(Dated: October 6, 2020)

#### Abstract

Genome-wide epistasis analysis is a powerful tool to infer gene interactions, which can guide drug and vaccine development and lead to deeper understanding of microbial pathogenesis. We have considered all complete SARS-CoV-2 genomes deposited in the GISAID repository until four different cut-off dates, and used Direct Coupling Analysis together with an assumption of QuasiLinkage Equilibrium to infer epistatic contributions to fitness from polymorphic loci. We find eight interactions, of which three between pairs where one locus lies in gene ORF3a, both loci holding non-synonymous mutations. We also find interactions between two loci in gene nsp13, both holding non-synonymous mutations, and four interactions involving one locus holding a synonymous mutation. Altogether we infer interactions between loci in viral genes ORF3a and nsp2, nsp12 and nsp6, between ORF8 and nsp4, and between loci in genes nsp2, nsp13 and nsp14. The paper opens the prospect to use prominent epistatically linked pairs as a starting point to search for combinatorial weaknesses of recombinant viral pathogens.

## I. INTRODUCTION

The pandemic of the disease COVID-19 has so far led to the confirmed deaths of more than 991,224 people [1] and has hurt millions. As the health crisis has been met by Non-Pharmacological Interventions [2, 3, there has been significant economic disruption in many countries. The search for vaccine or treatment against the new coronavirus SARS-CoV-2 is therefore a world-wide priority. The GISAID repository [4] contains a rapidly increasing collection of SARS-CoV-2 whole-genome sequences, and has already been leveraged to identify mutational hotspots and potential drug targets [5]. Coronaviruses in general exhibit a large amount of recombination [6-9]. The distribution of genotypes in a viral population can therefore be expected to be in the state of Quasi-Linkage Equilibrium 10-12, and directly related to epistatic contributions to fitness [13, 14. We have determined a list of the largest such contributions from 51,676 SARS-CoV-2 genomes by a Direct Coupling Analysis (DCA) [15, 16]. This family of techniques has earlier been used to infer the fitness landscape of HIV-1 Gag [17, 18] to connect bacterial genotypes and phenotypes through coevolutionary landscapes [19] and to enhance models of amino acid sequence evolution [20. We apply a recent enhancement of this technique to eliminate predictions that can be attributed to phylogenetics (shared inheritance) 21. We find that eight predictions stand out between pairs of polymorphic sites located in genes nsp2

[^0]and ORF3a, nsp4 and ORF8, and between genes nsp2, nsp6, nsp12, nsp13, nsp14 and ORF3a. Most of these sites have been documented in the literature when it comes to single-locus variations $22-27$. The nsp4-ORF8 pair was additionally found to be strongly correlated in an early study [28]. It does not show prominent correlations today, but is ranked second in our global analysis. The epistasis analysis of this paper brings a different perspective than correlations, and highlights pairwise associations that have remained stable as orders of more SARS-CoV-2 genomes have been sequenced.

## II. DATA AND METHODS

## A. Genome Data of SARS-CoV-2

We analyzed the consensus sequences deposited in the GISAID database 4 with high quality and full lengths (number of bps $\approx 30,000$ ). Four data-sets are used for our investigation according to the collection date in GISAID database. The dates are 2020-04-01, 2020-04-08, 2020-05-02 and 2020-08-08 respectively. The list of GISAID sequences used is available on the Github repository [29]. The numbers of selected genomes are 2,268, $3,490,10,587$ and 51,676 for each collection date.

## B. Multiple-Sequence Alignment (MSA)

Multiple sequence alignments were constructed with the online alignment server MAFFT [30, 31 for the two smaller data sets with cut-off dates 2020-04-01 and 2020-

04-08. To align the two larger data-set with more than 10,000 sequences, a pre-aligned reference MSA is recommended to accelerate the alignment and reduce the burden on computational resources. Here, we took the collection with cut-off date 2020-04-08 as the pre-aligned reference MSA for the two largest data set with cut-off dates 2020-05-02 and 2020-08-08. The MSAs used are available on the Github repository 29 .

The MSA is a big matrix $\mathbf{S}=\left\{\sigma_{i}^{n} \mid i=1, \ldots, L, n=\right.$ $1, \ldots, N\}$, composed of $N$ genomic sequences which are aligned over $L$ positions [16, 21]. Each entry $\sigma_{i}^{n}$ of matrix $\mathbf{S}$ is either one of the 4 nucleotides (A,C,G,T), or "not known nucleotide" (N), or the alignment gap '-' introduced to treat nucleotide deletions or insertions, or some minorities.

## C. MSA filtering

Before filtering, we transform the MSA in two different ways as follows:

- The gaps '-' are transformed to ' N ' while the minors 'KFY...' are mapped to ' N '. There thus 5 states remains, where 'NACGT' are represented by '12345';
- The minors 'KFY...' are mapped to ' N '. Then there are 6 states, with '-NACGT' represented by '012345'.

The following criteria are used for pre-filtering of the MSA from the 2020-08-08 data-set. If for one locus the same nucleotide is found in more than $96.5 \%$ of this column, or if the sum of the percentages of A, C, G and T at this position is less than $20 \%$, then this locus will be deleted. For each sequence, if the percentage of a certain nucleotide is more than $80 \%$, or if the sum of the percentages of $A, C, G$ and $T$ in this sequence is less than $20 \%$, then this sequence will be deleted. With this filtering criteria, many loci but no sequences are deleted. There are left 51,676 sequences and 689 loci.

## D. B-effective number

To mitigate the effects of dependent samplings, it is standard practice to attach to each collected genome sequence $\sigma^{(b)}$ a weight $w_{b}$ [15, 16, 32, which normalizes its impact on the inference procedure. An efficient way to measure the similarity between two sequences $\sigma^{(a)}$ and $\sigma^{(b)}$ is to compute the fraction of identical nucleotides and compare it with a preassigned threshold value $x$ in the range $0 \leq x \leq 1$. The weight of a sequence $\sigma^{(b)}$ can be set as $w_{b}=\frac{1}{m_{b}}$, with $m_{b}$ the number of sequences in the MSA that are similar to $\boldsymbol{\sigma}^{(b)}$ :

$$
\begin{equation*}
m_{b}=\mid\{a \in\{1, \ldots, B\}\}: \text { overlap }\left(\boldsymbol{\sigma}^{(a)}, \boldsymbol{\sigma}^{(b)}\right) \geq x \mid \tag{1}
\end{equation*}
$$

here overlap is the fraction of loci where the two sequences are identical. The B-effective number of the transformed sequences is defined as

$$
\begin{equation*}
B_{e f f}=\sum_{b=1}^{B} w_{b} \tag{2}
\end{equation*}
$$

We compare the $B_{\text {eff }}$ value with different $x$ for the filtered MSA with $q=5$ and $q=6$ respectively. As shown in Fig. 1. the data-set with 6 states shows larger $B_{\text {eff }}$ number for all tested $x$. We thus perform our analysis on the data-set with $q=6$ states, where '-NACGT' represented by '012345'.

