(Dated: October 28, 2020)

The linear spin wave theory study of PbFeBO<sub>4</sub> spin dynamics is presented. It is shown that the modes observed in Raman scattering experiments below Néel temperature in [1] are optical magnon and two-magnon excitations. Based on the magnon energy, two-magnon band lineshape, and Weiss temperature [2], the consistent set of the exchange coupling constants up the third neighbor is derived and compared with the results of *ab initio* calculations [3–5]. The small deviation of the observed two-magnon band from the one-magnon density of states suggests a surprisingly negligible role of magnon-magnon interactions.

## I. INTRODUCTION

The promising field of antiferromagnetic spintronics [6–9] constantly demands the discovery of the new functional materials with specified properties and the development of reliable theoretical models. Some potential material candidates manifest intrinsic coupling of different subsystems such as magnetic, orbital, electronic, and lattice, allowing for additional degrees of freedom to control spin excitations [10–12].

The PbMBO<sub>4</sub> (M=Cr, Mn, Fe) family of compounds belongs to the sillimanite group [13], where the presence of the stereochemically active Pb<sup>2+</sup> cations leads to the reduction of the connectivity between magnetic ions resulting in the unique topology of the exchange structure [14]. Moreover, the types of magnetic ions drastically affect magnetic properties, such as magnetic structures, critical temperatures, and dispersion of the magnetic excitations without change of crystal symmetry. Notably, PbMnBO<sub>4</sub> is an extremely rare example of insulating ferromagnets [15, 16], while other (PbFeBO<sub>4</sub> and PbCrBO<sub>4</sub>) are known to be antiferromagnets [15]. There are a few predicted compounds with other 3*d* ions PbMBO<sub>4</sub> (M=Ti,V,Co) [4], which yet to be synthesized.

In this family, the PbFeBO<sub>4</sub> exhibits the highest transition temperature of  $T_N = 114$  K, shows anisotropic and negative thermal expansion observed with X-ray and neutron diffraction [17], anomalies in the vicinity of  $T_N$  in both dielectric susceptibility [2] and phonon energies [1] indicating coupling between magnetic and lattice subsystems. Magnetostatic and dielectric properties of PbFeBO<sub>4</sub> and PbMnBO<sub>4</sub> were studied in detail in [2, 16]. There are a number of *ab initio* calculations [3– 5, 18] dedicated to the determination of the exchange constants. Simultaneously, the reliable determination of the exchange constants is the crucial step in understanding both the static and dynamical properties of the material and its further potential for applications.

In this paper, we report on the linear spin-wave theory calculations allowing us to derive closed-form magnon dispersion relation for PbFeBO<sub>4</sub> (and equivalent compounds), calculation of the two-magnon (2M) band lineshape, and ground-state phase diagram for exchange couplings up to the third neighbor. The consistent set of the exchange constants  $(J_0, J_1, J_2)$  is proposed based on the experimentally observed energy of the optical branch, shape of 2M band [1], and Curie-Weiss temperature [2]. It is shown that both interchain couplings  $(J_1, J_2)$  are crucial to capture peculiarities of the spin dynamics. Their values, considering coordination numbers, are comparable with intrachain one the  $(J_0)$  classifying PbFeBO<sub>4</sub> as 3D Heisenberg antiferromagnet. The symmetry allowed Dzyaloshinskii-Moriya interaction (DMI) on  $J_0$ path could explain magnetic susceptibility anomaly [2] in the absence of weak ferromagnetic moment and could be directly observed by the zero-field splitting of the acoustical magnon branch. The estimated energy range of magnetic excitations for PbCrBO<sub>4</sub> is briefly discussed at the end.

