(Dated: August 26, 2020)

Adaptive networks change their connectivity with time, depending on their dynamical state. While synchronization in structurally static networks has been studied extensively, this problem is much more challenging for adaptive networks. In this Letter, we develop the master stability approach for a large class of adaptive networks. This approach allows for reducing the synchronization problem for adaptive networks to a low-dimensional system, by decoupling topological and dynamical properties. We show how the interplay between adaptivity and network structure gives rise to the formation of stability islands. Moreover, we report a desynchronization transition and the emergence of complex partial synchronization patterns induced by an increasing overall coupling strength. We illustrate our findings using adaptive networks of coupled phase oscillators and FitzHugh-Nagumo neurons with synaptic plasticity.

In nature and technology, complex networks serve as a ubiquitous paradigm with a broad range of applications from physics, chemistry, biology, neuroscience, socio-economic and other systems [1]. Dynamical networks are composed of interacting dynamical units, such as, e.g., neurons or lasers. Collective behavior in dynamical networks has attracted much attention over the last decades. Depending on the network and the specific dynamical system, various synchronization patterns of increasing complexity were explored [2–5]. Even in simple models of coupled oscillators, patterns such as complete synchronization [6], cluster synchronization [7–11], and various forms of partial synchronization have been found, such as frequency clusters [3], solitary [13] or chimera states [14–22]. In brain networks, particularly, synchronization is believed to play a crucial role: for instance, under normal conditions in the context of cognition and learning [23, 24], and under pathological conditions, such as Parkinson’s disease [25], epilepsy [26–30], tinnitus [31, 32], schizophrenia, to name a few [33]. Also in power grid networks, synchronization is essential for the stable operation [34–37].

The powerful methodology of the master stability function [38] has been a milestone for the analysis of synchronization phenomena. This method allows for separating dynamical from structural features for a given dynamical network. It drastically simplifies the problem by reducing the dimension and unifying the synchronization study for different networks. Since its introduction, the master stability approach has been extended and refined for multilayer [39], multiplex [40, 41] and hypernetworks [42, 43]; to account for single and distributed delays [44–49]; and to describe the stability of clustered states [50–53]. The master stability function has been used to understand effects in temporal [54, 55] as well as adaptive networks [56] within a static formalism. Beyond the local stability described by the master stability func-

tion, Belykh et. al. have developed the connection graph stability method to provide analytic bounds for the global asymptotic stability of synchronized states [57–60]. Despite the apparent vivid interest in the stability features of synchronous states on complex networks, only little is known about the effects induced by an adaptive network structure. This lack of knowledge is even more surprising regarding how important adaptive networks are for the modeling of real-world systems.

Adaptive networks are commonly used models for synaptic plasticity [61–66] which determines learning, memory, and development in neural circuits. Moreover, adaptive networks have been reported for chemical [67, 68], epidemic [69], biological [70], transport [71], and social systems [72, 73]. A paradigmatic example of adaptively coupled phase oscillators has recently attracted much attention [1–5, 41, 74, 75, 77, 81], and it appears to be useful for predicting and describing phenomena in more realistic and detailed models [7, 82, 83, 85]. Systems of phase oscillators are important for understanding synchronization phenomena in a wide range of applications [86–88].

In this Letter, we report on a surprising desynchronization transition induced by an adaptive network structure. We find various parameter regimes of partial synchronization during the transition from the synchronized to an incoherent state. The partial synchronization phenomena include multi-frequency-cluster and chimera-like states. By going beyond the static network paradigm, we develop a master stability approach for networks with adaptive coupling. We show how the adaptivity of the network gives rise to the emergence of stability islands in the master stability function that result in the desynchronization transition. With this, we establish a general framework to study those transitions for a wide range of dynamical systems. In order to provide analytic insights, we use the generalized Kuramoto-Sakaguchi system on

an adaptive and complex network. Finally, we show that our findings also hold for a more realistic neuronal set-up of coupled FitzHugh-Nagumo neurons with synaptic plasticity.

We consider the following general class of N adaptively coupled systems [1–5, 41, 74, 75, 77, 89]

$$\dot{\mathbf{x}}_i = f(\mathbf{x}_i) - \sigma \sum_{j=1}^N a_{ij} \kappa_{ij} g(\mathbf{x}_i, \mathbf{x}_j), \quad (1)$$

$$\dot{\kappa}_{ij} = -\epsilon (\kappa_{ij} + a_{ij} h(\mathbf{x}_i - \mathbf{x}_j)), \quad (2)$$

where $\mathbf{x}_i \in \mathbb{R}^d$, $i = 1, \dots, N$, is the d -dimensional dynamical variable of the i th node, $f(\mathbf{x}_i)$ describes the local dynamics of each node, and $g(\mathbf{x}_i, \mathbf{x}_j)$ is the coupling function. The coupling is weighted by scalar variables κ_{ij} which are adapted dynamically according to Eq. (2) with the nonlinear adaptation function $h(\mathbf{x}_i - \mathbf{x}_j)$. We assume that the adaptation depends on the difference of the corresponding dynamical variables, similar to the neuronal spike timing-dependent plasticity [62, 63, 90, 91]. The base connectivity structure is given by the matrix elements $a_{ij} \in \{0, 1\}$ of the $N \times N$ adjacency matrix A which possesses a constant row sum r , i.e., $r = \sum_{j=1}^N a_{ij}$ for all $i = 1, \dots, N$. The assumption of the constant row sum is necessary to allow for synchronization. The Laplacian matrix is $L = r\mathbb{I}_N - A$ where \mathbb{I}_N is the N -dimensional identity matrix. The eigenvalues of L are called Laplacian eigenvalues of the network. The parameter $\sigma > 0$ defines the overall coupling input, and $\epsilon > 0$ is a time-scale separation parameter. In particular, if the adaptation is slower than the local dynamics, the parameter ϵ is small.

Complete synchronization is defined by the $N - 1$ constraints $\mathbf{x}_1 = \mathbf{x}_2 = \dots = \mathbf{x}_N$. Denoting the synchronization state by $\mathbf{x}_i(t) = \mathbf{s}(t)$ and $\kappa_{ij} = \kappa_{ij}^s$, we obtain from Eqs. (1)–(2) the following equations for $\mathbf{s}(t)$ and κ_{ij}^s

$$\dot{\mathbf{s}} = f(\mathbf{s}) + \sigma r h(0) g(\mathbf{s}, \mathbf{s}), \quad (3)$$

$$\dot{\kappa}_{ij}^s = -a_{ij} h(0). \quad (4)$$

In particular, we see that $\mathbf{s}(t)$ satisfies the dynamical equation (3), and κ_{ij}^s are either $-h(0)$ or zero, if the corresponding link in the base connectivity structure exists ($a_{ij} = 1$) or not ($a_{ij} = 0$), respectively.