FIG. 1. $B_{e f f}$ number of the 2020-08-08 pre-filtered data-set with threshold $x$. Red for $q=6$ states ('-NACGT') and black for $q=5$ states ('NACGT'). The number of states are determined by the transform criteria of the pre-filtered MSA.

The re-weighting procedure partially addresses a point raised 33, that sequenced viral genomes are not a random sample of the global population. That is, even if sequencing is biased by the country they occur in and by contact tracing, sufficiently similar genomes will have lower weight and so each will contribute less to predictions.

## E. Elements of Quasi-Linkage-Equilibrium (QLE)

The phenomenon of QLE was discovered by M. Kimura while investigating the steady-state distribution over two bi-allelic loci evolving under mutation, recombination and selection, with both additive and epistatic contributions to fitness 10. In the absence of epistasis such a system evolves toward Linkage Equilibrium (LE) where the distribution of alleles at the two loci are independent. The covariance of alleles at the two loci then vanishes. In the presence of pairwise epistasis and sufficiently high rate of recombination, the steady-state distribution takes form of a Gibbs-Boltzmann form

$$
\begin{equation*}
P\left(\sigma_{1}, \ldots, \sigma_{L}\right)=\frac{1}{Z} \exp \left\{-H\left(\sigma_{1}, \ldots, \sigma_{L}\right)\right\} \tag{3}
\end{equation*}
$$

with an "energy function"

$$
\begin{equation*}
H\left(\sigma_{1}, \ldots, \sigma_{L}\right)=\sum_{i} h_{i}\left(\sigma_{i}\right)+\sum_{i j} J_{i j}\left(\sigma_{i}, \sigma_{j}\right) \tag{4}
\end{equation*}
$$

In above $J_{i j}$ can be related to the epistatic contribution to fitness between loci $i$ and $j$ with alleles $\sigma_{i}$ and $\sigma_{j}$ [1113. The quantity $h_{i}$ is similarly a function of allele $\sigma_{i}$ which depends on both additive and epistatic contributions to fitness involving locus $i$. It has been verified in in silico testing that when the terms in (4) can be recovered
this is a means to infer epistatic fitness from samples of genotypes in a population [14. In the bacterial realm this approach was used earlier to infer epistatic contributions to fitness in the human pathogens Streptococcus pneumonia 34] and Neisseria gonorrhoeae [35], both of which are characterized by a high rate of recombination. The method was also tested on data on the bacterial pathogen Vibrio parahemolyticus 36. In that study the results from DCA were not superior from an analysis based on Fisher exact test, see Appendix G for a discussion. This is consistent with the approach taken here, as V. parahemolyticus has low rate of recombination. Further details on the QLE state of evolving populations are given in Appendix A.

## F. Inference Method for epistasis between loci

The basic assumption of modeling the filtered MSA is that it is composed by independent samples that follows the Gibbs-Boltzmann distribution (3) with $H$ as in (4) Higher order interactions are also possible to include, but we ignore them here [37]. This assumption is a simplification of the biological reality, however provides an efficient way to extract information from massive data.

On the other hand, in the context of inference from protein sequences, it has been argued that the one en-
coded in Eq. (3-4) is the minimal generative model i.e. capable not only to reproduce the empirical frequencies and correlations but also to generate new sequences indistinguishable from natural sequences [16, 38, 39].

Many techniques have been developed to infer the direct couplings in Eq. (3), as reviewed in [40] and references therein, see also Appendix C. We employ the maximum pseudo-likelihood (PLM) method [13, 32, 41,44] to infer the epistatic effects between loci from the aligned MSA. PLM estimates parameters from conditional probabilities of one sequence conditioned on all the others. For Potts model with multiple states $q>2$, this conditional probability is

$$
\begin{equation*}
P\left(\sigma_{i} \mid \boldsymbol{\sigma}_{\backslash i}\right)=\frac{\exp \left(h_{i}\left(\sigma_{i}\right)+\sum_{j \neq i} J_{i j}\left(\sigma_{i}, \sigma_{j}\right)\right)}{\sum_{\mathbf{u}} \exp \left(h_{i}(u)+\sum_{j \neq i} J_{i j}\left(u, \sigma_{j}\right)\right)} \tag{5}
\end{equation*}
$$

with $\mathbf{u}=\{0,1,2,3,4,5\}$ the possible state of $\sigma_{i}$. Eq. (5) depends on a much smaller parameter set compared with that in Eq. (3). This leads a much faster inference procedure of parameters compared with the maximum likelihood method. With a given independent sample sets, one can maximize the corresponding log-likelihood function

$$
\begin{equation*}
P L_{i}\left(h_{i},\left\{J_{i j}\right\}\right)=\frac{1}{N} \sum_{s} h_{i}\left(\sigma_{i}^{(s)}\right)+\frac{1}{N} \sum_{s} \sum_{j \neq i} J_{i j}\left(\sigma_{i}^{(s)}, \sigma_{j}^{(s)}\right)-\frac{1}{N} \sum_{s} \log \sum_{\mathbf{u}} \exp \left(h_{i}(u)+\sum_{j \neq i} J_{i j}\left(u, \sigma_{j}^{(s)}\right)\right), \tag{6}
\end{equation*}
$$

where $s$ labels the sequences (samples), from 1 to $N$. With the filtered MSA, we then run the asymmetric version of PLM [32] in the implementation PLM available on [45] with regularization parameter $\lambda=0.1$. The inferred interactions between loci $i$ and $j$ are scored by the Frobenius norm.

## G. Relation to correlation analysis

In LE the distributions of alleles over different loci are independent. Given unlimited data and unlimited computational resources, the terms $J_{i j}$ in (4) inferred from the data would then be zero. The locus-locus covariances, defined as

$$
\begin{equation*}
c_{i j}(a, b)=\left\langle\mathbf{1}_{\sigma_{i}, a} \mathbf{1}_{\sigma_{j}, b}\right\rangle-\left\langle\mathbf{1}_{\sigma_{i}, a}\right\rangle\left\langle\mathbf{1}_{\sigma_{j}, b}\right\rangle \tag{7}
\end{equation*}
$$

would also be zero. The Frobenius norm of $c_{i j}(a, b)$ over indices $(a, b)$ as a score of strength of correlations would be zero as well. The qualitative difference between correlation analysis and global model inference based on (3) and (4) is that two loci $i$ and $j$ may be correlated ("indirectly coupled") even if their interaction $J_{i j}$ is zero, provided they both interact with a third locus $k$. Data in Table IV and Fig. 5 show that the leading interactions retrieved by DCA cannot be stably recovered in correlation analysis. A different score of statistical dependency
between two categorical random variables is mutual information (MI). Appendix G shows that the result does not substantially change if using MI instead of Frobenuis norm of correlation matrices. Circos plots of interactions based on correlation scores are available on [29.

