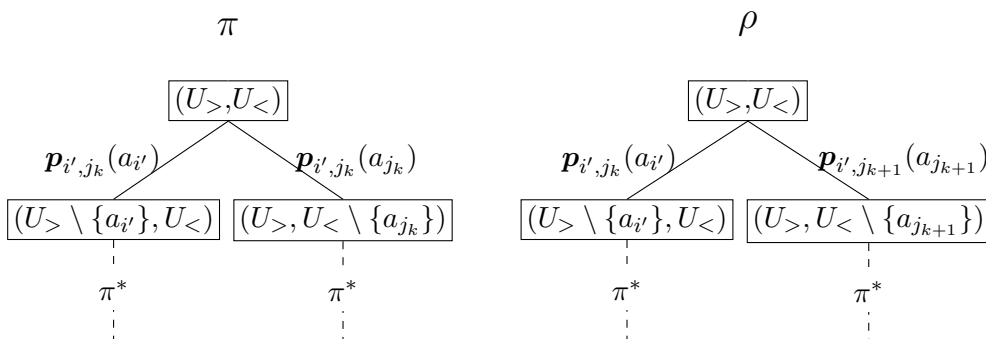

Figure 4: Illustration of the policies π, ρ from Step 1 of Theorem 2. Notice that the left sub-trees of π and ρ are identical.

Step 1 Fix $a_{i'} \in U_>$. We show that for every $k, 1 \leq k < K_2$ it holds that $W_{i', j_k}^*(s) \geq W_{i', j_{k+1}}^*(s)$. We define the ordered, \mathcal{P} -valid policy π^* by $\sigma_{\pi^*}^{\text{left}} = (a_{i'}, \dots)$ namely, $\sigma_{\pi^*}^{\text{left}}$ ranks $a_{i'}$ first and all the other arms in $U_>$ arbitrarily, and $\sigma_{\pi^*}^{\text{right}} = (a_{j_1}, a_{j_2}, \dots, a_{j_{K_2}})$. Due to the inductive assumption, for every state s with $|s| < |U|$, $W^*(s) = W(\pi^*, s)$. Next, we define the policies π, ρ explicitly, as follows:

$$\pi(s) = \begin{cases} \mathbf{p}_{i', j_k} & \text{if } s = (U_>, U_<) \\ \pi^*(s) & \text{otherwise} \end{cases}, \quad \rho(s) = \begin{cases} \mathbf{p}_{i', j_{k+1}} & \text{if } s = (U_>, U_<) \\ \pi^*(s) & \text{otherwise} \end{cases}.$$

We illustrate π and ρ in Figure E. Note that both π, ρ have on-path states that are off-path for π^* . For instance, ρ reaches the state $(U_>, U_< \setminus \{a_{j_{k+1}}\})$ with positive probability, while π^* cannot reach it at all. In addition, π and ρ are left-ordered with $\sigma_\pi^{\text{left}} = \sigma_\rho^{\text{left}} = \sigma_{\pi^*}^{\text{left}}$. Due to the inductive assumption, it is enough to show that $W(\pi, U) - W(\rho, U) \geq 0$, as this implies $W_{i', j_k}^*(s) \geq W_{i', j_{k+1}}^*(s)$.

Next, we factorize $W(\pi, U)$ as follows: for every state $U' \subset U$, we factor $W(\pi, U')$ as long as $a_{j_k}, a_{j_{k+1}} \in U'$. Once we reach a term $W(\pi, U')$ with $a_{j_k}, a_{j_{k+1}} \notin U'$, we stop. Let $\Psi \stackrel{\text{def}}{=} \text{prefix}(a_{j_1}, a_{j_2}, \dots, a_{j_{k-1}})$ be the set of (possibly empty) prefixes of the first $k-1$ arms in $U_<$ according to π^* . Observe that¹⁴

$$\begin{aligned} W(\pi, U) &= \sum_{\psi \in \Psi} \Pr(s \xrightarrow{\pi} (U_< \setminus \psi)) R(U_< \setminus \psi) + \Pr(s \xrightarrow{\pi} (U_< \setminus (\psi \cup \{a_{j_k}\}))) R(U_< \setminus (\psi \cup \{a_{j_k}\})) \\ &\quad + \underbrace{\sum_{Z \in \text{suffix}(\sigma_\pi^{\text{left}})} f_Z^\pi \cdot W(\pi, Z, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\})}_{I^\pi} \end{aligned} \quad (26)$$

The coefficients (f_Z^π) follow from the factorization process. Using similar factorization,

$$\begin{aligned} W(\rho, U) &= \sum_{\psi \in \Psi} \Pr(s \xrightarrow{\rho} (U_< \setminus \psi)) R(U_< \setminus \psi) + \Pr(s \xrightarrow{\rho} (U_< \setminus (\psi \cup \{a_{j_{k+1}}\}))) R(U_< \setminus (\psi \cup \{a_{j_{k+1}}\})) \\ &\quad + \underbrace{\sum_{Z \in \text{suffix}(\sigma_\rho^{\text{left}})} f_Z^\rho \cdot W(\rho, Z, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\})}_{I^\rho}. \end{aligned} \quad (27)$$

Next, we express $(f_Z^\pi)_Z$ in terms of Q . By relying on the Equivalence lemma, we show that

Claim 3. *For every $Z \in \text{suffix}(\sigma_\pi^{\text{left}}) = \text{suffix}(\sigma_\rho^{\text{left}})$, it holds that $f_Z^\pi = f_Z^\rho$.*

To see why Claim 3 holds, notice that we can represent f_Z^π as

$$Q(\pi, U_> \setminus Z \cup \{a_{i(Z)}\}, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\}) - Q(\pi, U_> \setminus Z, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\}),$$

where $a_{i(Z)}$ is the minimal element in Z according to σ_π^{left} . By invoking the Equivalence lemma, we can replace π in the above expression with ρ and thus for every $Z \in \text{suffix}(\sigma_\pi^{\text{left}}) = \text{suffix}(\sigma_\rho^{\text{left}})$, it holds that $f_Z^\pi = f_Z^\rho$. Combining Claim 3 with the inductive step and $\sigma_\pi^{\text{left}}, \sigma_\rho^{\text{left}}$ being equal, we conclude that $I^\pi = I^\rho$.