In order to describe the local stability of the synchronous state, we introduce the variations $\xi_i = \mathbf{x}_i - \mathbf{s}$ and $\chi_{ij} = \kappa_{ij} - \kappa_{ij}^s$. The linearized equations for these variations read

$$\dot{\xi}_i = Df(\mathbf{s})\xi_i - \sigma g(\mathbf{s}, \mathbf{s}) \sum_{j=1}^N a_{ij} \chi_{ij} \quad (5)$$

$$+ \sigma h(0) \sum_{j=1}^N a_{ij} (D_1 g(\mathbf{s}, \mathbf{s})\xi_i + D_2 g(\mathbf{s}, \mathbf{s})\xi_j),$$

$$\dot{\chi}_{ij} = -\epsilon (\chi_{ij} + a_{ij} Dh(0)(\xi_i - \xi_j)), \quad (6)$$

where Df and Dh are the Jacobians ($d \times d$ matrix and $1 \times d$ matrix, respectively), and $D_1 g$ and $D_2 g$ are the Jacobians with respect to the first and the second variable, respectively.

The system (5)–(6) is used to calculate the Lyapunov exponents of the synchronous state; it possesses very high dimension $N^2 + Nd$. However, one can introduce a new coordinate frame which separates an $N(d + 1)$ -dimensional master from an $N(N - 1)$ -dimensional slave system. The new variables of the master system depend only on the variables of the master system itself and they are independent of the dynamics of the slave system. Further, we find that the dynamics of the slave system is ruled by the dynamics of the master system. With these new coordinates, we reduce the system's dimension significantly. Moreover, as in the classical master stability approach, we diagonalize the $N(d + 1)$ -dimensional master system into blocks of $d + 1$ dimensions. Hence, the dynamics in each block is described by the new coordinates ζ and κ which are d - and one-dimensional dynamical variables, respectively. Our analysis shows that the coupling structure enters just as a complex parameter μ , the network's Laplacian eigenvalue. For all details and the proof of the master stability function, we refer to the Supplemental Material [105].

As a result, the stability problem is reduced to the largest Lyapunov exponent $\Lambda(\mu)$, depending on a complex parameter μ , for the following system

$$\dot{\zeta} = \left(Df(\mathbf{s}) + \sigma r h(0) [D_1 g(\mathbf{s}, \mathbf{s}) + (1 - \frac{\mu}{r}) D_2 g(\mathbf{s}, \mathbf{s})] \right) \zeta - \sigma g(\mathbf{s}, \mathbf{s}) \kappa, \quad (7)$$

$$\dot{\kappa} = -\epsilon (\mu Dh(0) \zeta + \kappa), \quad (8)$$

The function $\Lambda(\mu)$ is called master stability function. Note that the first bracketed term in ζ of (7) resembles the master stability approach for static networks, which, in this case, is equipped by an additional interaction representing the adaptation.

To obtain analytic insights into the stability features of synchronous states that are induced by an adaptive coupling structure, we consider the following model of N adaptively coupled phase oscillators [1, 3]

$$\dot{\phi}_i = \omega + \sigma \sum_{j=1}^N a_{ij} \kappa_{ij} \sin(\phi_i - \phi_j + \alpha), \quad (9)$$

$$\dot{\kappa}_{ij} = -\epsilon (\kappa_{ij} + a_{ij} \sin(\phi_i - \phi_j + \beta)), \quad (10)$$

where ϕ_i represents the phase of the i th oscillator, ω is its natural frequency which we set to zero in a rotating frame.

The synchronous state of (9)–(10) is given by $\mathbf{s}(t) = (\sigma r \sin \alpha \sin \beta) t$ and $\kappa_{ij}^s = -a_{ij} \sin \beta$. Using (7)–(8), the stability of the synchronous state is described by the

FIG. 1. Master stability function $\Lambda(\mu)$ for the adaptive phase oscillator network (9)–(10). Regions belonging to negative Lyapunov exponents Λ are colored blue. The curve where $\Lambda(\mu) = 0$ is given as a black solid line. In panels (a) and (b) the case without adaptation ($\epsilon = 0$) is presented for $\beta = -0.35\pi$ and $\beta = 0.2\pi$, respectively. Other panels: $\epsilon = 0.01$ and (c) $\beta = -0.95\pi$, (d) $\beta = -0.35\pi$, (e) $\beta = 0.2\pi$, and (f) $\beta = 0.98\pi$. In all panels $\alpha = 0.3\pi$.

quadratic characteristic polynomial

$$\lambda^2 + (\epsilon - \sigma\mu \cos(\alpha) \sin(\beta)) \lambda - \epsilon\sigma\mu \sin(\alpha + \beta) = 0. \quad (11)$$

The master stability function for the synchronous solution is given as the maximum real part $\Lambda = \max \text{Re}(\lambda_{1,2})$ of the solutions $\lambda_{1,2}$ of the polynomial (11). These solutions $\lambda_{1,2}$ should be considered as functions of the complex parameter μ determining the network structure. It is convenient, however, to use the parameter $\sigma\mu$ in our case.

Figure 1 displays the master stability function determined for different adaptation rules controlled by β . The blue-colored areas correspond to regions that lead to stable dynamics. By changing the control parameter β , various shapes of the stable regions are visible. For some parameters, e.g., Fig. 1(c,d,e), almost a whole half-space either left or right of the imaginary axis belongs to the stable regime. This resembles the case of no adaptation where the stability of the synchronous state is solely described by the sign of the real part of $\sigma\mu \sin \beta \cos \alpha$, see Fig. 1(a,b). We also find parameters where most values $\sigma\mu$ correspond to unstable dynamics, except for an island, i.e., a bounded region in $\sigma\mu$ parameter space, see Fig. 1(f).

To understand the emergence of the stability islands, we analyze the boundary that separates the stable ($\Lambda < 0$) from the unstable region ($\Lambda > 0$). This boundary is given by the condition $\Lambda = \text{Re}\lambda = 0$, or, equivalently, $\lambda = i\gamma$. Substituting this into Eq. (11), we obtain a parameterized expression for the boundary as a function

of γ that has the form $\sigma\mu = Z(\gamma)$ with $Z(\gamma)$ given explicitly in the Supplemental material [105]. The latter parametrization of the boundary is displayed in Fig. 1 as the solid black line. It is straightforward to show that a stability island exists if $\sin(\alpha + \beta)/(\cos \alpha \sin \beta) < 0$. The latter condition indicates a certain balance between the coupling and adaptation function. We emphasize that the emergence of stability islands is a direct consequence of adaptation. Without adaptation, the boundary simplifies to the axis $\text{Re} \mu = 0$, see Figs. 1(a,b).

In the following, we analyze the behavior of the adaptive network of phase oscillators (9)–(10) in the presence of a stability island, and show how such an island introduces a desynchronization transition with increasing overall coupling σ . To measure the coherence, we use the cluster parameter R_C [1, 2], which is given by the number of pairwise coherent oscillators normalized by the total number of pairs N^2 . In the case of complete synchronization, frequency clustering, or incoherence, the cluster parameter values are $R_C = 1$, $1 < R_C < 0$, or $R_C = 0$, respectively, see Supplemental Material for details [105].