## H. Epistasis analysis with PLM scores

PLM procedure yields a fully connected paradigm between pairwise loci. To extract important information form massive SARS-CoV-2 genomic sequences, we focus on the significant scores between loci, the top-200 pairs. With a reference sequence "Wuhan-Hu-1", we identify the positions of the corresponding nucleotides. The visualization of these epistasis is performed by 'circos' software 46].

## I. Randomized background distributions

A way to assess the validity of a small number of leading retained predictions among a much larger set of mostly discarded predictions is to compare to randomized backgrounds. The retained predictions are then in any case large (by some measure) and would also be retained if selection would be made according to some cut-
off, or an empirical $p$-value. The problem is thus how to distinguish the case where a small sub-set of retained values are large because they are different, from the case when in a large number of samples such values would appear at random. This problem can be addressed by comparing the retained values to the largest values from the same procedure applied to randomized data, as was done for predicted RNA-RNA binding energies in a noncoding RNA discovery pipeline 47. In the context of DCA (PLM) applied to genome-scale MSAs, two earlier studies relying on randomized background distributions are 48] and [13].

## J. PLM scores with randomization

To understand the nature of the top-200 PLM scores we perform two distinct randomization strategies on the MSA, such that its conservation patterns and (or) phylogenetic relations are preserved, while intrinsic coevolutionary couplings (epistatic interactions) are removed [49. Running DCA on artificial sequences ensembles generated by these strategies, and comparing them to the results obtained from original MSA allows to disentangle spurious couplings given by finite-size effects or by phylogeny. The first strategy, we refer as 'profile', randomizes the input MSA by random but independent permutation of all its columns conserving the single-columns statistics for all sites. This destroys all kind of correlations and DCA couplings inferred from such samples are only non-zero due to the noise caused by finite samplesize. In the second strategy referred as 'phylogeny', the original MSA is randomized by a simulated annealing schedule where columns and rows are changed simultaneously but so that inter-sequence distances are kept invariant. Phylogeny inferred from inter-sequence distance information would therefore be unchanged. Conversely, if the predicted epistatic interactions are due to phylogeny, they should also show up in terms recovered by PLM from MSAs scrambled by 'phylogeny'. More details on the randomization strategies can be found in Appendix D.

## III. RESULTS

The predicted effective interactions between loci were obtained from Pseudo-Likelihood Maximization (PLM) scores, a standard computational method to perform DCA. Manual inspection shows that about half of the top-50 links and most of the top-200 involve noncoding sites in the 5 ' or 3 ' region on the "Wuhan-Hu-1" 50 reference sequence, many of them have very short range and most of them with a large fraction of the gap or N (unknown nucleotide) symbols (data available on 29 for other data-set). We present the links with both terminal loci located in coding regions and the mutations excluding gaps or ' N 's.

In Table I we list the significant links for the 2020-08-08 data-set. The first column is the index of each pairwise interaction in the top 200s. The second column indicates the locus with lower genomic position in
the pair and the name of the SARS-CoV-2 proteins it belongs to. The third column lists the major / minor allele (most prevalent, second most prevalent nucleotide) and the mutation type at that locus. The following two columns provide similar information on the locus with higher genomic position in the pair. The last column contains the PLM scores indicating the strength of effects between pairs of loci. The pairwise epistasis listed in Table $\square$ for 2020-08-08 dataset are visualized by circos software in Fig. 2, where the red ones for the close effects (the distance between two loci is less or equal to 3 locus) while blue for distant effects. Analogous results for the 2020-05-02 dataset is shown in Appendix L and for the 2020-04-01 and 2020-04-08 data-sets on [29].

To check if the interactions can be explained by phylogeny (inherited variations) we used two randomization strategies 'profile' and 'phylogeny' of the Multiple Sequence Alignments (MSAs). Profile preserves the distribution over alleles at every locus but does so independently at each locus. Profile hence destroys all systematic co-variations between loci. Phylogeny additionally preserves the genetic distance between each pair of sequences. Viral genealogies inferred from this information are therefore unchanged under this randomization. PLM scores run on these two types of randomized data (scrambled MSAs) is a background from which the significance of the interactions from the original data can be assessed. Each randomization strategy is repeated 50 times with different realizations of the scrambling, see Appendix E and [29]. As shown in Fig. 3 the distribution of PLM scores using phylogeny and profile are qualitatively different from PLM scores of the original MSA, with progressively fewer interactions at high score values. With profile randomization, no interactions predicted by PLM appear with scores standing out from the background. Phylogeny randomization on the other hand preserves some interactions found by PLM in a fraction of the realizations of the random background. Table $\Pi$ lists interactions predicted by PLM that appear in some phylogeny randomizations with scores large compared to the background. In the following analysis we have not retained them, see Appendix Efor circos visualizations. Table III lists the eight interactions found by PLM which either do not appear in any phylogeny randomization with scores that stand out from the background, or, in the case of (1059-25563), shows up three times in top-200 out of 50 samples. We retain these eight predicted epistatic interactions in the sampled populations of SARS-CoV-2 genomes. The top ones listed in Table III are marked by red arrows in Fig. 3(a).

Epistatic interactions obtained from DCA reflect pairwise statistical associations, but not correlations. As reviewed in 40, and described in Appendix C, DCA is based on a global probabilistic model, and therefore ranks inter-dependency differently than correlations. Fig. 4 compared to Fig. 3 shows that the distribution of correlation scores is qualitatively different from the distributions of DCA scores in the GISAID data set. Fig. 5 further shows that the rank of the epistatic interaction predicted in Table III have remained stable, while the corresponding correlations have merged into the background.

The first-ranked interaction between 1059 and 25563 is between a $(\mathrm{C} / \mathrm{T})$, resulting in the T 85 I non-synonymous mutation in gene $n s p 2$ and a $(G / T)$, resulting in the Q57H non-synonymous mutation in gene ORF3a. nsp2, expressed as part of the ORF1a polyprotein, binds to host proteins prohibitin 1 and prohibitin 2 (PHB1 and PHB2) in SARS-CoV 51. The variations in the site 1059 have been predicted to modify nsp2 RNA secondary structure [52] and have previously been reported to co-occur together with the Q57H variant in ORF3a in a dataset of SARS-CoV-2 genomes from the United States [53]. ORF3a, also known as ExoN1 hypothetical protein sars3a, forms a cation channel of which the structure in SARS-CoV-2 is known by Cryo-EM 54. In SARS-CoV ORF3a been shown to up-regulate expression of fibrinogen subunits FGA, FGB and FGG in host lung epithelial cells [55], to form an ion channel which modulates virus release 56, to activate the NLRP3 inflammasome 57, and has been found to induce apoptosis [58]. The Q57H variant was reported early in the COVID-19 pandemic [59 and occurs in the first transmembrane alpha helix, TM1 [54, where it changes the amino acid glutamine (Q) with a non-charged polar side chain to histidine ( H ), which has a positively charged polar side chain. This amino acid is at the interface of interaction between the two dimeric subunits of ORF3a that forms the constrictions of the ion channel but the Q57H alteration does not seem to change the ion channel properties compared to wildtype 3a [54]. Nevertheless, its incidence is increasing in SARS-CoV-2 genomes in the United States 53 and the effect of Q57H may therefore affect the virulence in other beneficial ways than changing the conductance properties of the ion pore.