Next, we focus on the first sum of $W(\pi, U)$ in Equation (26). For every $\psi \in \Psi$, we denote the event E_ψ^π as a shorthand for

$$E_\psi^\pi \stackrel{\text{def}}{=} (s \xrightarrow{\pi} (U_< \setminus \psi)) \cup (s \xrightarrow{\pi} (U_< \setminus (\psi \cup \{a_{j_k}\}))).$$

In words, E_ψ^π is the event that the GMDP reaches the final state $(U_< \setminus \psi)$ or $(U_< \setminus (\psi \cup \{a_{j_k}\}))$ after starting in s_0 and following π . We use conditional expectation to simplify the summands in

¹⁴The reader can think of ψ as the set of arms from $(a_{j_1}, a_{j_2}, \dots, a_{j_{k-1}})$ that were explored.

the first sum of Equation (26),

$$\begin{aligned}
& \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) R(U_{<} \setminus \psi) + \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_k}\}))) R(U_{<} \setminus (\psi \cup \{a_{j_k}\})) \\
&= \Pr(E_{\psi}^{\pi}) \cdot \underbrace{\left(\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) | E_{\psi}^{\pi}) R(U_{<} \setminus \psi) + \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_k}\})) | E_{\psi}^{\pi}) R(U_{<} \setminus (\psi \cup \{a_{j_k}\})) \right)}_{\alpha_{\psi}^{\pi}} \\
&= \Pr(E_{\psi}^{\pi}) \alpha_{\psi}^{\pi}.
\end{aligned} \tag{28}$$

Similarly for ρ , by letting

$$E_{\psi}^{\rho} \stackrel{\text{def}}{=} \left(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) \right) \cup \left(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \right)$$

and following the derivation in Equation (28) for ρ , we get

$$\begin{aligned}
& \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) R(U_{<} \setminus \psi) + \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\}))) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \\
&= \Pr(E_{\psi}^{\rho}) \cdot \underbrace{\left(\Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) | E_{\psi}^{\rho}) R(U_{<} \setminus \psi) + \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) | E_{\psi}^{\rho}) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \right)}_{\alpha_{\psi}^{\rho}} \\
&= \Pr(E_{\psi}^{\rho}) \alpha_{\psi}^{\rho}.
\end{aligned} \tag{29}$$

Due to the fact that $I^{\pi} = I^{\rho}$ and relying on Equations (26)-(29), we have

$$W(\pi, U) - W(\rho, U) = \sum_{\psi \in \Psi} \left(\Pr(E_{\psi}^{\pi}) \alpha_{\psi}^{\pi} - \Pr(E_{\psi}^{\rho}) \alpha_{\psi}^{\rho} \right). \tag{30}$$

At this point, we might be tempted to show that every summand of the sum in Equation (30) is non-negative. Unfortunately, this approach would not work—stochastic dominance does not mean $\Pr(E_{\psi}^{\pi}) \alpha_{\psi}^{\pi} \geq \Pr(E_{\psi}^{\rho}) \alpha_{\psi}^{\rho}$. Instead, we take a different approach. For every $l, 1 \leq l \leq k-1$ let E_l^{π} denote the event that a_{j_l} was observed in the final state. Formally,

$$E_l^{\pi} \stackrel{\text{def}}{=} \bigcup_{\substack{\psi' \in \Psi \\ a_{j_l} \in \psi'}} \left(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi') \right) \cup \left(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus (\psi' \cup \{a_{j_k}\})) \right).$$

In addition, we let E_k^{π} denote the empty event, and E_0^{π} be the full event (that occurs w.p. 1). For every non-empty $\psi \in \Psi$, i.e. $|\psi| \geq 1$, let $\max(\psi) \stackrel{\text{def}}{=} \arg \max_{j_l: a_{j_l} \in \psi} \sigma_{\pi^*}^{\text{right}}(a_{j_l})$. According to our assumption about the index of the arms, $\max(\psi)$ is simply the maximal index of an arm in ψ (that is well-defined when $|\psi| \geq 1$). In addition, for completeness, if $\psi = \emptyset$ we let $\max(\emptyset) = 0$. We can use the terms $(E_l^{\pi})_{l=0}^k$ to provide an alternative form for E_{ψ}^{π} :

$$E_{\psi}^{\pi} = E_{\max(\psi)}^{\pi} \setminus E_{\max(\psi)+1}^{\pi}.$$

Put differently, for ψ with $\max(\psi) < k-1$, E_{ψ}^{π} can be viewed as the collection of all of events in which arm $a_{j_{\max(\psi)}}$ was explored, but arm $a_{j_{\max(\psi)+1}}$ was not (where the ‘‘arm’’ a_{j_0} for $\psi = \emptyset$ refers to E_0^{π}). Recall that for ψ with $\max(\psi) = k-1$, $E_{\psi}^{\pi} = E_{\max(\psi)}^{\pi}$ since E_k^{π} is the empty event.

Since $E_{\max(\psi)+1}^{\pi} \subseteq E_{\max(\psi)}^{\pi}$, we have that for every $\psi \in \Psi$,

$$\Pr(E_{\psi}^{\pi}) = \Pr(E_{\max(\psi)}^{\pi}) - \Pr(E_{\max(\psi)+1}^{\pi}), \tag{31}$$

taking care of edge cases too. By renaming α_ψ^π to $\alpha_{\max(\psi)}^\pi$, i.e., $\alpha_{\max(\psi)}^\pi \stackrel{\text{def}}{=} \alpha_\psi^\pi$, and rearranging Equation (26) using Equations (28) and (31),

$$W(\pi, U) = I^\pi + \sum_{\psi \in \Psi} \Pr(E_\psi^\pi) \alpha_\psi^\pi = I^\pi + \sum_{l=0}^{k-1} (\Pr(E_l^\pi) - \Pr(E_{l+1}^\pi)) \alpha_l^\pi. \quad (32)$$

By defining E_l^ρ analogously,

$$E_l^\rho \stackrel{\text{def}}{=} \bigcup_{\substack{\psi' \in \Psi \\ a_{j_l} \in \psi'}} \left(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi') \right) \cup \left(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi' \cup \{a_{j_{k+1}}\})) \right),$$

and following similar arguments, we conclude that

$$W(\rho, U) = I^\rho + \sum_{\psi \in \Psi} \Pr(E_\psi^\rho) \alpha_\psi^\rho = I^\rho + \sum_{l=0}^{k-1} (\Pr(E_l^\rho) - \Pr(E_{l+1}^\rho)) \alpha_l^\rho. \quad (33)$$

By rephrasing Equation (30) using Equations (32) and (33),

$$W(\pi, U) - W(\rho, U) = \sum_{l=0}^{k-1} (\Pr(E_l^\pi) - \Pr(E_{l+1}^\pi)) \alpha_l^\pi - (\Pr(E_l^\rho) - \Pr(E_{l+1}^\rho)) \alpha_l^\rho. \quad (34)$$

Next, we show two monotonicity properties.