### **II. RESULTS AND DISCUSSION**

Below  $T_N = 114 \text{ K}$  PbFeBO<sub>4</sub> undergoes paramagnetic to antiferromagnetic phase transition with magnetic propagation vector  $\mathbf{k} = 0$  according to neutron diffraction measurements [15]. The resulting magnetic structure can be described as coupled antiferromagnetic chains of [FeO<sub>6</sub>] octahedra. Based on exchange interactions up to the third neighbor, the  $\mathbf{k} = 0$  ground state phase diagram is calculated through energy minimization [19] and shown in Fig. 1. Two cases of antiferromagnetic and ferromagnetic intrachain interactions were considered, and it is shown that all possible  $\mathbf{k} = 0$  magnetic structures could be realized in both cases, however taking into account dominant role of J<sub>0</sub> the most probable structures are AFM2 and AFM1 for J<sub>0</sub> > 0 and FM and AFM3 for J<sub>0</sub> < 0, respectively.

The following Hamiltonian based on isotropic exchange interactions and single-ion anisotropy (SIA) terms is con-

FIG. 2. Spin-waves dispersion along the high-symmetry path in the Brillouin zone according to Eq. (4). To obtain the energy of the highlighted points equations should be multiplied by the 2S (e.g. S = 5/2 for PbFeBO<sub>4</sub>). Purple circle shows the energy of the experimentally observed optical branch [1].

sidered for spin-wave calculations:

$$\mathcal{H} = \sum_{\langle i,j \rangle} J_0 \mathbf{S}_i \mathbf{S}_j + \sum_{\langle \langle i,j \rangle \rangle} J_1 \mathbf{S}_i \mathbf{S}_j + \sum_{\langle \langle \langle i,j \rangle \rangle \rangle} J_2 \mathbf{S}_i \mathbf{S}_j + \sum_i D(\mathbf{S}_i^z)^2 ,$$
(1)

where **S** is the spin operator,  $J_0..J_2$  stands for superexchange constants corresponding to paths shown in Fig. 1. J > 0 corresponds to AFM exchange.

Utilizing Holstein-Primakoff transformations [20] and Fourier transformation of the exchange couplings the bosonic matrix form of the Hamiltonian is obtained:

$$\begin{pmatrix}
a \ b^* \ 0 \ 0 \ 0 \ 0 \ c^* \ e^* \\
b \ a \ 0 \ 0 \ 0 \ 0 \ d \ c^* \\
0 \ 0 \ a \ b^* \ c \ d^* \ 0 \ 0 \\
0 \ 0 \ c^* \ e^* \ a \ b^* \ 0 \ 0 \\
0 \ 0 \ c^* \ e^* \ a \ b^* \ 0 \ 0 \\
c \ d^* \ 0 \ 0 \ 0 \ a \ b^* \\
e \ c \ 0 \ 0 \ 0 \ b \ a \ b^*
\end{pmatrix},$$
(2)

where

$$a = 2S (-D + J_0 - 2J_1 + 4J_2),$$
  

$$b = S J_1 (1 + e^{2\pi i h}) (1 + e^{2\pi i l}),$$
  

$$c = S J_0 (1 + e^{2\pi i k}),$$
  

$$d = 8S J_2 \cos(\pi h) \cos(\pi k) \cos(\pi l) e^{\pi i (h - k + l)},$$
  

$$e = S J_2 (1 + e^{2\pi i h}) (1 + e^{2\pi i k}) (1 + e^{2\pi i l}).$$
  
(3)

Diagonalization [21] of the matrix Eq. (2) leads to two positive doubly-degenerate, in the absence of external magnetic field, spin-wave modes corresponding to acoustical and optical branches:

$$\begin{aligned} \omega &= 2\mathrm{S} \big[ (\mathrm{D} - \mathrm{J}_0 + 2\mathrm{J}_1 - 4\mathrm{J}_2)^2 \\ &\mp 4\cos(\pi h)\cos(\pi l)(\mathrm{D}\mathrm{J}_1 + 2\mathrm{J}_1(\mathrm{J}_1 - 2\mathrm{J}_2) \\ &+ \mathrm{J}_0(\mathrm{J}_2 - \mathrm{J}_1) + \mathrm{J}_0\mathrm{J}_2\cos(2\pi k) \mp \mathrm{J}_1^2\cos(\pi h)\cos(\pi l)) \\ &- \cos^2(\pi k)(\mathrm{J}_0^2 + 16\mathrm{J}_2^2\cos^2(\pi h)\cos^2(\pi l)) \big]^{1/2} , \end{aligned}$$