The association between 8782 and 28144 (rank 5), reported early in SARS-CoV-2 studies [28] is between a $(\mathrm{C} / \mathrm{T})$ synonymous mutation in the gene nsp4, and a (T/C) non-synonymous mutation resulting in the L84S alteration in the gene ORF8. The first of these genes participates in the assembly of virally-induced cytoplasmic double-membrane vesicles necessary for viral replication. The site 8782 is located in a region annotated as CpGrich and is the site of a CpG for the major allele (C); it has the minor ( T ) allele in other related viruses [28]. Orf8 has been implicated in regulating the immune response [60, 61]. The L84S variant is, together with the C8782T nsp4 mutation characterizing the GISAID clade S 62].

The interaction between 14805 and 26144 (rank 9) leads to non-synonymous alterations in nsp12 (T455I, note that the reference is Y ) and ORF3a (G251V) respectively. The G251V has been reported by many studies and is defining the GISAID V clade 62 together with the L37F nsp6 variant (position 11083, rank 47). The widely reported G251V variant is unfortunately outside of the proposed Cryo-EM structure [54] and it is unknown how this glycine to valine substitution affects protein function. nsp12 is the RNA-dependent RNA polymerase and the T455I substitution is found where the reference Wuhan-Hu-1 has a tyrosine residue in one of the alpha helices of the polymerase "finger" domain [63]. Threonine can similarly to tyrosine be phosphorylated but also glycosylated, it is polar, uncharged and can
form hydrogen bonds that may stabilize the alpha helix. Isoleucine on the other hand is non-polar and uncharged and both the residues are smaller than the aromatic tyrosine.

The second interaction partner of G251V is the nsp6 L37F variant. nsp6 has been shown to induce autophagosomes in the host cells in favour for viral replication and propagation SARS-CoV [51]. There is currently no experimentally validated model of nsp6 structure but an early model suggest that the L37P variant is situated in an unordered loop between two alpha helices 64.

The interaction between 17747 and 17858 (rank 27) is between two non-synonymous mutations ( $\mathrm{C} / \mathrm{T}$, resulting in P504L) and (A/G, resulting in T541C) within the gene nsp13 that codes for a helicase enzyme that unwinds duplex RNA 51. It is the only epistatic interaction in Table III within one protein. These same two loci reappear in the list with ranks 26 and 36 as interacting with a $\mathrm{C} / \mathrm{T}$ synonymous mutation ( L 7 L ) in gene nsp14 at position 18060. The P504L and T541C are both located in the Rec 2 A part of the protein that is not in direct interaction with the other members of the RNA-dependent RNA polymerase holoenzyme, in which two molecules of nsp13 forms a stable complex with nsp12 replicase, nsp7, and nsp8. The nsp14 protein is a bifunctional protein that has a N7-methyltransferase domain and an a domain exonuclease activity, responsible for replication proof reading (cite Denison et al "An RNA proofreading machine regulates replication fidelity and diversity"). The nsp14/nsp10 proof reading machinery is thought to interact with the replication-transcription complex but the exact details of this interaction are not known.

The final interaction (rank 21) is a link between a locus carrying a non-synonymous mutation ( $\mathrm{C} / \mathrm{T}, \mathrm{T} 541 \mathrm{C}$ ) in nsp2 position 1059, with a locus carrying a synonymous mutation (C/T, L280L) in nsp14, position 18877. As the knowledge on nsp2 protein structure is poor there is no evidence for the effect of this mutation. Also, how the synonymous $\mathrm{C} / \mathrm{T}$ alterations in nsp14, as well as in the synonymous mutations of the other interactions affect the virus are unknown, but can be proposed to change RNA secondary structure, RNA modification or codon usage.

## IV. DISCUSSION

The COVID-19 pandemic is a world-wide public health emergency caused by the $\beta$-coronavirus SARS-CoV-2. A very large and continuously increasing number of high-quality whole-genome sequences are available. We have investigated whether these sequences show effects of epistatic contributions to fitness. In a population evolving under high rate of recombination, such effects of natural selection can be detected by Direct Coupling Analysis, a global model learning technique. The paper opens up the prospect to leverage very large collections of genome sequences to find new combinatorial weaknesses of highly recombinant pathogens.

In this work we have considered all whole-genome sequences of SARS-CoV-2 deposited in GISAID up to different cut-off dates. As this coronavirus has extensive
recombination we have assumed that the distribution of genotypes is well described by Kimura's Quasi-Linkage Equilibrium, and used Direct Coupling Analysis to infer epistatic contributions to fitness from the sequences. After filtering out all but the strongest effects and variations in non-coding regions with many gaps in the MSA, the remaining predictions are few in number, i.e. 19 predictions in Table $\mathbb{I}$.

Co-variations between allele distributions at different loci can be due to epistasis and also to inherited effects (phylogeny). We have tested for the second type by randomizing Multiple Sequence Alignment of sequences such that pair-wise distances between sequences are left invariant. We find that the top link 1059-25563 appears 3 times in 50 phylogeny randomizing samples, though with much lower rank. The other predicted epistatic contributions disappear under phylogenetic randomization, except for pairs in the triple (3037, 14408, 23403) which appear in from $20 \%$ to $35 \%$ of 50 randomizations. After eliminating these links as well as links between adjacent loci (28881, 28882, 28883, which appear in from $14 \%$ to $16 \%$ in 50 samples), we are left with eight predictions listed in Table III. We consider it likely that these retained interactions are due to epistasis, and not to inherited co-variation. An analogous investigation on a smaller dataset obtained with an earlier cut-off date (2020-05-02) and reported in Appendix L yield six retained predictions, involving however the same eight viral genes. The question on epistasis vs. effects of inheritance (phylogeny) clearly merits further investigation and testing as more data will become available.

Biological fitness is a many-sided concept and can also include aspects of game and cooperation 65-67. A fitness landscape describes the propensity of an individual to propagate its genotype in the absence of strategic interactions with other genotypes, and has traditionally been used to model the evolution of pathogens colonizing a host, for earlier use relating to HIV and using DCA techniques, see 68. The additive and epistatic contributions to fitness of the virus which we find describe the virus in its human host and therefore likely reflect hostpathogen interactions to a large extent. A conceptual simplification made is that all hosts have been assumed equivalent. In future methodological studies it would be of interest to consider possible effects of evolution in a collection of landscapes, representing different hosts, and to correlate such dynamics to host genotypes. As this requires other data than available on GISAID, and less abundant at this time, we leave this for future work. On the other hand, it is unlikely that the inferred couplings involve the host as a temporal variable, due to the much faster time scale of the evolution of the virus.