Proposition 10. *Under Assumption 1,*

1. for every $l \in \{0, 1, \dots, k-1\}$, it holds that $\alpha_l^\pi \geq \alpha_l^\rho$.
2. for every $l \in \{0, 1, \dots, k-2\}$, it holds that $\alpha_{l+1}^\pi \geq \alpha_l^\pi$ and $\alpha_{l+1}^\rho \geq \alpha_l^\rho$.

In fact, this is the only place in the proof of Theorem 2 where we rely on Assumption 1. Equipped with Proposition 10, we can make the final argument. For every $r, r \in \{1, \dots, k-1\}$ let

$$f(r) \stackrel{\text{def}}{=} (\Pr(E_r^\pi) - \Pr(E_r^\rho)) \alpha_{r-1}^\pi.$$

In addition, let

$$g(r) \stackrel{\text{def}}{=} \sum_{l=0}^r (\Pr(E_l^\pi) - \Pr(E_{l+1}^\pi)) \alpha_l^\pi - (\Pr(E_l^\rho) - \Pr(E_{l+1}^\rho)) \alpha_l^\rho$$

We shall show that for every $r, r \in \{0, \dots, k-2\}$ it holds that

$$W(\pi, U) - W(\rho, U) \geq f(r+1) + g(r). \quad (35)$$

For $r = k-2$, we have

$$\begin{aligned} \text{Eq. (34)} &= (\Pr(E_{k-1}^\pi) - \Pr(E_k^\pi)) \alpha_{k-1}^\pi - (\Pr(E_{k-1}^\rho) - \Pr(E_k^\rho)) \alpha_{k-1}^\rho + g(k-2) \\ &\stackrel{E_k^\pi, E_k^\rho \text{ are empty}}{=} \Pr(E_{k-1}^\pi) \alpha_{k-1}^\pi - \Pr(E_{k-1}^\rho) \alpha_{k-1}^\rho + g(k-2) \\ &\stackrel{\text{Prop. 10.1}}{\geq} (\Pr(E_{k-1}^\pi) - \Pr(E_{k-1}^\rho)) \alpha_{k-1}^\pi + g(k-2) \\ &\stackrel{\text{Prop. 10.2}}{\geq} (\Pr(E_{k-1}^\pi) - \Pr(E_{k-1}^\rho)) \alpha_{k-2}^\pi + g(k-2) \\ &= f(k-1) + g(k-2). \end{aligned}$$

Assume Inequality (35) holds for $r + 1$. Then, for r we have

$$\begin{aligned}
f(r+1)+g(r) &= (\Pr(E_{r+1}^\pi) - \Pr(E_{r+1}^\rho))\alpha_r^\pi + g(r-1) \\
&\quad + (\Pr(E_r^\pi) - \Pr(E_{r+1}^\pi))\alpha_r^\pi - \underbrace{(\Pr(E_r^\rho) - \Pr(E_{r+1}^\rho))\alpha_r^\rho}_{\geq 0, \text{ Eq. (31)}} \\
&\stackrel{\text{Prop. 10.1}}{\geq} (\Pr(E_{r+1}^\pi) - \Pr(E_{r+1}^\rho))\alpha_r^\pi + g(r-1) \\
&\quad + (\Pr(E_r^\pi) - \Pr(E_{r+1}^\pi))\alpha_r^\pi - (\Pr(E_r^\rho) - \Pr(E_{r+1}^\rho))\alpha_r^\pi \\
&= \Pr(E_r^\pi)\alpha_r^\pi - \Pr(E_r^\rho)\alpha_r^\pi + g(r-1) \\
&\stackrel{\text{Prop. 10.2}}{\geq} \Pr(E_r^\pi)\alpha_{r-1}^\pi - \Pr(E_r^\rho)\alpha_{r-1}^\pi + g(r-1) \\
&= f(r) + g(r-1).
\end{aligned}$$

Ultimately, by setting $r = 0$ in Inequality (35),

$$\begin{aligned}
W(\pi, U) - W(\rho, U) &\geq f(1) + g(0) \\
&= (\Pr(E_1^\pi) - \Pr(E_1^\rho))\alpha_0^\pi \\
&\quad + (\Pr(E_0^\pi) - \Pr(E_1^\pi))\alpha_0^\pi - (\Pr(E_0^\rho) - \Pr(E_1^\rho))\alpha_0^\rho \\
&\geq \Pr(E_0^\pi)\alpha_0^\pi - \Pr(E_0^\rho)\alpha_0^\rho \\
&= 0.
\end{aligned}$$

This concludes the first step of the theorem.

Step 2 In this step, we show that for every k , $1 \leq k < K_1$ it holds that $W_{i_k, j_1}^*(s) = W_{i_{k+1}, j_1}^*(s)$. Define an ordered, \mathcal{P} -valid policy π^* by $\sigma_{\pi^*}^{\text{left}} = (a_{i_1}, a_{i_2}, \dots, a_{i_{K_1}})$, namely, $\sigma_{\pi^*}^{\text{left}}$ ranks the elements of $U_{>}$ according to the stochastic order, and $\sigma_{\pi^*}^{\text{right}} = (a_{j_1}, a_{j_2}, \dots, a_{j_{K_2}})$. Due to the inductive assumption, for every state s with $|s| < |U|$, $W^*(s) = W(\pi^*, s)$. Next, we define the policies π, ρ explicitly, as follows:

$$\pi(s) = \begin{cases} \mathbf{p}_{i_k, j_1} & \text{if } s = (U_{>}, U_{<}) \\ \pi^*(s) & \text{otherwise} \end{cases}, \quad \rho(s) = \begin{cases} \mathbf{p}_{i_{k+1}, j_1} & \text{if } s = (U_{>}, U_{<}) \\ \pi^*(s) & \text{otherwise} \end{cases}.$$

As in the previous step, the inductive step suggests that showing $W(\pi, s) = W(\rho, s)$ is suffice. However, unlike the previous step, here the set of reachable terminal state is the same for π and ρ ; hence, this equality is almost immediate due to the Equivalence lemma. Let $\Psi' \stackrel{\text{def}}{=} \text{prefix}(a_{j_1}, a_{j_2}, \dots, a_{j_{K_2-1}})$ be the set of (possibly empty) prefixes of the arms in $U_{<} \setminus \{a_{j_{K_2}}\}$ according to π^* . Observe that we can factorize $W(\pi, s)$ as follows:

$$W(\pi, s) = Q(\pi, U) \cdot R(\emptyset) + \sum_{\psi \in \Psi'} \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) R(U_{<} \setminus \psi). \tag{36}$$

The next Claim 4 suggests we can replace probabilities with functions of Q .