The top panel in Fig. 2 shows the cluster parameter R_C for different values of the overall coupling constant σ . We observe that for small σ , the synchronous state is stable, see Fig. 2(a,d,g). This stability follows directly from the master stability function since all values $\sigma\mu_i$ for all Laplacian eigenvalues lie within the stability island, see Fig. 2(a).

By increasing the coupling strength σ , the values $\sigma\mu_i$ move out of the stability island (μ_i remain the same), and the synchronous state becomes unstable, see Fig. 2(b,c). For intermediate values of σ , multiclusters with hierarchical structure in the cluster size emerge, see Fig. 2(e,h) for a three-cluster state. Increasing the coupling constant further leads to the emergence of incoherence. In Fig. 2(f,i), the coexistence of a coherent and an incoherent cluster is presented. Such chimera-like states have been numerically studied for adaptive networks in [1, 2, 5].

In the following, we show how our findings are transferred to a more realistic set-up of coupled neurons with synaptic plasticity. For this, we consider a network of FitzHugh-Nagumo neurons [92–95] coupled through chemical excitatory synapses [96–98] equipped with plasticity:

$$\tau \dot{u}_i = u_i - \frac{u_i^3}{3} - v_i - \sigma u_i \sum_{j=1}^N a_{ij} \kappa_{ij} I_j, \quad (12)$$

$$\dot{v}_i = u_i + a - b v_i, \quad (13)$$

$$\dot{I}_i = \alpha(u_i)(1 - I_i) - I_i/\tau_{\text{syn}}, \quad (14)$$

$$\dot{\kappa}_{ij} = -\epsilon \left(\kappa_{ij} + a_{ij} e^{-\beta_1(u_i - u_j + \beta_2)^2} \right). \quad (15)$$

Here u_i denotes the membrane potential and v_i summarizes the recovery processes for each neuron; I_i describes

FIG. 2. Dynamics in the network of 200 oscillators (9)–(10) with random adjacency matrix A_c [105], and different values of overall coupling strength σ . Adiabatic continuation for increasing σ with the stepsize of 0.001, starting with the synchronous state $\phi_i = 0$, $\kappa_{ij} = -a_{ij} \sin \beta$. The top panel shows the cluster parameter R_C vs σ . For the three values of σ : (a,d,g) $\sigma = 0.003$, (b,e,h) $\sigma = 0.007$, and (c,f,i) $\sigma = 0.019$, the plots show: in (a,b,c) the master stability function color coded as in Fig. 1, together with $\sigma\mu_i$, where μ_i are the N Laplacian eigenvalues of A_c ; in (d,e,f) snapshots for ϕ_i at $t = 30000$; and in (g,h,i) the temporal average of the phase velocities $\langle \dot{\phi}_i \rangle$ over the last 5000 time units. Other parameters: $\alpha = 0.49\pi$, $\beta = 0.88\pi$, $\epsilon = 0.01$.

the synaptic output for each neuron; the parameters $a = 0.7$ and $b = 0.2$ are fixed to the values corresponding to self-sustained oscillatory dynamics of uncoupled neurons; and $\tau = 0.08$ and $\epsilon = 0.01$ are fixed time scale separation parameters between the fast activation and slow inhibitory processes in each neuron, and between the fast oscillatory dynamics and the slow adaptation of the coupling weights, respectively. The synaptic recovery function is given by $\alpha(u) = 2/(0.08(1 + \exp(-u/0.05)))$. The synaptic timescale is $\tau_{\text{syn}} = 5/6$. For more details on the model, we refer to [98, 105]. The form of the synaptic plasticity is similar to the rules used in [6, 7]. We consider β_1 and β_2 as control parameters of the adaptation

function. Note that β_1 and β_2 are uniquely determined by the values of $h(0)$ and $Dh(0)$ of the plasticity rule, and these are the only essential parameters of the plasticity function, regarding the stability of the synchronous state, see Eqs. (7)–(8).

The synchronous state of the network of FitzHugh-Nagumo neurons (12)–(15) satisfies Eqs. (3)–(4), and it is periodic for the chosen parameter values. Using our extended master stability approach, we determine numerically the master stability function which is the maximum Lyapunov exponent of Eqs. (7)–(8).

In Fig. 3(a,b,c), we show the master stability function in dependence on the parameter μ/r for different values of the overall coupling constant σ . We observe a stability island for the chosen set of parameters, see the Supplemental material for other parameter values [105]. In contrast to the phase oscillator network in Fig. 2, the master stability function does not scale linearly with σ . This is due to the non-diffusive coupling function in Eq. (12). Moreover, with increasing σ , the size of the stability island shrinks. Since all Laplacian eigenvalues μ_i are independent of σ , we observe that μ_i/r move out of the stability island with increasing σ . For the globally coupled network, in particular, we have either $\mu_i/r = 0$ or $\mu_i/r = 1$. Therefore, with increasing σ , we find a transition from complete coherence, see Fig. 3(a,d,g) to partial synchronization and incoherence. We further observe that closely after destabilization, a large frequency cluster remains visible, see Fig. 3(b,e,h). For higher overall coupling, the cluster sizes shrink, and the number of small clusters increases, see Fig. 3(c,f,i).

In summary, we have developed a master stability approach for a general class of adaptive networks. This approach allows for studying the subtle interplay between nodal dynamics, adaptivity, and a complex network structure. The master stability approach has been first applied to a paradigmatic model of adaptively coupled phase oscillators. We have presented several typical forms of the master stability function for different adaptation rules, and observed adaptivity-induced stability islands. Besides, we have shown that stability islands give rise to the emergence of multicluster states and chimera-like states in the desynchronization transition for an increasing overall coupling strength. Qualitatively the same phenomena have been shown for a more realistic network of non-diffusively coupled FitzHugh-Nagumo neurons with synaptic plasticity. In this set-up, the emergence of a stability island and a desynchronization transition have been found as well.