Epistatic interactions are pairwise statistical associations, but are not simply correlations. The interaction between sites 8782 and 28144, which is the second largest in Table III, was identified as a very strong correlation in a very early study [28. As shown in Table 5 this correlation has generally decreased over time (using data with successively later cut-off dates). In the alternative global model learning method of DCA which we use in the present work, the score of statistical inter-dependency of this pair has remained large, and the pair is consistently
ranked first or second over four different cut-off dates, see Fig. 5. While our data hence supports the observation of statistical inter-dependency in this pair first made in [28], it does not support the interpretation made in the same work that the effect is due to phylogeny. The later criticism in [33] therefore does not apply to our work since an epistatic interaction, recovered through DCA and a Quasi-Linkage Equilibrium assumption in a population thoroughly mixed by recombination, is different in nature from a phylogenetic effect.

DCA techniques have been applied to find candidate targets for vaccine development. In a series of studies it was found that combinations of mutations implied by sequence variability in the HIV-1 Gag protein correlate well with in vitro fitness measurements, and clinical observations on escape strains (HIV strains that tend to dominate in one patient over time) and the immune system of elite controllers (HIV-positive individuals progressing slowly towards AIDS) [18, 68, 69. While this may be a promising future avenue in COVID-19 research, in the present study we have not found any epistatic interactions involving Spike, only pairs that also show up under phylogeny randomization or that are quite weak, see Appendix J. The Spike protein has been the main target of coronovirus vaccine development to date [70], including against SARS-CoV-2 71 73].

An epistatic interaction means that loss of fitness by a mutation at one locus is enhanced (positive epistasis) or compensated (sign epistasis) by a mutation at another locus. Suppose there are drugs that act on targets around both loci, modulating the fitness of the respective variants. Epistasis then points to the possibility that using both drugs simultaneously may have a more than additive effect. To search if our analysis offers such a guide to combinatorial drug treatment, we scanned the recent comprehensive compilation of drugs known or predicted to target SARS-CoV-2 [74. Five out of the eight predictions in Table III involve either one synonymous mutations or are between two mutations in the same gene. For all the three remaining pairs of non-synonymous mutations, $(1059,25563),(11083,26144)$ and $(14805,26144)$, the second locus lies in ORF3a for which no potential drugs are listed in [74. The first locus in the same three pairs lie respectively in genes nsp2, nsp6 and nsp12. One or more already approved and practical drugs targeting nsp2 and nsp6 are listed in 74]. Ponatinib, listed for nsp12, is not appropriate against a pandemic disease like COVID-19 on account of its large cost. Potential drugs for the proteins listed in Table III are summarized in Table IX in Appendix K, following [74.

Nevertheless, the number of combinations of potential drug targets, in COVID-19 and many other diseases, is very large. Direct Coupling Analysis applied to many sampled sequences predicts which genes/loci have mutual dependencies in fitness, and can be used to rank combinations for further more detailed investigation. We note that one can also start a search for drug treatment from conserved positions, assuming these to be unconditionally necessary for the virus. If so, all potential pairs would however be ranked equal based on sample information, and there would be no analogous short-cut to the combinatorial explosion of possibilities. Even if the
scan discussed above did not lead to any direct suggestions based on the lists of potential drugs in 74], we hope the general approach could have value given the continuing increase and availability of genome sequences of both viral and bacterial pathogens. We finally note three out of eight of our list of predictions involve loci in viral gene ORF3a, the action of which is related to severe manifestations of COVID-19 disease [56-58].

FIG. 2. Top-200 significant pairwise epistasis from the 2020-08-08 data-set between loci in coding regions. Colored lines indicate for top 50s, grey lines top 50-200. Red lines show short-distance links (distance less than or equal to 3 bp ) blue lines show links of longer distance. The colourful links are the same pairs as listed in Table I Analogous circos plots for the 2020-05-02 data set is shown in Appendix L and for the 2020-04-01 and 2020-04-08 data-sets on the GitHub repository [29].

## ACKNOWLEDGMENTS

We thank Profs Martin Weigt and Roberto Mulet for numerous discussions, and Martin Weigt for sharing the use of the 'phylogeny' developed with ERH. EA thanks Arne Elofsson and other participants of the Science for Life Labs (Solna, Sweden) "Viral sequence evolution research program" for input and suggestions. The work of HLZ was sponsored by National Natural Science Foundation of China (11705097), Natural Science Foundation of Jiangsu Province (BK20170895), Jiangsu Government Scholarship for Overseas Studies of 2018, and Scientific Research Foundation of Nanjing University of Posts and Telecommunications (NY217013). The work of Vito Dichio was supported by Extra-Erasmus Scholarship (University of Trieste) and Collegio Universitario 'Luciano Fonda'. ERH acknowledges funding by the EU H2020 research and innovation programme MSCARISE-2016 under grant agreement No. 734439 INFERNET.

## Appendix A: Quasi-linkage equilibrium (QLE) and its range of validity

Quasi-linkage equilibrium was discovered by Kimura 75 and investigated more recently by Neher and

ability distribution

$$
\begin{equation*}
P^{(e)}(\sigma)=\frac{1}{N} \sum_{s} \mathbf{1}_{\sigma, \sigma^{(s)}} \tag{A1}
\end{equation*}
$$

In above $\sigma^{(s)}$ is the genotype of individual ( $s$ ) and $\mathbf{1}_{\sigma, \sigma^{(s)}}$ means that individuals of genotype $\sigma$ are counted in the sum. Each genotype can hence appear zero, once or many times; if more than zero such a group is referred to as a clone, and if more than once a multi-individual clone, or a proper clone. We will in the following for simplicity take $N$ to be fixed. In QLE there are few proper clones, i.e. most individuals in the population have a unique genotype.

b This link appears in 3 out of $50(6 \%)$ phylogeny randomizations; once (experiment 23 ) with rank 34 , and twice (experiments 29 and 47) with ranks in $51-200$, see Appendix E
c Amino acid in the reference sequence Wuhan-Hu-1 at the position specified by the number between major and minor alleles.

In models of evolution where the QLE concept is pertinent populations change in time due to mutations, recombination, fitness and genetic drift. Mutation and recombination are random events characterized by average rates. Fitness is the propensity of an individual to have offspring in the next generation and genetic drift is the randomness associated with this process. The population history is hence given by a sequence of empirical probability distributions indexed by time $(t), P^{(e)}(\sigma, t)$.

The development in time can alternatively be formulated on the level of ensemble probability distributions. In

FIG. 4. Frobenius norm of pairwise correlations between loci for the original 2020-08-08 data-set. The score pointed by the red arrow corresponds to the link of 1059-25563.