Claim 4. *For every $\psi \in \Psi'$, it holds that*

$$\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) = Q(\pi, U_{>}, \psi) - Q(\pi, U_{>}, \psi \cup \{a_{j_{\max(\psi)+1}}\}).$$

By applying the Equivalence lemma on the statement of Claim 4, we obtain that for every $\psi \in \Psi$

$$\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) = \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi));$$

hence, we can rewrite Equation (36) as

$$\begin{aligned} W(\pi, s) &= Q(\rho, U) \cdot R(\emptyset) + \sum_{\psi \in \Psi} \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) R(U_{<} \setminus \psi) \\ &= W(\rho, s). \end{aligned}$$

This concludes the second step of the theorem.

Step 3 (final) We are ready to prove the theorem. Fix arbitrary $a_{\bar{i}}$ and $a_{\bar{j}}$ such that $a_{\bar{i}} \in U_{>}$ and $a_{\bar{j}} \in U_{<}$. By the previous steps, we know that

$$W_{i_1, j_1}^*(U) \stackrel{\text{Step 2}}{=} W_{\bar{i}, \bar{j}}^*(U) \stackrel{\text{Step 1}}{\geq} W_{\bar{i}, \bar{j}}^*(U).$$

This ends the proof of Theorem 2. \square

F Statements for Theorem 2

Proposition 11. *Let U be a state such that $|\text{above}(U)| \geq 2$ and $|\text{below}(U)| = 1$. It holds that $W(\pi^*, U) = W^*(U)$.*

Proof of Proposition 11. Denote $\text{below}(U) = \{a_j\}$. We can assume w.l.o.g. that the realization of all arms in $\text{above}(U)$ are non-positive, as otherwise every \mathcal{P} -valid policy will explore all the arms; thus, $W^*(U) = Q^*(U) \cdot \max\{0, X_{a_j}\}$. Finally, the Equivalence lemma suggests that $Q^*(U)$ is policy invariant; hence, $W(\pi, U) = W^*(U)$ holds for any \mathcal{P} -valid policy π , and in particular for $\pi = \pi^*$. \square

Proposition 12. *Let U be a state such that $|\text{above}(U)| = 1$ and $|\text{below}(U)| \geq 2$. It holds that $W(\pi^*, U) = W^*(U)$.*

Proof of Proposition 12. This statement is a special case of Proposition 13 for instances satisfying Assumption 1. \square

Proposition 13. *Let U be a state such that $|\text{above}(U)| = 1$ and $|\text{below}(U)| \geq 2$. Let f^* be a real-valued function, $f^* : \text{below}(U) \rightarrow \mathbb{R}$, such that for every $a_l \in \text{below}(U)$,*

$$f^*(a_l) = \frac{\Pr(X_{a_l} > 0) \mathbb{E}(\max_{a_j \in U} X_{a_j} \mid X_{a_l} > 0)}{|\mu(a_l)|}.$$

Denote by π_{f^} the right-ordered policy that orders $\text{below}(U)$ according to decreasing order of f^* . Then, $W(\pi_{f^*}, U) = W^*(U)$.*

Proof of Proposition 13. Denote $\text{above}(U) = U_{>} = \{a_i\}$ and $\text{below}(U) = U_{<} = \{a_{j_1}, \dots, a_{j_k}\}$ for $k = |U_{<}|$. Let π be any right-ordered policy with the matching $\sigma_\pi^{\text{right}}$, such that $\pi \neq \pi_{f^*}$. Assume that there are indices r, l , for $1 \leq r, l \leq k$, such that $\sigma_\pi^{\text{right}}(a_l) < \sigma_\pi^{\text{right}}(a_r)$ yet $f(a_l) < f(a_r)$, for arms $a_l, a_r \in U_{<}$. Moreover, if such a pair (l, r) exists, assume w.l.o.g. that $\sigma_\pi^{\text{right}}$ orders them

consequentially, i.e., for every arm $a \in U$ such that $a \notin \{a_l, a_r\}$, either $\sigma_\pi^{\text{right}}(a) < \sigma_\pi^{\text{right}}(a_l)$ or $\sigma_\pi^{\text{right}}(a) > \sigma_\pi^{\text{right}}(a_r)$.

Denote by π' the right-ordered policy that swaps a_l and a_r . If we show that π' yields a better reward than π , we could swap the order of π one pair at a time, thereby showing that π_{f^*} is indeed optimal. To simplify notation, we denote by $\mathbb{1}_a$ the event that $X_a > 0$ for arm $a \in U$.

Let $U'_<$ be the set of all arms in $U_<$ such that $U'_< = \{a \in U_< \mid \sigma_\pi^{\text{right}}(a) < \sigma_\pi^{\text{right}}(a_l)\}$. We divide the analysis into two cases: in case $X_{a_i} > 0$ or $\max_{a \in U'_<} X_a > 0$, both π, π' obtain the same reward. Otherwise, assume that $X_{a_i} \leq 0$ and $\max_{a \in U'_<} X_a \leq 0$; hence, in case arm a_i is selected, the policy reaches a terminal state with a reward of 0. The reward of π is given by

$$W(\pi, U) = C_1 \left(\mathbf{p}_{i,l}(l) \mathbb{E}(\mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,l}(l) \mathbf{p}_{i,r}(r) \mathbb{E}((1 - \mathbb{1}_l) \mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,l}(l) \mathbf{p}_{i,r}(r) C_2 \right),$$

where C_1 and C_2 are constants that depend on $\sigma_\pi^{\text{right}}$. Similarly, the reward of π' is given by

$$W(\pi', U) = C_1 \left(\mathbf{p}_{i,r}(r) \mathbb{E}(\mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,r}(r) \mathbf{p}_{i,l}(l) \mathbb{E}((1 - \mathbb{1}_r) \mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,r}(r) \mathbf{p}_{i,l}(l) C_2 \right),$$

where C_1 and C_2 are the same constants. If $W(\pi, U) \geq W(\pi', U)$, then

$$\begin{aligned} & \mathbf{p}_{i,l}(l) \mathbb{E}(\mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,l}(l) \mathbf{p}_{i,r}(r) \mathbb{E}((1 - \mathbb{1}_l) \mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j}) \\ & \geq \mathbf{p}_{i,r}(r) \mathbb{E}(\mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j}) + \mathbf{p}_{i,r}(r) \mathbf{p}_{i,l}(l) \mathbb{E}((1 - \mathbb{1}_r) \mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j}), \end{aligned}$$

implying that

$$\mathbf{p}_{i,l}(l) \mathbb{E}(\mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j}) (1 - \mathbf{p}_{i,r}(r)) \geq \mathbf{p}_{i,r}(r) \mathbb{E}(\mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j}) (1 - \mathbf{p}_{i,l}(l)).$$