The theoretical approach introduced in this Letter provides a powerful tool to study collective effects in more realistic neuronal network models, including synaptic plasticity [32, 82]. While our approach is presented for differentiable models, it might be generalized to non-continuous models of spiking neurons equipped with spike timing-dependent plasticity [90, 91]. Our findings

FIG. 3. Dynamics of globally coupled network of 200 FitzHugh-Nagumo neurons with plasticity Eqs. (12)–(15). Adiabatic continuation for an increasing overall coupling strength σ with the step size 0.0005, starting with the synchronous state. For the three values of σ : (a,d,g) $\sigma = 0.002$, (b,e,h) $\sigma = 0.0025$, and (c,f,i) $\sigma = 0.005$, the plots show: in (a,b,c), the master stability function, together with μ_i/r , where μ_i are the Laplacian eigenvalues (color code as in Fig. 1), in (d,e,f) the average frequency $\langle f_i \rangle$, and in (g,h,i) snapshots for u_i at $t = 10000$. Here $\langle f_i \rangle = M_i/1000$, where M_i is the number of rotations (spikes) of neuron i during the time interval of length 1000. The control parameters for the adaptation rule β_1 and β_2 are chosen such that $h(0) = 0.8$ and $Dh(0) = (80, 0, 0)$.

on the transition from coherence to incoherence reveal the role adaptivity plays for the formation of partially synchronized patterns which are important for understanding the functioning of neuronal systems [100]. Beyond neuronal networks, adaptation is a well-known control paradigm [101–104]. Our extended master stability approach provides a generalized framework to study various adaptive control schemes for a wide range of dynamical systems.

I. DERIVATION OF THE MASTER STABILITY FUNCTION FOR ADAPTIVE COMPLEX NETWORKS

In this section, we derive the master stability function for system (1)–(2) from the main text. For convenience, we repeat these equations here:

$$\dot{\mathbf{x}}_i = f(\mathbf{x}_i) - \sigma \sum_{j=1}^N a_{ij} \kappa_{ij} g(\mathbf{x}_i, \mathbf{x}_j), \quad (\text{S1})$$

$$\dot{\kappa}_{ij} = -\epsilon (\kappa_{ij} + a_{ij} h(\mathbf{x}_i - \mathbf{x}_j)), \quad (\text{S2})$$

where the adjacency matrix has constant row sum $r = \sum_{j=1}^N a_{ij}$.

Let $(\mathbf{s}(t), \kappa_{ij}^s)$ be the synchronous state, i.e., $\mathbf{x}_i = \mathbf{s}(t)$ and $\kappa_{ij} = \kappa_{ij}^s$ for all $i, j = 1 \dots, N$. This state solves the set of differential Eqs. (3)–(4) of the main text.

In order to describe the local stability of the synchronous state, we derive the variational equation for small perturbations close to this state. For this, we introduce the following vector variables denoting the deviations from the synchronized state: $\boldsymbol{\xi} = \mathbf{x} - \mathbb{1}_N \otimes \mathbf{s}$, and $\boldsymbol{\chi} = \boldsymbol{\kappa} - \boldsymbol{\kappa}^s$ with

$$\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_N)^T, \\ \boldsymbol{\kappa} = (\kappa_{11}, \dots, \kappa_{1N}, \kappa_{21}, \dots, \kappa_{NN})^T,$$

where \otimes denotes the Kronecker product. Using the following notations

$$\mathbf{a}_i = (a_{i1}, \dots, a_{iN}), \\ \text{diag}(\mathbf{a}_i) = \begin{pmatrix} a_{i1} & & \\ & \ddots & \\ & & a_{iN} \end{pmatrix},$$

and the $N \times N^2$, $N^2 \times N$, and $N^2 \times N$ matrices

$$B = \begin{pmatrix} \mathbf{a}_1 & & \\ & \ddots & \\ & & \mathbf{a}_N \end{pmatrix},$$

$$C = B^T - D,$$

$$D = \begin{pmatrix} \text{diag}(\mathbf{a}_1) \\ \vdots \\ \text{diag}(\mathbf{a}_N) \end{pmatrix},$$

respectively, the variational equation reads

$$\begin{pmatrix} \dot{\boldsymbol{\xi}} \\ \dot{\boldsymbol{\chi}} \end{pmatrix} = \begin{pmatrix} S & -\sigma B \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon C \otimes Dh(0) & -\epsilon \mathbb{1}_{N^2} \end{pmatrix} \begin{pmatrix} \boldsymbol{\xi} \\ \boldsymbol{\chi} \end{pmatrix}, \quad (\text{S3})$$

where

$$S = \mathbb{1}_N \otimes Df(\mathbf{s}) \\ + \sigma h(0) (r \mathbb{1}_N \otimes D_1 g(\mathbf{s}, \mathbf{s}) + A \otimes D_2 g(\mathbf{s}, \mathbf{s})).$$

We note that matrices B , C , and D satisfy the relations $B \cdot B^T = r \mathbb{1}_N$, $B \cdot D = A$, and $B \cdot C = L$, which can be obtained by straightforward calculation.

Due to the structure of the variational equation (S3), there exist $N^2 - N$ eigenvalues $\lambda = -\epsilon$. The corresponding time-independent eigenspace can be found from

$$\begin{pmatrix} S - \epsilon \mathbb{1}_{Nd} & -\sigma B \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon C \otimes Dh(0) & 0 \end{pmatrix} \begin{pmatrix} \boldsymbol{\xi} \\ \boldsymbol{\chi} \end{pmatrix} = 0.$$

One can see that $(\boldsymbol{\xi}, \boldsymbol{\chi})$ such that $\boldsymbol{\xi} = 0$ and $B\boldsymbol{\chi} = 0$ are the time-independent eigenvectors. Moreover, the relation $B\boldsymbol{\chi} = 0$ defines $N^2 - N$ linearly independent eigenvectors spanning the eigenspace corresponding to the eigenvalues $\lambda = -\epsilon$. This follows from the fact that $\boldsymbol{\chi}$ is N^2 -dimensional and $\text{rank}(B) = N$ if the row sum r of A is non-zero.

With these prerequisites we are now able to simplify the local stability analysis on adaptive networks and find a master stability function.

Let (S1)–(S2) possess a synchronous solution $(\mathbf{s}, \kappa_{ij}^s)$. Further, let (S3) be the variational equations around this synchronous solution and assume that the Laplacian matrix L is diagonalizable. Then, the synchronous solution is locally stable if and only if for all eigenvalues $\mu \in \mathbb{C}$ of the Laplacian matrix, the largest Lyapunov exponent (if it exists), i.e., the master stability function $\Lambda(\mu)$, of the following system is negative

$$\frac{d\zeta}{dt} = \left(Df(\mathbf{s}) + \sigma r h(0) (D_1 g(\mathbf{s}, \mathbf{s}) \right. \\ \left. + (1 - \frac{\mu}{r}) D_2 g(\mathbf{s}, \mathbf{s})) \right) \zeta - \sigma g(\mathbf{s}, \mathbf{s}) \kappa, \quad (\text{S4})$$

$$\frac{d\kappa}{dt} = -\epsilon (\mu Dh(0) \zeta + \kappa). \quad (\text{S5})$$

Here, $\zeta \in \mathbb{C}^d$ and $\kappa \in \mathbb{C}$.