FIG. 5. Ranks for significant epistatic effects with data collection date (2020-04-01, 2020-04-08, 2020-05-02 and 2020-$08-08$ ) by PLM (dashed lines) and correlation analysis (solid lines). The ranks of the PLM scores are almost constant while the ranks of the correlations vary significantly and mostly drop as more data accumulate (later cut-off dates).
general that will be the time-dependent joint probability distributions of $N$ genomes $P_{N}\left(\sigma_{1}, \sigma_{1}, \ldots, \sigma_{N}, t\right)$. Mutation, fitness and genetic drift act on each genotype in the population separately. They can thus be formulated for the marginalization $P_{N}$ to a one-genome ensemble probability distribution $P(\sigma, t)$. Recombination acts on two genomes at a time. They can thus be formulated on the level of two-genome ensemble probability distributions $P_{2}\left(\sigma_{1}, \sigma_{2}, t\right)$.

QLE is characterized by multi-genome distribution functions factorizing i.e. by

$$
\begin{equation*}
P\left(\sigma_{1}, \ldots, \sigma_{N}\right) \approx P\left(\sigma_{1}\right) \ldots P\left(\sigma_{N}\right) \tag{A2}
\end{equation*}
$$

As a consequence, evolution can be considered on the level of one-genome ensemble probability distributions only. The resulting equations have been written out and discussed in [11-14] and are structurally similar to the Boltzmann equation in gas kinetics, where recombination plays the role of a collision term. It is a reasonable picture to consider the list of $N$ genotypes given by $P^{(e)}$ as $N$ samples from $P$. However, as follows from above, the relation between the two distributions is not direct: $P^{(e)}$ changes according to a stochastic and frequency-

${ }^{\text {a }}$ Rank for top-10 links as ranked by correlation analysis. Correlations between loci of which at least one outside coding regions are omitted.
independent evolution law while $P$ obeys a deterministic nonlinear partial differential equation.

The form of QLE, for only bi-allelic loci and only onelocus fitness terms (additive fitness) and two-loci fitness terms (epistatic fitness) is that of the Ising model of statistical mechanics i.e. for a genome $\sigma=\left(s_{1}, \ldots, s_{L}\right)$

$$
\begin{equation*}
P(\sigma)=\frac{1}{Z} \exp \left(\sum_{i} h_{i} s_{i}+\sum_{i j} J_{i j} s_{i} s_{j}\right) \tag{A3}
\end{equation*}
$$

In above both sums go over the loci of variability on the genome. In some applications they could be all or almost all positions, but in the application to SARS-CoV-2 genomes they are but a small fraction. At most genomic positions all samples carry the same variant; those positions are not included in the sums in A3 which focus on the variable portions. Further, $s_{i}=1$ in A3) encodes one of the alleles (typically the major allele) and $s_{i}=-1$ encodes the other allele (typically the minor allele), $h_{i}$ and $J_{i j}$ parametrize the distribution and $Z$ is a normalization constant (partition function). The extension of the above to more the bi-allelic loci ("Potts genomes") is given in 13, and restated in main body of the paper, Eqs. (3) and (4). Although we in this work only find properties of almost bi-allelic pairs of loci, the intermediate analysis allows multi-allelic states (see below).

Known sufficient conditions for QLE are that recombination is sufficiently high everywhere compared to selection, and mutation rate is non-zero. The part of the argument concerning recombination was made on the physical level of rigor in [12, by estimating terms in a Taylor series in inverse recombination rate. The part of the argument concerning mutation is implicit in [12], and based on the observation that without mutations, the most fit genotype will eventually take over in a finite population. This means that mutation must be non-zero, as otherwise QLE will only be a (possibly long-lived) transient [14]. On a qualitative level the argument for QLE is analogous to the accuracy of Boltzmann equation and the stationary state being of Gibbs-Boltzmann type when collision rate is high enough [13].

Many realistic models encode that recombination acts more weakly between closely spaced loci. Taken at face
value, the conditions in $11-13$ would then imply that the conditions for QLE can be at hand for loci sufficiently far apart on the genome, but not for closely spaced loci. A quantitative theory of this effect as it relates to QLE is at this point lacking. Numerical results in [11, 12] showed that the characteristics of QLE may be present, and numerical results in 14 showed that QLE can be used for inference in this setting.

Necessary conditions for the validity of QLE are at this point not known. It may be that states similar to QLE can also be found in other parameter ranges than at high recombination. An argument in favor is the recent in silico result in [76] where a modified form of QLE inference was shown to work also for moderate recombination, given instead high enough mutation rates.

## Appendix B: Approximate inference in QLE

QLE gives quantitative relations between evolutionary dynamics and distributions over genotypes in a population. In this section we state and briefly describe what these relations are, and how we use them in this work.

We are only here concerned with the most important relation, which connects the parameters $J_{i j}$ in A3 to parameters describing how fitness and recombination shape the population. Fitness is here taken as a propensity of a genotype to propagate in the next generation. It is parametrized as

$$
\begin{equation*}
F(\sigma)=\sum_{i} f_{i} s_{i}+\sum_{i j} f_{i j} s_{i} s_{j} \tag{B1}
\end{equation*}
$$

where the $f_{i}$ and $f_{i j}$ are respectively the additive and the epistatic components of fitness and the genome is assumed bi-allelic as in A3); for the extension to multiallelic sites see (13. The meaning of (B1) is that individuals with higher total fitness (higher $F(\sigma)$ ) will have higher expected number of offspring. Recombination is described by an overall rate $r$ and a locus-pair-dependent quantity $c_{i j}$ which is the probability that alleles at loci $i$ and $j$ are inherited from different parents if a recombination event has taken place. In many cases it is reasonable
to assume that this quantity is small (close to zero) when $i$ and $j$ lie sufficiently closely on the genome, and approximate $\frac{1}{2}$ if they are distant.

The relation first found by Kimura for a two-locus problem is

$$
\begin{equation*}
J_{i j}=\frac{f_{i j}}{r \cdot c_{i j}} \tag{B2}
\end{equation*}
$$

In a world abundant in sequenced genomes the left hand side of above can be inferred from samples. It is thus what can be considered known, while what causes it, $f_{i j}$ and the influence of recombination, are quantities not known directly. It is therefore useful to re-state (B2) as

$$
\begin{equation*}
f_{i j}^{*}=J_{i j}^{*} \cdot r c_{i j} \tag{B3}
\end{equation*}
$$

where the star indicates that these quantities are inferred from data.

Finally, for sites far enough apart on the genome the above can be summarized that epistatic term in fitness $\left(f_{i j}\right)$ is proportional to pair-wise term in the distribution $\left(J_{i j}\right)$. A ranking of pairs in descending order of $J_{i j}$ is hence also a ranking of pairs in descending order of epistatic fitness, if closely spaced pairs are excluded. This is hence the theoretical basis of the analysis in the main body of the paper, where we rank pairs as to the values of $J_{i j}^{*}$, as inferred from samples. The extension of the above to Potts genomes (multi-allelic states) is given in 13 and 14 .