Stated otherwise,

$$\frac{\mathbf{p}_{i,l}(l) \mathbb{E}(\mathbb{1}_l \max_{a_j \in U_< \setminus U'_<} X_{a_j})}{1 - \mathbf{p}_{i,l}(l)} > \frac{\mathbf{p}_{i,r}(r) \mathbb{E}(\mathbb{1}_r \max_{a_j \in U_< \setminus U'_<} X_{a_j})}{1 - \mathbf{p}_{i,r}(r)}.$$

Finally, due to the definitions of $\mathbf{p}_{i,r}$, $\mathbb{1}_l$ and $\mathbf{p}_{i,l}$, $\mathbb{1}_r$,

$$\frac{\Pr(X_{a_l} > 0) \mathbb{E}(\max_{a_j \in U_< \setminus U'_<} X_{a_j} \mid X_{a_l} > 0)}{|\mu(a_l)|} \geq \frac{\Pr(X_{a_l} > 0) \mathbb{E}(\max_{a_j \in U_< \setminus U'_<} X_{a_j} \mid X_{a_r} > 0)}{|\mu(a_r)|},$$

which contradicts our assumption that $f(a_l) < f(a_r)$. \square

Proof of Claim 3. Notice that we can represent f_Z^π as

$$Q(\pi, U_> \setminus Z \cup \{a_{i(Z)}\}, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\}) - Q(\pi, U_> \setminus Z, U_< \setminus \{a_{j_1}, a_{j_2}, \dots, a_{j_k}, a_{j_{k+1}}\}),$$

where $a_{i(Z)}$ is the minimal element in Z according to σ_π^{left} . This process is similar in spirit to the proof of Proposition 4 and is hence omitted. Then, we can mirror the same arguments for f_Z^ρ . Finally, the Equivalence lemma suggests that the two representations are equal. \square

Proof of Proposition 10. We address the two parts separately below.

Part 1 Notice that the terminal state $(U_{<} \setminus \psi)$ is reachable from the left sub-tree of π and ρ solely (see Figure E for illustration). Due to the construction of π and ρ ,

$$\begin{aligned}
\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) &= \mathbf{p}_{i_1, j_k}(a_{i_1}) \Pr(s \setminus \{a_{i_1}\} \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) \\
&= \frac{-\mu(a_{j_k})}{-\mu(a_{j_k}) + \mu(a_{i_1})} \Pr(s \setminus \{a_{i_1}\} \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) \\
&= \frac{-\mu(a_{j_k})}{-\mu(a_{j_k}) + \mu(a_{i_1})} \Pr(s \setminus \{a_{i_1}\} \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) \\
&\leq \frac{-\mu(a_{j_{k+1}})}{-\mu(a_{j_{k+1}}) + \mu(a_{i_1})} \Pr(s \setminus \{a_{i_1}\} \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) \\
&\leq \mathbf{p}_{i_1, j_{k+1}}(a_{i_1}) \Pr(s \setminus \{a_{i_1}\} \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) \\
&= \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)), \tag{37}
\end{aligned}$$

since $\mu(a_{j_{k+1}}) \geq \mu(a_{j_k})$, and due to monotonicity of $f(x) = \frac{x}{x+c}$ for positive c . Using similar arguments,

$$\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_k}\}))) \geq \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\}))). \tag{38}$$

Now, observe that

$$\begin{aligned}
\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\pi}) &= \frac{\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi))}{\Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi)) + \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_k}\})))} \\
&\stackrel{\text{Eq. (37),(38)}}{\leq} \frac{\Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi))}{\Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi)) + \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})))} \\
&= \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\rho}), \tag{39}
\end{aligned}$$

where the second to last step follows again from monotonicity of $f(x) = \frac{x}{x+c}$ for positive c . Further, due to monotonicity of the reward function R ,

$$R(U_{<} \setminus (\psi \cup \{a_{j_k}\})) \geq R(U_{<} \setminus \psi), \quad R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \geq R(U_{<} \setminus \psi).$$

In addition, due to Assumption 1, $R(U_{<} \setminus (\psi \cup \{a_{j_k}\})) \geq R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\}))$. Wrapping up,

$$\begin{aligned}
\alpha_{\psi}^{\pi} &= \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\pi}) R(U_{<} \setminus \psi) + (1 - \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\pi})) R(U_{<} \setminus (\psi \cup \{a_{j_k}\})) \\
&\geq \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\pi}) R(U_{<} \setminus \psi) + (1 - \Pr(s \overset{\pi}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\pi})) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \\
&\stackrel{\text{Eq. (39)}}{\geq} \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\rho}) R(U_{<} \setminus \psi) + (1 - \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\rho})) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \\
&= \alpha_{\psi}^{\rho}.
\end{aligned}$$

This completes the proof of the first part.