In the following we present the derivation of (S4)–(S5). As it is shown above, there are $N^2 - N$ independent vectors \mathbf{w}_l ($l = 1, \dots, N^2 - N$) spanning

the kernel of B , i.e. $B\mathbf{w}_l = 0$. Using the Gram-Schmidt procedure we find an orthonormal basis for $\ker(B) = \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_{N^2-N}\}$. With this, we define the $N^2 \times (N^2 - N)$ matrix $Q = (\mathbf{v}_1, \dots, \mathbf{v}_{N^2-N})$. Consider now the $(N^2 + Nd) \times (N^2 + Nd)$ matrix

$$R = \begin{pmatrix} \mathbb{I}_{Nd} & 0 & 0 \\ 0 & (1/r)B^T & Q \end{pmatrix}$$

with left inverse

$$R^{-1} = \begin{pmatrix} \mathbb{I}_{Nd} & 0 \\ 0 & B \\ 0 & Q^T \end{pmatrix},$$

i.e., $R^{-1}R = \mathbb{I}_{N^2+Nd}$. Introduce the new coordinates given by $R \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix} = \begin{pmatrix} \xi \\ \chi \end{pmatrix}$ for which the variational equation then reads

$$\frac{d}{dt} \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix} = R^{-1} \begin{pmatrix} S & -\sigma B \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon C \otimes Dh(0) & -\epsilon \mathbb{I}_{N^2} \end{pmatrix} R \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix}.$$

We further obtain

$$\begin{aligned} & R^{-1} \begin{pmatrix} S & -\sigma B \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon C \otimes Dh(0) & -\epsilon \mathbb{I}_{N^2} \end{pmatrix} R \\ &= R^{-1} \begin{pmatrix} S & -\sigma \mathbb{I}_N \otimes g(\mathbf{s}, \mathbf{s}) & 0 \\ -\epsilon C \otimes Dh(0) & -\epsilon/r B^T & -\epsilon Q \end{pmatrix} \\ &= \begin{pmatrix} S & -\sigma \mathbb{I}_N \otimes g(\mathbf{s}, \mathbf{s}) & 0 \\ -\epsilon L \otimes Dh(0) & -\epsilon \mathbb{I}_N & 0 \\ -\epsilon Q^T C \otimes Dh(0) & 0 & -\epsilon \mathbb{I}_{N^2-N} \end{pmatrix}. \end{aligned}$$

These equations yield that there are $Nd + N$ coupled differential equations left

$$\frac{d}{dt} \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix} = \begin{pmatrix} S & -\sigma \mathbb{I}_N \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon L \otimes Dh(0) & -\epsilon \mathbb{I}_N \end{pmatrix} \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix} \quad (\text{S6})$$

with $\tilde{\chi} = \hat{\chi}_1$ that determine the stability for the synchronous state, and $N^2 - N$ slave equations

$$\frac{d}{dt} \tilde{\chi} = \begin{pmatrix} -\epsilon Q^T C \otimes Dh(0) & 0 & -\epsilon \mathbb{I}_{N^2-N} \end{pmatrix} \begin{pmatrix} \hat{\xi} \\ \tilde{\chi} \\ \hat{\chi} \end{pmatrix}$$

with $\bar{\chi} = (\hat{\chi}_2^T, \dots, \hat{\chi}_N^T)^T$ which are driven by the variables $\hat{\xi}$ and $\tilde{\chi}$ and, hence, can be solved explicitly once the latter once are known. By assumption, there is a unitary matrix $D_L = U^H L U$ where D_L is the diagonalization of the Laplacian matrix L . Transforming the differential equation (S6) by using the unitary transformation U , we get

$$\frac{d}{dt} \begin{pmatrix} \zeta \\ \kappa \end{pmatrix} = \begin{pmatrix} \mathbb{I}_N \otimes Df(\mathbf{s}) + \sigma h(0) (r \mathbb{I}_N \otimes D_1 g(\mathbf{s}, \mathbf{s}) + (r \mathbb{I}_N - D_L) \otimes D_2 g(\mathbf{s}, \mathbf{s})) & -\sigma \mathbb{I}_N \otimes g(\mathbf{s}, \mathbf{s}) \\ -\epsilon D_L \otimes Dh(0) & -\epsilon \mathbb{I}_N \end{pmatrix} \begin{pmatrix} \zeta \\ \kappa \end{pmatrix}$$

where $\begin{pmatrix} U \otimes \mathbb{I}_d & 0 \\ 0 & U \end{pmatrix} \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \end{pmatrix} = \begin{pmatrix} \zeta \\ \kappa \end{pmatrix}$.

Remarkably, the master stability function Λ depends explicitly on the row sum r . Moreover, the master stability function seems to depend on σ , r , and μ independently. The time scale separation parameter ϵ is always kept fixed. However, in any case, one parameter can be disregarded. To see this, we note that the solution to the Eq. (S5) is explicitly solvable and the solution reads

$$\kappa = \kappa_0 e^{-\epsilon(t-t_0)} - \epsilon \mu Dh(0) \int_{t_0}^t e^{-\epsilon(t-t')} \zeta(t') dt',$$

where the first term vanishes for $t \rightarrow \infty$ and hence can be neglected (when studying asymptotic stability for $t \rightarrow \infty$). We use this and rewrite the asymptotic dynamics

of (S4)–(S5) in its integro-differential form

$$\begin{aligned} \frac{d\zeta}{dt} &= (Df(\mathbf{s}) + \sigma r h(0) (D_1 g(\mathbf{s}, \mathbf{s}) \\ &\quad + (1 - \frac{\mu}{r}) D_2 g(\mathbf{s}, \mathbf{s}))) \zeta \\ &\quad + \epsilon \sigma r \frac{\mu}{r} g(\mathbf{s}, \mathbf{s}) Dh(0) \int_{t_0}^t e^{-\epsilon(t-t')} \zeta(t') dt'. \end{aligned}$$

Hence, the master stability function can be regarded as a function of two parameters, i.e., $\Lambda(\sigma, \mu, r) = \Lambda(\sigma r, \mu/r)$. Furthermore, in case of diffusive coupling, i.e., $g(\mathbf{x}, \mathbf{y}) = g(\mathbf{x} - \mathbf{y})$, the master stability function can be regarded as a function of only one parameter $\Lambda(\sigma, \mu, r) = \Lambda(\sigma \mu)$.

II. MASTER STABILITY FUNCTION FOR ADAPTIVE PHASE OSCILLATOR NETWORKS

In this section, we provide a brief analysis of the master stability function for the adaptive Kuramoto-Sakaguchi network (9)–(10) of the main text. Using the result of Section I, the stability of the synchronous state of system (9)–(10) of the main text is governed by the two differential equations

$$\frac{d}{dt} \begin{pmatrix} \zeta \\ \kappa \end{pmatrix} = \begin{pmatrix} \mu\sigma\cos(\alpha)\sin(\beta) & -\sigma\sin(\alpha) \\ -\epsilon\mu\cos(\beta) & -\epsilon \end{pmatrix} \begin{pmatrix} \zeta \\ \kappa \end{pmatrix},$$

where $\mu \in \mathbb{C}$ stands for all eigenvalues of the Laplacian matrix L corresponding to the base network described by the adjacency matrix A . The characteristic polynomial in λ of the latter system is of degree two and reads

$$\lambda^2 + (\epsilon - \sigma\mu\cos(\alpha)\sin(\beta))\lambda - \epsilon\sigma\mu\sin(\alpha + \beta) = 0. \quad (\text{S7})$$

The master stability function is given as $\Lambda(\sigma\mu) = \max(\text{Re}(\lambda_1), \text{Re}(\lambda_2))$ where λ_1 and λ_2 are the two solutions of the quadratic polynomial (S7). Figure 1 of the main text displays the master stability function for different parameters.