## Appendix C: Methods of DCA

Determining the coefficients in a distribution of the type (A3) from data has been called a problem of inference in exponential families in statistics [77], an inverse Ising problem in statistical physics [40, 43, 78] and direct coupling analysis (DCA) in computational biology [15, 16]. The benchmark method for such problems is maximum likelihood (ML). This is built from the assumption that $N$ observed genotypes are independent draws from a distribution of type (A3). The logarithm of the probability of the joint distribution (log-likelihood) is then

$$
\begin{equation*}
\mathcal{L}\left(\left\{h_{i}\right\},\left\{J_{i j}\right\}\right)=\sum_{i} h_{i}\left(\frac{1}{N} \sum_{s} s_{i}^{s}\right)+\sum_{i j} J_{i j}\left(\frac{1}{N} \sum_{s} s_{i}^{s} s_{j}^{s}\right)-\log Z \tag{C1}
\end{equation*}
$$

The averages on the right hand side multiplying $h_{i}$ and $J_{i j}$ are empirical averages. Since these are the only properties of the samples which enter into the log-likelihood they are sufficient statistics for ML inference. The partition function $(Z)$ is computationally difficult to evaluate, and a large number of other inference procedures to circumvent this problem are therefore widely used, reviewed recently in [16, 40].

One family of widely used approaches is variational
methods. This is based on minimizing the distance between the empirical distribution and a suitable trial distribution, in practice mostly factorized distribution [77, although later distribution of the type (A3) have also been used 40 (and references therein). The most widely used variational inference is naive mean-field which is equivalent to treating the Ising (or Potts) distribution over discrete variables as if it were a Gaussian distribution over continuous variables. While naive mean-
field inference was the basis for important advances in protein structure prediction [15, 79, it has more recently been overtaken by pseudo-likelihood maximization (PLM) [16, 40-43. PLM is the DCA method used in this work. The principles are described in Materials \& Methods section of the main body of the paper, text around Eqs. (5) and (6). The implementation of PLM which we have used (also called PLM), due to Chen-Yi Gao 80 is available on [45].

## Appendix D: Phylogenetic randomization of DCA: principles

This section describes the two means of phylogenetic randomization used in the main paper. A full-length technical description of both methods is available (from co-author ERH) at 49 .

Profile randomization: This approach is built on the principle of randomizing the input multi-sequence alignment (MSA) by conserving the single-columns statistics $w_{i}(\sigma)$, for all sites $i=1, \ldots, L$ and all nucleotides or gaps $\sigma \in\{-, N, A, C, G, T\}$. This is done by independent columns shuffling which destroys all kinds of correlations (both coevolutionary ones and phylogenetic ones) present in the alignment, only the residue conservation patterns of the original MSA are preserved. The randomized sequences become an independently and identically distributed sample from the profile model

$$
P\left(\sigma_{1}, \ldots, \sigma_{L}\right)=\prod_{i=1}^{L} w_{i}\left(\sigma_{i}\right)
$$

Profile randomization hence serves to verify that the effects found are not due to random sampling. An alternative way to reach the same goal, and high-lighted in the main body of the paper, is to repeat the analysis with successively larger collections of genomes obtained from using successively later cut-off dates.

Phylogeny randomization: This more advanced approach is built on the principle of randomizing the input MSA preserving both single columns statistics and pairwise Hamming distances between sequences representing the genotypes. This method was first presented in detail in 49. Computational methods to infer phylogeny which rely on such pair-wise Hamming distances would by design be insensitive to phylogeny randomization, i.e. the give the same result as using input MSA. Phylogeny randomization hence serves to distinguish covariation between loci due to phylogeny (inheritance) from co-variation due to co-evolution (epistasis).

The method is initialized with an alignment resulting from the "profile" randomization, eliminating all preexisting correlations, to then start a simulated annealing based method to construct a sequence alignment with inter-sequences distances of the original MSA as target. Single variables $\sigma_{k}^{(i)}$ are permuted in the following way: at each move t , a column $k$ and two rows $m$ and $n$ are chosen at random, and an attempt to exchange $\sigma_{k}^{(m)}$ and $\sigma_{k}^{(n)}$ is made. The probability of the exchange to take place is the Metropolis-Hastings acceptance probability:

$$
\begin{equation*}
P_{\text {acc }}(t, \beta)=\min \left(1, \exp \left(\beta\left(\left\|\boldsymbol{h}^{t}-\boldsymbol{h}_{\text {target }}\right\|-\left\|\boldsymbol{h}^{t-1}-\boldsymbol{h}_{\text {target }}\right\|\right)\right)\right) \tag{D1}
\end{equation*}
$$

where $\boldsymbol{h}^{t-1}$ and $\boldsymbol{h}^{t}$ are the Hamming distance matrices of the current alignment before and after the exchange, $\boldsymbol{h}_{\text {target }}$ the Hamming distance matrix corresponding to the original alignment, $\|\ldots\|$ stands for the Frobenius matrix norm, and $\beta$ is an inverse temperature parameter. Thus, a move is more likely to be accepted if it makes the Hamming distance matrix of the alignment closer to that of the target. Parameter $\beta$ is initialized at a low value and then slowly increased as more moves are made, When $\beta$ goes to infinity and annealing has proceeded slowly enough $\boldsymbol{h} \rightarrow \boldsymbol{h}_{\text {target }}$.

This procedure never changes the single site statistics of the target alignment, since exchanges are made inside one column. On other hand all the epistatic correlations are destroyed. If we assume that the target Hamming distance matrix is a measure of the phylogenetic information in the original MSA, as is done in several tree building methods (distance-based methods) [81, 82, then we expect that resulting alignment present this hierarchical signal.

Appendix E: Phylogenetic randomization of DCA: results and visualization

Starting from the filtered MSA for the 2020-08-08 data-set, we apply the two randomization strategies described above. For profile randomization 50 samples are generated and the PLM procedure is implemented to infer the epistasis between pairwise loci.

As stated in main body of the paper, for further analysis we only retained pairs where both the inferred loci are located in the coding region and the first and second prevalent nucleotides of these loci in the analyzed data-set are entries in $\{\mathrm{A}, \mathrm{C}, \mathrm{G}, \mathrm{T}\}$. We observed no such pairs in the top-200 PLM scores, for any profile randomized samples. Therefore, the examined ranks of PLM scores are extended to top-2000s. In Fig. 6, the inferred top-2000 epistasis for each sample are shown. There are 24 out of 50 samples which contain interactions found by PLM. However, as they all have low rank, none of these links show up in Table $\square$ in the main body of the paper.