Part 2 We prove the claim for $\alpha_{l+1}^{\rho} \geq \alpha_l^{\rho}$, and the other part is symmetrical. Let $\psi = \psi(l)$ such that $\max(\psi) = l$. Notice that the reward function R is a set function, and is, by definition monotonically decreasing; hence, $R(U_{<} \setminus \psi) \leq R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\}))$. Consequently,

$$\begin{aligned}
\alpha_{\psi}^{\rho} &= \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi) \mid E_{\psi}^{\rho}) R(U_{<} \setminus \psi) + \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \mid E_{\psi}^{\rho}) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \\
&\leq R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})).
\end{aligned}$$

Further, let ψ' such that $\max(\psi') = l + 1$, namely $\psi' = \psi \cup \{a_{j_{l+1}}\}$. Using the same properties of R , we have that $R(U_{<} \setminus \psi') \leq R(U_{<} \setminus (\psi' \cup \{a_{j_{k+1}}\}))$; thus,

$$\begin{aligned} \alpha_{\psi'}^\rho &= \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus \psi') | E_{\psi'}^\rho) R(U_{<} \setminus \psi') + \Pr(s \overset{\rho}{\rightsquigarrow} (U_{<} \setminus (\psi' \cup \{a_{j_{k+1}}\}) | E_{\psi'}^\rho) R(U_{<} \setminus (\psi' \cup \{a_{j_{k+1}}\})) \\ &\geq R(U_{<} \setminus \psi'). \end{aligned}$$

Next, let V_ψ denote the event that $(X_a)_{a \in \psi}$ attain value below α . Observe that

$$\begin{aligned} R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) &= \Pr(V_\psi) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) + (1 - \Pr(V_\psi)) R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \\ &= \Pr(V_\psi) \max\{\alpha, X_{a_{j_{k+1}}}\} + (1 - \Pr(V_\psi)) \max\{a_{j_1}, \dots, a_{j_l}, a_{j_{k+1}}\} \\ &\leq \Pr(V_\psi) \max\{\alpha, X_{a_{j_{l+1}}}\} + (1 - \Pr(V_\psi)) \max\{a_{j_1}, \dots, a_{j_l}, a_{j_{l+1}}\} \\ &= R(U_{<} \setminus \psi'), \end{aligned}$$

where the second to last inequality is due to Assumption 1 and independence of $(X_{a_i})_{i=1}^K$. Ultimately,

$$\alpha_{l+1}^\rho = \alpha_{\psi'}^\rho \geq R(U_{<} \setminus \psi') \geq R(U_{<} \setminus (\psi \cup \{a_{j_{k+1}}\})) \geq \alpha_\psi^\rho = \alpha_l^\rho.$$

This completes the proof of the second part. \square

Proof of Claim 4. The proof goes along the lines of Claim 3, and is hence omitted. \square

G Proofs of Observations and Propositions from Sections 3 and 4

Proof of Observation 1. Let $x(a_i) > 0$ for some $i \in [K]$, let j be an index of unexplored arm, and let \mathcal{I} be the information of the algorithm. We overload the notation $\mathbf{p}_{i,j}$ to acknowledge the realized value $x(a_i)$; that is,

$$\mathbf{p}_{i,j}(a) = \begin{cases} \frac{-\mu(a_j)}{x(a_i) - \mu(a_j)} & \text{if } a = a_i \\ \frac{x(a_i)}{x(a_i) - \mu(a_j)} & \text{if } a = a_j \\ 0 & \text{otherwise} \end{cases}.$$

Notice that

$$\begin{aligned} \sum_{a \in A} \mathbf{p}(a) \mathbb{E}[X(a) | \mathcal{I}] &= \mathbf{p}_{i,j}(a_i) x(a_i) + \mathbf{p}_{i,j}(a_j) \mu(a_j) \\ &= x(a_i) \cdot \frac{-\mu(a_j)}{x(a_i) - \mu(a_j)} + \mu(a_j) \cdot \frac{x(a_i)}{x(a_i) - \mu(a_j)} = 0; \end{aligned}$$

hence, $\mathbf{p}_{i,j}$ is safe w.r.t. to \mathcal{I} . After playing $\mathbf{p}_{i,j}$, either a_i was realized or a_j . In the former, the information remains the same, and we can repeat this experiment again. The probability of a_j realizing is positive and constant, and hence after finite time we will eventually realize it. Once we do, the number of unexplored arms decreases by one. We can follow this process until all arms are explored. \square

Proof of Observation 2. The proof of this observation relies on constructing a policy π that simulates ALG. Since by definition $W(\pi, A) \leq W^*(A)$, it is enough to show that $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{ALG}) \leq W(\pi, A)$. In every round, π plays precisely what ALG plays, and if the realized arm was already explored by ALG, π ignores it. The infinite time expected value of ALG cannot exceed $W(\pi, A)$. The full details are similar to [8, Theorem 3] and are hence omitted. \square

Proof of Observation 3. Fix any policy π . Let $\text{ALG}(\pi)$ be the modification of Algorithm 1 that uses π instead of OGP in Lines 2-3. Once π reaches a terminal state, $\text{ALG}(\pi)$ secures the reward of π in finite time. Overall, $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{ALG}(\pi)) = W(\pi, A)$. \square

Proof of Proposition 1. Fix an IBS-P instance such that $(X(a_i))_i \in \{x^-, x^+\}$ (for $x^- \leq x^+$) almost surely. For the problem to be non-trivial, we must have $x^- < 0$ and $x^+ > 0$. Otherwise, if $x^-, x^+ < 0$ the only safe action is a_0 , and if $x^-, x^+ \geq 0$, we can explore all arms using the singleton portfolios $(\mathbf{p}_{ii})_{i \in [K]}$. From here on, we assume w.l.o.g. that $x^- = -1$ and $x^+ = H$. For convenience, we state SEGB' explicitly in Algorithm 2. Before we prove the proposition, we remark that

1. Since $(X(a_i))_i$ take either -1 or H , Assumption 1 implies a stochastic order on all arms, not only on below(A).
2. Any asymptotically optimal algorithm conducts at most K exploration rounds before it exploits. This implies an immediate crude bound of $\mathcal{U}_T(\text{SEGB}') \geq \left(1 - \frac{KH}{T}\right) \text{OPT}_T$.
3. This proof uses the analysis presented in Section A.

The proof is composed of two steps. In the first step, we show that if $T > T_0$ for some T_0 , any optimal algorithm must explore the arms according to a policy that admits the same structure of OGP. In the second step, we show that all such policies have an identical exploration time, and hence all achieve the same utility.

Step 1: In the case of realizing a positive reward, any algorithm would stop exploring and exploit that realized reward. Consequently, we can separate exploration rounds from exploitation rounds. Notice, however, that the exploration policy can select portfolios different than OGP for finite T . To illustrate, reconsider Example 2. In the extreme case of $T = 1$, there is no point in playing $\mathbf{p}_{1,3}$, since exploring a_3 is futile; we only care about maximizing the current round's reward.