$$(4)$$

where h, k, l are given in reciprocal lattice units, and different branches are distinguished by  $\mp$  sign. Obtained dispersion curves and surfaces are shown in Fig. 2 and Fig. 3, respectively.

All the calculations and plots were done with a small value of the single ion easy-axis type anisotropy of -0.01 meV (along the c axis) to reproduce the observed magnetic structure of  $PbFeBO_4$  [15]. Despite the fact that it is impossible to derive the precise value of SIA based on the existing experimental data, which will require the frequency of the acoustical magnon, it is possible to estimate its boundaries. No acoustical modes were observed above 10 cm<sup>-1</sup>  $\approx$  1.24 meV according to [1], thus it can be used to estimate a higher boundary of SIA. The lower one could be estimated by taking into account the absence of acoustic mode up to 140 GHz  $\approx$  $4.17 \text{ cm}^{-1} \approx 0.58 \text{ meV}$  in antiferromagnetic resonance (AFMR) experiments [2]. Thus using the set of the exchange constants from Table I and with Eq. (4) will get anisotropy bounds of -0.015 < D < -0.0033 meV. The validity of the obtained analytical results was confirmed by numerical calculations with SpinW library [19, 22].

### A. Two-magnon scattering

The most prominent feature observed in the magnetic Raman scattering spectra [1] below  $T_N$  is the broad and complex-shaped band attributed to the two-magnon scattering process due to its spectral and temperaturedependent characteristics. First, we will start with the selection rules. The effective two-magnon Raman Hamiltonian can be written according to the exchange scattering Fleury-Loudon mechanism [23]:

$$\mathcal{H}_R \propto \sum_{i,d} (\mathbf{e}_I \cdot \mathbf{d}) (\mathbf{e}_S \cdot \mathbf{d}) \mathbf{S}_i \mathbf{S}_j ,$$
 (5)

where  $e_I$  and  $e_S$  denote the polarization vectors of the incident and scattered light, and d is the vector connecting *i*-th ion with its nearest-neighbor for the specific exchange coupling. Thus, taking into account only dominant intrachain  $J_0$  interaction, this analysis predicts nonzero two-magnon scattering intensity only in (*bb*) polarizations, the case where both incident and scattered light polarized along the chains, which was, indeed, observed in the experiment [1].

It is known that two-magnon excitations observed, e.g., by Raman scattering, reflect the spin-wave density of states (DOS) [23], which can be directly calculated based on dispersion relations Eq. (4). It is necessary to use the full form of Hamiltonian Eq. (1) including all the exchange interactions to calculate the energy-depended shape of the two-magnon band. Density of states is calculated according to:

$$DOS = \oint_{\substack{E(x,y,z)=\epsilon}} \frac{dS}{|\nabla E(x,y,z)|} , \qquad (6)$$

where integral is taken numerically through constant energy surfaces within the first Brillouin zone. The results of the calculations for different sets of exchange couplings from Table I in comparison with the experiment are shown in Fig. 4. Note how drastically the shape is affected by  $J_1$ , and  $J_2$ , which allows us to undoubtedly determine them.

This approach, along with a proposed set of the optimized exchange constants  $J_0 = 1.67$ ,  $J_1 = -0.18$ ,  $J_2 = 0.094$  meV allowed us to capture all essential experimental observations [1] such as (i) high energy cut-off of the band at 28 meV (ii) characteristic curvature of the band in the 24–28 meV range (iii) nearly linear DOS of maximal energy in within 21–24 meV (iv) nonzero and nonlinear low-energy tail for energies less than 18 meV.