The boundary of the region in $\sigma\mu$ parameter space that corresponds to stable local dynamics, is given by $\lambda = i\gamma$ with $\gamma \in \mathbb{R}$. Plugging this into Eq. (11) of the main text, we obtain

$$\sigma\mu = Z(\gamma) = a(\gamma) + ib(\gamma)$$

with

$$a(\gamma) = \epsilon \frac{\gamma^2 (\cos \alpha \sin \beta - \sin(\alpha + \beta))}{\gamma^2 \cos^2 \alpha \sin^2 \beta + \epsilon^2 \sin^2(\alpha + \beta)},$$

$$b(\gamma) = \frac{\gamma^3 \cos \alpha \sin \beta + \epsilon^2 \gamma \sin(\alpha + \beta)}{\gamma^2 \cos^2 \alpha \sin^2 \beta + \epsilon^2 \sin^2(\alpha + \beta)}.$$

Due to the symmetry of the master stability function, a necessary condition to observe a stability island is that the curve $\sigma\mu(\gamma)$ possesses two crossings with the real axis, i.e., two real solutions for $b(\gamma) = 0$. The three crossings are given by $\gamma_1 = 0$ and as real solutions γ_2 and γ_3 of $\gamma^2 \cos \alpha \sin \beta = -\epsilon^2 \sin(\alpha + \beta)$. From this we deduce the existence condition for stability islands: $\sin(\alpha + \beta)/(\cos \alpha \sin \beta) < 0$ ($\epsilon > 0$). Note that $a(\gamma_2) = a(\gamma_3)$.

III. THE CLUSTER PARAMETER

In this section, we introduce the cluster parameter R_C as a measure for coherence in a system of coupled phase oscillators. A measure that can be used in order to detect frequency synchronization between two oscillators relies

on the mean phase velocity (average frequency) of each phase oscillator

$$\Omega_i = \lim_{T \rightarrow \infty} \frac{1}{T} (\phi_i(t_0 + T) - \phi_i(t_0)). \quad (\text{S8})$$

The frequency synchronization measure between nodes is given by

$$\Omega_{ij} = \begin{cases} 1, & \text{if } \Omega_i - \Omega_j = 0, \\ 0, & \text{otherwise.} \end{cases} \quad (\text{S9})$$

Numerically the limit is approximated by a very long averaging window. In addition, we use a sufficiently small threshold ϖ in order to detect frequency synchronization numerically, i.e., $\Omega_{ij} = 1$ if $|\Omega_i - \Omega_j| < \varpi$. For the analysis presented here and in the main text, we use $\varpi = 0.001$. Using the measure Ω_{ij} , we define the cluster parameter

$$R_C = \frac{1}{N^2} \sum_{i,j=1}^N \Omega_{ij}. \quad (\text{S10})$$

The cluster parameter measures the following. First, for each frequency cluster, the total number of pairwise synchronized nodes is computed. Second, all pairs of two nodes from the same cluster are summed up and normalized by the number of all possible pairs of nodes N^2 . In case of full synchronization, frequency clustering, or incoherence the values of the cluster parameter are $R_C = 1$, $1 < R_C < 0$, or $R_C = 0$, respectively. A similar measure can be found in Refs. [1, 2].

IV. DESYNCHRONIZATION TRANSITION AND THE FORMATION OF PARTIAL SYNCHRONIZATION PATTERNS IN ADAPTIVE PHASE OSCILLATOR NETWORKS

In this section, we provide further details on the desynchronization transition in a network of adaptively coupled phase oscillators (9)–(10).

Figure S1 shows the cluster parameter R_C for different values of the coupling constant σ . In the adiabatic continuation, we increase σ step-wise after an integration time of $t = 10000$. For each simulation, the final state of the previous simulations is taken as the initial condition with an additional small perturbation. Note that $R_C = 1$ refers to full in-phase synchrony of the oscillators. We observe that, for small σ , the synchronous state is stable, see Fig. S1(d,g,j). Here, the stability of the synchronous state is directly implied by the master stability function. We note that all Laplacian eigenvalues μ_i of a globally coupled network are given by either $\mu_i = 0$ or $\mu_i = N$. In Figure S1(a), all master function parameters $\sigma\mu$ lie within the stability island.

By increasing the coupling constant, the values $\sigma\mu_i$ move out of the stability regions and the synchronous