However, if T is large *enough*, any optimal algorithm must employ an asymptotically optimal policy. To see this, let (π, ALG^π) be a pair of exploration policy and the algorithm that employs it, and assume π does not admit the structure of OGP. The utility of ALG^π satisfies

$$\mathcal{U}_T(\text{ALG}^\pi) \leq KH + (T - K)W(\pi, A). \quad (40)$$

Similarly, taking into account the optimality of OGP,

$$\mathcal{U}_T(\text{ALG}^{\text{OGP}}) \geq -K + (T - K)W^*(A). \quad (41)$$

Using similar arguments to those in Proposition 3, we can assume w.l.o.g. that π belongs to $\{2^A \rightarrow \mathcal{P} \cup \mathcal{P}'\}$ (recall the definition of \mathcal{P} and \mathcal{P}' from Subsection A.2). To see this, observe that any safe policy can be formulated as a convex combination of policies that use $\mathcal{P} \cup \mathcal{P}'$ solely, and therefore we can assume that π is the one for which ALG^π gets the highest utility. Furthermore, due to the proof of Theorem 2 (precisely Equation (29)) it follows that if π does not admit the structure of OGP, then it is strictly sub-optimal. Next, let

$$\omega \stackrel{\text{def}}{=} \min_{\substack{\rho \in \{2^A \rightarrow \mathcal{P} \cup \mathcal{P}'\}, \\ W(\rho, A) < W^*(A)}} W^*(A) - W(\rho, A) > 0. \quad (42)$$

The quantity ω concerns the distributions of $(X(a_i))_i$ and is completely independent of the time T . We can further quantify or bound ω but this abstract and simple form is sufficient for our purposes. Let $T_0 \stackrel{\text{def}}{=} K + \frac{K(H+1)}{\omega}$. Combining Inequalities (40), (41), and (42) we get

$$\begin{aligned} \mathcal{U}_T(\text{ALG}^{\text{OGP}}) - \mathcal{U}_T(\text{ALG}^\pi) &\geq -K + (T - K)W^*(A) - KH - (T - K)W(\pi, A) \\ &\geq -K(H + 1) + (T - K)\omega \\ &> 0, \end{aligned}$$

provided that $T > T_0$. To conclude this step, we know that π is a variation of OGP.

Step 2: Notice, however, that OGP is a class of policies differing from one another in the choices of arms from above(A) (Line 4 in Policy 1); hence, one policy may attain a better reward than the other by reaching exploitation faster.

As we commented in Line 3 of Algorithm 2, when the state s does not contain arms from below(A) we prioritize singleton portfolios according to the stochastic order. That is, we favor $\mathbf{p}_{i,i}$ over $\mathbf{p}_{i',i'}$ if $\mu(a_i) > \mu(a_{i'})$. This modification ensures that the time to exploitation from such states is minimal.

Nevertheless, we might face a problem in states for which below(s) $\neq \emptyset$. To illustrate, consider the action $\mathbf{p}_{i,j}$ for some $a_i \in \text{above}(A)$, $a_j \in \text{below}(A)$. The probability we discover a reward of H when playing $\mathbf{p}_{i,j}$ is

$$\mathbf{p}_{i,j}(a_i) \Pr(X(a_i) = H) + \mathbf{p}_{i,j}(a_j) \Pr(X(a_j) = H). \quad (43)$$

Consequently, we might favor $\mathbf{p}_{i,j}$ over $\mathbf{p}_{i',j}$ (for $a_{i'} \in \text{above}(A)$) if it allows faster discovery of a positive reward (which is necessarily H). However, as we show next, the probability in Equation (43) is the same regardless of the selection the arm from above(s). Observe that

$$\mu(a_i) = H \Pr(X(a_j) = H) + (-1) \cdot (1 - \Pr(X(a_j) = H)) = (H + 1) \Pr(X(a_j) = H) - 1;$$

thus, by reformulating Equation (43) we get

$$\begin{aligned} \text{Eq. (43)} &= \frac{-\mu(a_j)}{\mu(a_i) - \mu(a_j)} \Pr(X(a_i) = H) + \frac{\mu(a_i)}{\mu(a_i) - \mu(a_j)} \Pr(X(a_j) = H) \\ &= \frac{-(H+1)\Pr(X(a_j) = H) + 1}{\mu(a_i) - \mu(a_j)} \Pr(X(a_i) = H) + \frac{(H+1)\Pr(X(a_i) = H) - 1}{\mu(a_i) - \mu(a_j)} \Pr(X(a_j) = H) \\ &= \frac{\Pr(X(a_i) = H) - \Pr(X(a_j) = H)}{\mu(a_i) - \mu(a_j)} \\ &= \frac{\Pr(X(a_i) = H) - \Pr(X(a_j) = H)}{(H+1)\Pr(X(a_i) = H) - 1 - (H+1)\Pr(X(a_i) = H) + 1} \\ &= \frac{1}{H+1}. \end{aligned}$$

Since all OGP have the same expected exploration time, they all achieve the same utility. This completes the proof of Proposition 1. \square

Proof of Proposition 2. To prove the claim, we show that SEGB explores for at most $K(1 + \frac{\gamma}{\delta})$ rounds, and then exploits. First, SEGB uses $K_1 \leq K$ rounds following OGP until it reaches a terminal state (Lines 2–6). If all the realized rewards are negative, the exploration ends after then. Otherwise,

Algorithm 2 SEGB for Two-Supported Distributions

```

1:  $s \leftarrow A$ 
2: while  $\text{OGP}(s) \neq \emptyset$  do
3:   play  $\text{OGP}(s)$ , and denote the realized action by  $a_k$ .
4:   if  $x_{a_k} > 0$  then
5:     break.
6:    $s \leftarrow s \setminus \{a_k\}$ .
7: if  $x(a_k) = H$  for some explored arm  $a_k$  then
8:   exploit  $a_k$  forever.
9: else
10:  exploit  $a_0$  forever.
  