The limiting factors of further refinement of the exchange constants using 2M band are the presence of the intense phonon with the same  $A_g$  symmetry with the energy of  $\approx 19.5$  meV, overshadowing part of the expected singularities, a rather noisy spectrum, and the absence of quantitative information on the lower energy tail.

It should be noted that one-magnon DOS surprisingly well describes the experimentally observed two-magnon Usually, it is apparently different due to the band. magnon-magnon interactions [24] that strongly dampen and shift such excitations, which was demonstrated in paradigmatic examples of NiO [25] and RbMnF<sub>3</sub> [26]. The negligible role of the magnon-magnon interactions could mean an increased lifetime of spin excitations [27], which is a highly desirable goal for practical applications in antiferromagnetic spintronics [6]. An interesting aspect is the presence of the pronounced Van Hove singularities in the 2M band, which can provide access to magnons in the specific points in the Brillouin zone and could be potentially applied to modulate exchange interactions and to control magnetic order in ultrafast

FIG. 3. Spin-wave dispersion for  $PbFeBO_4$  given by Eq. (4) with exchange coupling constants from the first row of Table I.

FIG. 4. Comparison of experimental Raman scattering spectra of two-magnon band (red marks, data extracted from Fig. 5 in [1]) with the spin-wave density of states calculated with exchange constants from [3–5]. Note that DOS energy scale is doubled to match 2M excitation. Arrows indicate Van Hove singularities in DOS with corresponding critical points in the Brillouin zone.

timescales [28, 29]. Another striking feature is the accidental degeneracy of the high-energy (12.4 meV) optical magnon branch with  $A_g$  phonon in the low-temperature limit, which could be used for spin dynamics manipulation through optical phonon pumping [30].

### B. Comparison with ab initio calculations

Realization of both ferromagnetic and antiferromagnetic structures for different magnetic ions without change of the crystal symmetry in  $PbMBO_4$  (M=Cr, Mn, Fe) family spark the interest, and a few computational works [3–5] were done to shed light on this phenomenon. Lattice dynamics was addressed in [5, 17] and, in general, shows a good match with experimental data both on powdered samples [17] and single crystals [1].

Exchange constants up to the third neighbur were directly calculated in [3, 5] and, using energy mapping analysis (Eq. 3 in [3]), it is possible to extract constants from the energies of the magnetic structures from [4], which all summarized in Table I and graphically shown in Fig. 1. All calculations agree on the dominant role of the intrachain exchange (J<sub>0</sub>). The J<sub>1</sub> is either antiferromagnetic or zero in the case of Gibbs free energy calculations [5] and smaller than J<sub>2</sub>, which is also antiferromagnetic. It was shown that exchange constants are strongly dependent on Hubbard parameter U in DFT+U scheme [3]. The comparison of the sets, with the experimental 2M band presented in Fig. 4, clearly showing interchain coupling sensitivity, and substantial deviation for all the *ab initio* sets.

Besides the direct determination of the exchange constants based on one- and two-magnon excitations, it is possible to use static magnetic data as an additional consistency check. For example, Curie-Weiss temperature (sometimes referred to as Weiss or paramagnetic Curie temperature), which is the arithmetic average of all the exchange constants in the system [31], could be used. Taking into account the number and symmetry of the exchange couplings, it can be calculated as:

$$\Theta = -\frac{2}{3}S(S+1)[2J_0 + 4J_1 + 8J_2]/k_B .$$
 (7)

This parameter could be experimentally determined from the temperature dependence of the magnetic susceptibility for  $T > T_N$ . This was done experimentally [2], and the reported values are negative, suggesting predominantly antiferromagnetic interactions in the system, and slightly anisotropic  $\Theta_a = -256$ ,  $\Theta_b = -272$ ,  $\Theta_c = -262$  K. Most of the sets, proposed in *ab initio* works [3–5] overestimate  $\Theta$  by 54–81 %. In contrast the optimal set of the exchange constants results in much closer value  $\Theta = -228$  K. The deviation of  $\Theta$ from the proposed set could be explained by additional unaccounted superexchange couplings beyond J<sub>2</sub> or by the contribution of non-isotropic exchange interactions (see Section II C).