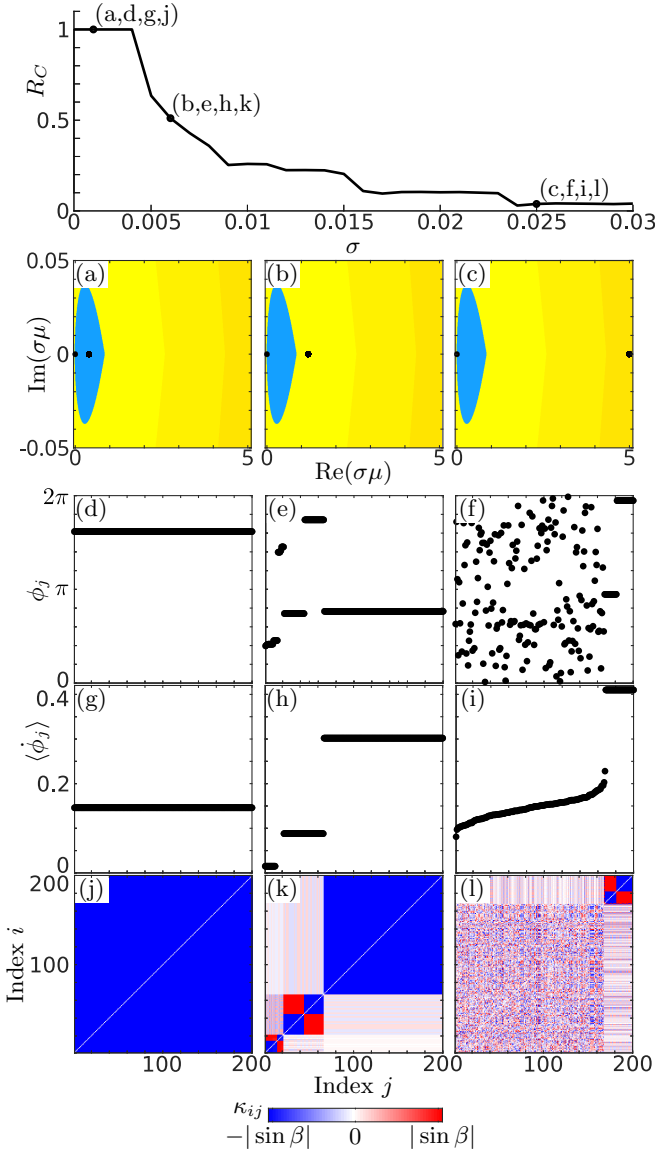

FIG. S1. Dynamics in a globally coupled network of 200 phase oscillators Eqs. (9)–(10) of the main text for different values of overall coupling strength σ than in Fig.2 of the main text. Adiabatic continuation for increasing σ with the step-size of 0.001, starting with the synchronous state $\phi_i = 0$, $\kappa_{ij} = -a_{ij} \sin \beta$. The top panel shows the cluster parameter R_C vs σ . For the three values of σ : (a,d,g,j) $\sigma = 0.002$, (b,e,h,k) $\sigma = 0.006$, and (c,f,i,l) $\sigma = 0.025$, the plots show: in (a,b,c) the master stability function (color coded as in Fig. 1 of the main text), together with $\sigma\mu_i$, where μ_i are the N Laplacian eigenvalues of A ; in (d,e,f) snapshots for ϕ_i at $t = 30000$; in (g,h,i) the temporal average of the phase velocities $\langle \phi_j \rangle$ over the last 5000 time units; and in (j,k,l) snapshots for the coupling matrix κ_{ij} at $t = 30000$. Other parameters: $\alpha = 0.49\pi$, $\beta = 0.88\pi$, $\epsilon = 0.01$.

state becomes unstable. For intermediate values of σ the emergence of multiclusters with hierarchical structure in the cluster size are observed. In Figure S1(e,h,k) a multicluster states is shown with three clusters. Note

u_i	membrane potential/activator
v_i	recovery/inhibitor variable
I_i	synaptic output variable
κ_{ij}	variable coupling weights
N	number of oscillators
a_{ij}	entries of adjacency matrix, $a_{ij} \in \{0, 1\}$
σ	overall coupling strength
r	row sum, i.e., $r = \sum_{j=1}^N a_{ij}$
$a = 0.7, b = 0.2$	bifurcation parameters of the FitzHugh-Nagumo neuron
$\tau = 0.08$	controls time separation between fast activation and slow inhibition
$\epsilon = 0.01$	controls time separation between fast oscillation and slow adaptation
$\tau_{\text{syn}} = 5/6$	synaptic decay rate
$u_{\text{shp}} = 0.05$	coupling shape parameter
β_1, β_2	adaption control parameters

TABLE S1. The table provides the meaning for each variable and parameter used in (S11)–(S14).

that for the system (9)–(10) of the main text, in-phase synchronous and antipodal clusters have the same properties [3, 4]. In Refs. [3, 4] the role of the hierarchical structure of the cluster sizes have been discussed. Increasing the coupling constant further shows the emergence of incoherence. In Figure S1(f,i,l), we show the coexistence of a coherent and an incoherent cluster. These states, also called chimera-like states, have been numerically analyzed in Refs. [1, 2, 5].

V. NETWORK OF COUPLED FITZHUGH-NAGUMO NEURONS WITH SYNAPTIC PLASTICITY

In this section, we describe the model of coupled FitzHugh-Nagumo neurons with synaptic plasticity and present the synchronous state used in the main text. The model is given by

$$\tau \dot{u}_i = u_i - \frac{u_i^3}{3} - v_i - \sigma \sum_{j=1}^N a_{ij} \kappa_{ij} u_i I_j, \quad (\text{S11})$$

$$\dot{v}_i = u_i + a - b v_i, \quad (\text{S12})$$

$$\dot{I}_i = \alpha(u_i)(1 - I_i) - I_i/\tau_{\text{syn}}, \quad (\text{S13})$$

$$\dot{\kappa}_{ij} = -\epsilon \left(\kappa_{ij} + a_{ij} e^{-\beta_1(u_i - u_j + \beta_2)} \right), \quad (\text{S14})$$

where $\alpha(u_i) = 2/(0.08(1 + \exp(-u_i/0.05)))$, see Eqs. (12)–(15) of the main text. All variables and parameters are explained in Tab. S1. The form of the synaptic plasticity is similar to the rules used in [6, 7]. We introduce β_1 and β_2 as control parameters. In particular, we have $\beta_1 = -h(0)/(2Dh(0)\beta_2)$ and $\beta_2 = (2Dh(0)_1 \ln(Dh(0)_1))/h(0)$ where $Dh(0)_1$ denotes the first component of $Dh(0)$.

The synchronous state of the equations (S11)–(S14) is

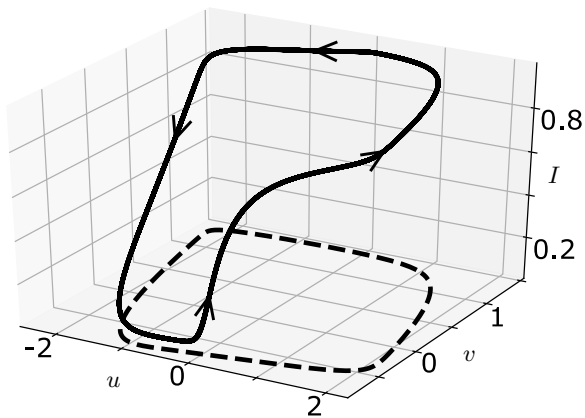

FIG. S2. Limit cycle in Eqs. (S15)–(S17) as solid line and the projection onto the u - v -plane as dashed line. Parameters: $\sigma = 0.002$, $r = 200$, $h(0) = 0.8$ and $Dh(0) = (80, 0, 0)$. All other parameters as in Tab. S1.

given by a solution of

$$\tau \dot{u}_s = u_s - \frac{u_s^3}{3} - v_s + \sigma r u_s I_s e^{-\beta_1 \beta_2^2}, \quad (\text{S15})$$

$$\dot{v}_s = u_s + a - b v_s, \quad (\text{S16})$$

$$\dot{I}_s = \alpha(u_s)(1 - I_s) - I_s / \tau_{\text{syn}}, \quad (\text{S17})$$

$$\kappa_{ij}^s = -a_{ij} e^{-\beta_1 \beta_2^2}, \quad (\text{S18})$$

where $(u_i, v_i, I_i) = \mathbf{s} = (u_s, v_s, I_s)$ for all $i = 1, \dots, N$. In Fig. S2, we display a limit cycle as a stable numerical solution of (S15)–(S18) for the set of parameters used in the main text.

VI. THE MASTER STABILITY FUNCTION AND DESYNCHRONIZATION TRANSITION IN ADAPTIVE NETWORKS OF FITZHUGH-NAGUMO NEURONS

In this section, we consider the model of adaptively coupled FitzHugh-Nagumo neurons (S11)–(S14). We give insights into the derivation of the system's master stability function as well as on the desynchronization transition induced by the adaptivity.