```

if it discovered a positive reward, the value of that reward is at least δ . Next, the Bernoulli trials will explore every unexplored arm w.p. of at least $\frac{\delta}{\delta+\gamma}$, or $\frac{\delta+\gamma}{\delta}$ rounds in expectation. Therefore, after $(K - K_1)(1 + \frac{\gamma}{\delta})$ rounds in expectation we explore all the remaining arms. Overall, the expected number of rounds devoted to exploration is

$$K_1 + (K - K_1) \left(1 + \frac{\gamma}{\delta}\right) \leq K \left(1 + \frac{\gamma}{\delta}\right).$$

Ultimately, recall that $\lim_{T \rightarrow \infty} \mathcal{U}_T(\text{SEGB}) = \lim_{T \rightarrow \infty} \text{OPT}_T$, so SEGB exploits an expected reward of $\lim_{T \rightarrow \infty} \text{OPT}_T$ after it completes its exploration. Therefore,

$$\begin{aligned} \mathcal{U}_T(\text{SEGB}) &\geq K \left(1 + \frac{\gamma}{\delta}\right) \cdot 0 + \left(T - K \left(1 + \frac{\gamma}{\delta}\right)\right) \lim_{T \rightarrow \infty} \text{OPT}_T. \\ &\geq \left(T - K \left(1 + \frac{\gamma}{\delta}\right)\right) \text{OPT}_T. \end{aligned}$$

□

H Proof of Statements from Section A

Proof of Proposition 3. Fix a non-terminal state $U \subseteq A$. Further, denote $V(a) \stackrel{\text{def}}{=} W^*(U \setminus \{a\})$ for every $a \in U$. Due to Equation (2), the action that maximizes the reward at state U is the solution $\mathbf{p} \in \Delta(U)$ of the following linear program:

$$\begin{aligned} \max_{\mathbf{p}} \quad & \sum_{a \in U} \mathbf{p}(a) V(a) \\ \text{subject to} \quad & \sum_{a \in U} \mathbf{p}(a) \mu(a) \geq 0 \\ & \sum_{a \in U} \mathbf{p}(a) = 1 \\ & 0 \leq \mathbf{p}(a) \leq 1 \quad \text{for all } a \in U \end{aligned} \tag{P1}$$

Observe that for every \mathbf{p} such that $\sum_{a \in U} \mathbf{p}(a) \mu(a) \geq 0$, there exist coefficients $(\alpha_{i,j})_{i,j}$ such that for every $a_i \in U$, $\mathbf{p}(a_i) = \sum_{a_j \in U} \alpha_{i,j} \mathbf{p}_{i,j}(i)$, and

$$\sum_{a \in U} \mathbf{p}(a) \mu(a) = \sum_{i,j} \alpha_{i,j} \left(\mathbf{p}_{i,j}(i) \mu(a_i) + \mathbf{p}_{i,j}(j) \mu(a_j) \right).$$

Hence, an equivalent form of Problem (P1) is

$$\begin{aligned}
& \max_{\alpha} && \sum_{a \in U} \alpha_{i,j} \left(\mathbf{p}_{i,j}(i)V(a_i) + \mathbf{p}_{i,j}(j)V(a_j) \right) \\
& \text{subject to} && \sum_{i,j} \alpha_{i,j} \left(\mathbf{p}_{i,j}(i)\mu(a_i) + \mathbf{p}_{i,j}(j)\mu(a_j) \right) \geq 0 \\
& && \sum_{i,j} \alpha_{i,j} = 1 \\
& && 0 \leq \alpha_{i,j} \leq 1 \quad \text{for all } (i,j) \in \{(i',j') \mid \mathbf{p}_{i',j'} \in \mathcal{P} \cup \mathcal{P}' \text{ and } i',j' \in U\}
\end{aligned} \tag{P2}$$

Finally, notice that the constraint $\sum_{i,j} \alpha_{i,j} \left(\mathbf{p}_{i,j}(i)\mu(a_i) + \mathbf{p}_{i,j}(j)\mu(a_j) \right) \geq 0$ holds for every selection of $(\alpha_{i,j})_{i,j}$ by the way we defined $\mathcal{P} \cup \mathcal{P}'$; thus, the maximum of Problem (P2) is obtain when we set $\alpha_{i,j} = 1$ for the pair (i,j) that maximizes $\left(\mathbf{p}_{i,j}(i)V(a_i) + \mathbf{p}_{i,j}(j)V(a_j) \right)$. \square

Claim 5. Consider a state $U \in \mathcal{S}$, such that $\text{below}(U) \geq 2$. Let $a_j = \arg \min_{a_{j'} \in \text{below}(U)} \sigma_{\pi}^{\text{right}}(a_{j'})$, and let $a_{\bar{j}} \in \text{below}(U)$, $a_{\bar{j}} \neq a_j$. Under Assumption 1, it might be the case that $W^*(U \setminus \{a_j\}) < W^*(U \setminus \{a_{\bar{j}}\})$.

Proof of Claim 5. We prove the claim by providing an example, that could be easily extended to a family of infinitely many examples. Consider $K = 3$, $A = \{a_1, a_2, a_3\}$ such that

$$X_1 = \begin{cases} -1 & \text{w.p. } 0.45 \\ 1 & \text{w.p. } 0.55 \end{cases}, \quad X_2 = \begin{cases} -10^6 - 2\epsilon & \text{w.p. } 0.5 \\ 10^6 & \text{w.p. } 0.5 \end{cases}, \quad X_3 = \begin{cases} -10^{\frac{1}{\epsilon}} & \text{w.p. } 0.5 \\ 10^6 & \text{w.p. } 0.5 \end{cases}$$

For small ϵ , say $\epsilon < \frac{1}{7}$, it is clear that X_2 stochastically dominates X_3 . The resulting expected values are $\mu(a_1) = 0.1$, $\mu(a_2) = -\epsilon$, and $\mu(a_3) = -\Theta(10^{\frac{1}{\epsilon}})$. The intuition behind our selection of rewards is that arm a_2 could have high reward, and can be explored with probability $\mathbf{p}_{1,2}(2) = 1 - O(\epsilon)$. On the other hand, arm a_3 has a high reward with the same probability, but it is highly unlikely to explore it. More precisely, $\mathbf{p}_{1,3}(3) = \Theta(10^{-\frac{1}{\epsilon}})$. To finalize the argument, notice that

$$W^*(A \setminus \{a_2\}) = \mathbf{p}_{1,3}(1) \cdot R(\{a_3\}) + \mathbf{p}_{1,3}(3) \cdot \mathbf{p}_{1,1}(1) \cdot R(\emptyset) = 0.5 \cdot 10^6 + 0.5 \cdot 0.55 \cdot 1 + O(\epsilon)$$

while

$$\begin{aligned}
W^*(A \setminus \{a_3\}) &= \mathbf{p}_{1,2}(1) \cdot R(\{a_2\}) + \mathbf{p}_{1,2}(2) \cdot \mathbf{p}_{1,1}(1) \cdot R(\emptyset) \\
&= 0.75 \cdot 10^6 + 0.25 \cdot 0.55 \cdot 1 + O(\epsilon).
\end{aligned}$$

The proof is completed by taking ϵ to zero. \square