The calculated exchange parameters in comparison with previously suggested ones are summarized in Table I. We hope that the proposed set of exchange constants, compatible with all up to date experimental observations, will be used for a systematic search of U parameter in such a challenging system as PbFeBO<sub>4</sub>.

### C. Beyond isotropic exchange

The unexplained anomaly was reported in [2], where unusual for typical easy-axis antiferromagnet peak-like maximum in the magnetic susceptibility for  $H \parallel b$  geometry was measured. Thus the potential presence of the anisotropic exchange couplings terms, such as Dzyaloshinskii-Moriya interaction, should be discussed. In most cases, such interaction leads to a spin canting resulting in similar anomalies in susceptibility and a presence of the weak macroscopic magnetic moment in antiferromagnets [32, 33], like in some well-known cases such as FeBO<sub>3</sub> [34], LiCoPO<sub>4</sub> [35], perovskite manganites [36], etc. However, no magnetic moment was registered in PbFeBO<sub>4</sub> for all the available field ranges and geometries [2].

It is known that DMI is governed by lattice symmetry [32]. Due to the presence of a mirror plane (.m.) perpendicular to the  $J_0$  exchange path and passing through its center, only  $[DM_x, 0, DM_z]$  components of the DMI vector are allowed. The  $DM_x$  will lead to a slight canting of the spins within *bc*-planes inducing small ferromagnetic moment along individual chains. However, due to the symmetry of the lattice, this canting is compensated by the same moment with the opposite direction from neighboring chains. This canting is fully compatible with previously suggested magnetic space group Pnma [1] and can be described with  $\Psi_x$  basis function. On the other hand, the contribution of the  $DM_z$  is negligible due to the orientation of the magnetic moments along the same axis.

Thus, the contribution of the antisymmetric exchange interaction with the  $DM_x$  component can simultaneously explain the kink-like anomaly in magnetic susceptibility for  $H \parallel b$  at  $T_N$  and the absence of weak ferromagnetic moment at lower temperatures. This interaction will also directly affect spin dynamics in the form of magnon degeneracy lifting even without external magnetic field presence. Numerical estimation of the acoustic mode splitting by the DMI with the semi-arbitrary value of 0.167 meV (1/10 of  $J_0$ ) leads to 2.46 cm<sup>-1</sup>  $\approx$  0.3 meV splitting of the acoustic mode which should be experimentally detectable with reasonably high-resolution Raman or IR spectroscopy setups.

### D. Magnetic structure dimensionality

The assumption of the (quasi) one-dimensional (1D) magnetism in PbFeBO<sub>4</sub> comes naturally considering its crystal structure, consistent from the well-separated chains of [FeO<sub>6</sub>] octahedra running along the *b*-axis [15]. The broad features above  $T_N$  in dc magnetic susceptibility on powdered samples [15] was also considered as a manifestation of short-range ordering characteristic for low-dimensional magnetic systems. However, the detailed susceptibility investigation on the high-quality single crystals [2] showed that broad features were caused by  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> contamination, and  $\chi$  behaves closer to three-dimensional Heisenberg antiferromagnet (except kink anomaly which was discussed in Section II C).

As the magnetic dimensionality measure, ratios of the intra- to interchain exchange couplings, taking into account coordination number  $(z_n)$ , could be used [37]. The set of the optimal constants gives following values: 1:0.22:0.22 of  $|J|_0 * z_0 : |J_1| * z_1 : |J_2| * z_2$  which is closer to a 3D case, in comparison with other well-known one-dimensional systems as TTF-CuBDT [38], CuGeO<sub>3</sub> [39], and KCuF<sub>3</sub> [40] with ratios  $J_{intra}/J_{inter} << 1$ . Moreover, in most 1D systems, only single, nearest neighbour (NN) interchain coupling is considered important to capture spin dynamics properties, while for PbFeBO<sub>4</sub>, all interaction up to third neighbour (NN, NNN), and NNNN couplings are essential.