In order to investigate the local stability of the synchronous states that solves Eqs. (S15)–(S18), see Fig. S2, we linearize Eqs. (S11)–(S14) around these states. Using the results of Section I, the stability of the synchronous solution is governed by the set of equations

$$\frac{d\zeta}{dt} = \left(Df(\mathbf{s}) + \sigma r h(0) (D_1 g(\mathbf{s}, \mathbf{s}) + (1 - \frac{\mu}{r}) D_2 g(\mathbf{s}, \mathbf{s})) \right) \zeta - \sigma g(\mathbf{s}, \mathbf{s}) \kappa,$$

$$\frac{d\kappa}{dt} = -\epsilon (\mu Dh(0) \zeta + \kappa).$$

FIG. S3. The master stability functions for the synchronous solution of (S11)–(S14) and different plasticity rules are displayed (color code as in Fig. 1 of the main text). Regions belonging to negative Lyapunov exponents are colored blue. Parameters: the control parameters β_1 and β_2 are chosen such that (a) $h(0) = 0.8$, $Dh(0) = (50, 0, 0)$ (b) $h(0) = -0.2$, $Dh(0) = (0, 0, 0)$, (c) $h(0) = 0.8$, $Dh(0) = (10, 0, 0)$, and (d) $h(0) = 0.4$, $Dh(0) = (50, 0, 0)$. The overall coupling constant is set to $\sigma = 0.005$. All other parameters are as in Fig. S2.

Here, the derivatives of the functions f , g , and h are

$$Df(\mathbf{s}) = \begin{pmatrix} \frac{1}{\tau} (1 - u_s^2) & -\frac{1}{\tau} & 0 \\ 1 & -b & 0 \\ \frac{\tau(\alpha(u_s))^2(1-I_s)}{\alpha_0 u_{\text{shp}} \exp(\frac{u_s}{u_{\text{shp}}})} & 0 & -\alpha(u_s) - \frac{1}{\tau_{\text{syn}}} \end{pmatrix},$$

$$D_1 g(\mathbf{s}, \mathbf{s}) = \begin{pmatrix} I_s & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$D_2 g(\mathbf{s}, \mathbf{s}) = \begin{pmatrix} 0 & 0 & u_s \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$Dh(0) = (-2\beta_1 \beta_2 \exp(-\beta_1 \beta_2^2) \ 0 \ 0).$$

Using this, we are able to determine numerically the maximum Lyapunov exponents and hence the stability of the periodic orbit displayed in Fig. S2. In Fig. S3, we show different shapes of the master stability function depending on the form of the plasticity rule, i.e., depending on $h(0)$ and $Dh(0)$. We observe that for certain parameters almost complete half spaces in the μ/r -plane refer to stable or unstable local dynamics, see Fig. S3(a,b). This is similar to Fig. 1(d,e) of the main text where we display the master stability function of the phase oscillator model. Most remarkably, similar to the phase oscillator model (9)–(10) we find parameters for which stability islands exist, see Fig. S3(d).

As we know from the example of phase oscillators, the presence of a stability island may induce a desynchroniza-

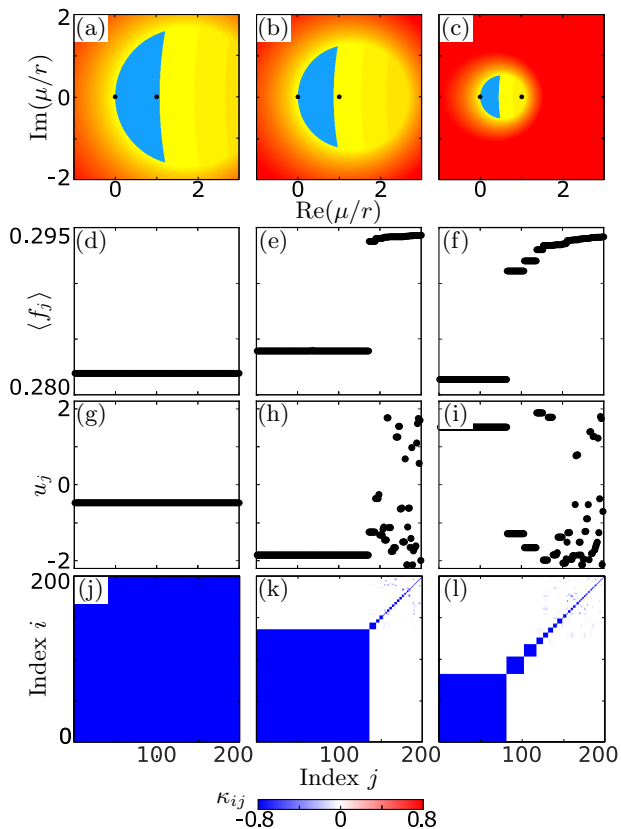

FIG. S4. Dynamics of globally coupled network of 200 FitzHugh-Nagumo neurons with plasticity Eqs. (12)–(15). Adiabatic continuation for an increasing overall coupling strength σ with the step size 0.0005, starting with the synchronous state of Eqs. (12)–(15). For the three values of σ : (a,d,g,j) $\sigma = 0.002$, (b,e,h,k) $\sigma = 0.0025$, and (c,f,i,l) $\sigma = 0.005$, the plots show: in (a,b,c), the master stability function, together with μ_i/r , where μ_i are the N Laplacian eigenvalues (color code as in Fig. 1 of the main text), in (d,e,f) the average frequency $\langle f_i \rangle$, in (g,h,i) snapshots for u_i at $t = 10000$, and in (j,k,l) snapshots for the coupling matrices κ_{ij} at $t = 10000$. Here $\langle f_i \rangle = M_i/1000$, where M_i is the number of rotations (spikes) of neuron i during the time interval of length 1000. The control parameters for the adaptation rule β_1 and β_2 are chosen such that $h(0) = 0.8$ and $Dh(0) = (80, 0, 0)$. All other parameters can be taken from Tab. S1.

tion transition for an increasing overall coupling strength σ . In order to show this transition, we follow the same approach already presented in Fig. S1. The results of the adiabatic continuation on a globally coupled network are shown in Fig. S4. We note that in contrast to the case of phase oscillators, here, the shape of the master

stability function depends explicitly on σ . The desynchronization is described in the main text. Additionally to the figure given in the main text, we provide plots for the coupling matrices in Fig. S4(j,k,l). The coupling matrices show very nicely the emergence of partial synchronization structures in the transition from coherence to incoherence which is induced by the stability island.

FIG. S5. Adjacency matrix A_c of a connected, directed random network of $N = 200$ nodes with constant row sum $r = 50$. The illustration shows the adjacency matrix where black and white refer to whether a link between two nodes exist or not, respectively.