Thus, based on the above, PbFeBO<sub>4</sub> should be considered a three-dimensional antiferromagnet in the lowtemperature limit  $T \ll T_N$ . However, according to the magnetic susceptibility anomaly observed in [2] and intense magnetic quasi-elastic scattering observed in polarization along the chains [1], there is a possibility of quasione-dimensional behavior manifestation in the vicinity of the phase transition.

#### E. Spin dynamics of PbCrBO<sub>4</sub>

In comparison with PbFeBO<sub>4</sub>, the magnetic structure of PbCrBO<sub>4</sub> differs only in the direction of the easy axis [15]; thus, all previously derived equations and conclusions could be directly applied for an estimation of the energy of one- and two-magnon excitations. Considering more than one order of magnitude lower  $T_N = 8$  K, and  $\Theta = 45$  K, the exchange constants are expected to be proportionally smaller. However, up to now, there are no published data on the spin dynamics of PbCrBO<sub>4</sub>.

According to [3] the exchange parameters of the optimized structure (calculated with Hubbard parameter U = 2.0 eV) are  $J_0 \approx 0.52 \text{ meV}$ ,  $J_1 \approx -0.0345 \text{ meV}$ , and

	$J_0$	$J_1$	$J_2$	$OM_{calc}$	$OM_{exp}$	$\Theta_{calc}$	$\Theta_{exp}$

<sup>2,3</sup>For only electronic energy and additional terms, respectively. For the details see Table 1 in [5].

TABLE I. Comparison of the exchange constants (meV, J > 0 corresponds to AFM) and derived parameters, such as energies of the optical magnon branch (OM, meV, calculated according to Eq. (4)), and Weiss temperatures  $\Theta_{calc}$  (K, calculated according to Eq. (7)).

 $J_2 \approx 0.069 \text{ meV}$ , which with reduced, in comparison with PbFeBO<sub>4</sub>, the spin value of Cr<sup>3+</sup> ions S = 3/2 gives expected energy of two-magnon excitation band maximum of  $\approx 5 \text{ meV}$  and the energy of optical magnon mode at  $\approx 2.7 \text{ meV}$  which are both accessible in typical low-energy Raman scattering experiments.

# **III. SUMMARY AND CONCLUSION**

With the use of linear spin-wave theory, the closedform of the magnon dispersion relation of PbFeBO<sub>4</sub> was derived, including exchange couplings up to the third neighbor and single-ion anisotropy of the easy axis type. It is demonstrated that magnetic excitations observed in Raman scattering [1] are optical (exchange) magnon and two-magnon band and based on their energy and magnetic susceptibility data [2], the consistent set of exchange coupling constants is proposed:  $J_0 = 1.67, J_1 =$  $-0.18, J_2 = 0.094$  meV. It is shown that *ab initio* calculations [3–5] overestimate both  $J_0$  and  $J_2$  while predicts the opposite sign for  $J_1$ . Nonzero components of the Dzyaloshinskii-Moriya interaction are allowed for the  $J_0$  exchange path, which could be responsible for the magnetic susceptibility anomaly [2]. Surprisingly, the shape of the two-magnon band is well described by the onemagnon density of states, which indicates a vanishingly small role of the magnon-magnon interactions. We hope that obtained results will stimulate both experimental research, such as IR and low-energy Raman spectroscopy to find acoustic modes and inelastic neutron scattering to directly probe magnon dispersion, and theoretical ones on spin dynamics and a systematic study of the exchange coupling constants dependence of Hubbard parameter (U) for *ab initio* calculations.