For phylogeny randomization we also generated 50 random samples. The inferred epistasis for these samples are shown in Fig. 7 and continued in Fig. 8. Unlike
profile strategy, a subset of the putative epistatic links of Table $\rrbracket$ in the main body of the paper also show up after phylogeny randomization. This subset of predictions is listed in Table $\Pi$ in the main body of the paper, and has been eliminated in the list of retained predictions in Table III

## Appendix F: Robustness as to thresholds

In the analysis in main body of the paper, the following criteria are used for pre-filtering of the MSA. First, if in one locus the same nucleotide is found in a percentage $P_{\text {major }} \geq 96.5 \%$ of the samples, or if the sum of the percentages of A, C, G and T at this position is $P_{\text {sum }} \leq 20 \%$, then this locus will be deleted. The inferred epistasis effects are found to be sensitive to $P_{\text {major }}$ at a certain locus but not to $P_{\text {sum }}$. We chose the criterion $P_{\text {major }} \geq 96.5 \%$ to keep consistency with earlier obtained results from the dataset of 2020-05-02 (presented below). For that earlier (smaller) dataset, the same results are obtained also with less permissive thresholds. To check the influence of $P_{\text {major }}$, we performed PLM inference over the 2020-08-08 dataset with $P_{\text {major }}=90 \%$ and $P_{\text {major }}=95 \%$ respectively. The inferred epistasis for these two $P_{\text {major }} \mathrm{s}$ are shown in the left and right panel of Fig. 9 respectively. By increasing the threshold, more epistasis effects are inferred. In summary, most of the links presented with lower $P_{\text {major }}$ remain in the results with higher thresholds.

For the visualization of epistasis effects, we focus on links with both terminals located in coding regions and mutation types are gaps and 'N's excluded. As shown in Fig. 9, different colors mean links with different ranks. Red (links with terminals located close to each other) and blue (the terminals are far away from each other) are for the epistasis links with ranks less than 50 while grey for links with ranks within 51 to 200. Both panels clearly show that with PLM method, most significant links are in top-50s. This indicates that the choice of visualization threshold are reasonable in the presentation of epistasis effects.

## Appendix G: Different quantifications of correlations

The correlation (co-variance) of two Boolean variables is given by one real number. If the Boolean variables are represented as spin variables $s_{i}$ and $s_{j}$ taking values 1 and -1 , this number is the physical correlation $\chi_{i j}=$ $\left\langle s_{i} s_{j}\right\rangle-\chi_{i} \chi_{j}$, where $\chi_{i}=\left\langle s_{i}\right\rangle$ and $\chi_{j}=\left\langle s_{j}\right\rangle$. Since every joint distribution on two Boolean variables can be written $p\left(s_{i}, s_{j}\right)=\frac{1}{4}\left(1+\chi_{i} s_{i}+\chi_{j} s_{j}+\left(\chi_{i} \chi_{j}+\chi_{i j}\right) s_{i} s_{j}\right)$ with marginals $p\left(s_{i}\right)=\frac{1}{2}\left(1+\chi_{i} s_{i}\right)$ and $p\left(s_{j}\right)=$ $\frac{1}{2}\left(1+\chi_{j} s_{j}\right)$, the contrast is

$$
\begin{align*}
c\left(s_{i}, s_{j}\right) & =\frac{p\left(s_{i}, s_{j}\right)}{p\left(s_{i}\right) p\left(s_{j}\right)} \\
& =\frac{1+\chi_{i} s_{i}+\chi_{j} s_{j}+\left(\chi_{i} \chi_{j}+\chi_{i j}\right) s_{i} s_{j}}{1+\chi_{i} s_{i}+\chi_{j} s_{j}+\chi_{i} \chi_{j} s_{i} s_{j}} \tag{G1}
\end{align*}
$$

The mutual information (MI), recently used in genomescale epistasis analysis in [83], is the expected logcontrast

$$
\begin{align*}
I_{i j}= & \sum_{s_{i}, s_{j}} p\left(s_{i}, s_{j}\right) \log c\left(s_{i}, s_{j}\right) \\
= & \frac{1}{4}\left(\left(1+\chi_{i}+\chi_{j}+a_{i j}\right) \log \frac{1+\chi_{i}+\chi_{j}+a_{i j}}{1+\chi_{i}+\chi_{j}+\chi_{i} \chi_{j}}\right. \\
& +\left(1-\chi_{i}+\chi_{j}-a_{i j}\right) \log \frac{1-\chi_{i}+\chi_{j}-a_{i j}}{1-\chi_{i}+\chi_{j}-\chi_{i} \chi_{j}} \\
& +\left(1+\chi_{i}-\chi_{j}-a_{i j}\right) \log \frac{1+\chi_{i}-\chi_{j}-a_{i j}}{1+\chi_{i}-\chi_{j}-\chi_{i} \chi_{j}} \\
& \left.+\left(1-\chi_{i}-\chi_{j}+a_{i j}\right) \log \frac{1-\chi_{i}-\chi_{j}+a_{i j}}{1-\chi_{i}-\chi_{j}+\chi_{i} \chi_{j}}\right) . \tag{G2}
\end{align*}
$$

with $a_{i j}=\chi_{i} \chi_{j}+\chi_{i j}$.
For given magnetizations ( $\chi_{i}$ and $\chi_{j}$ ), correlations and mutual information of Boolean variables are hence in one-to-one correspondence. In particular, zero correlation implies zero MI. For categorical data (more than two states per variable), correlation is conveniently defined as a matrix

$$
\begin{equation*}
f_{i j}(a, b)=\left\langle\mathbf{1}_{s_{i}, a} \mathbf{1}_{s_{j}, b}\right\rangle-f_{i}(a) f_{j}(b) \tag{G3}
\end{equation*}
$$

where $f_{i}(a)=\left\langle\mathbf{1}_{s_{i}, a}\right\rangle$ and $f_{j}(b)=\left\langle\mathbf{1}_{s_{j}, b}\right\rangle$. Mutual information is defined in the same way as in (G2), except that the sums go over the ranges of indices $a$ and $b$. Frobenius norm (or score) of a correlation matrix is defined as

$$
\begin{equation*}
s_{i j}=\sqrt{\sum_{a, b} f_{i j}^{2}(a, b)} \tag{G4}
\end{equation*}
$$

Mutual information and Frobenius norm of correlations of categorical variables are not generally related. It could therefore be the case that the information Fig. (3) and Table IV in main body of the paper would be different if the assessment would be done for mutual information. Fig. 10 and Table V show that this is substantially not the case.

Another way to quantify interdependence between two random variables is the $p$-value of Fisher's exact test 84, recently used in the present context in 36. If in $n$ samples in total outcome $a b$ is found $n_{a b}$ time then the $p$-value of Fisher's exact test is the probability that these outcomes would have been observed in independent draws of independently distributed variables. For Boolean variables that has the exact expression

FIG. 6. Links within top-2000 PLM scores of samples with profile randomization. The links located in coding regions and terminals have mutations excluding gaps and 'N's are retained in these circos plots. There are 24 out of 50 samples contain links. However, all of these are ranked low starting from the original MSA, and none of them show up in Table $\square$ in the main body of the paper.

$$
\begin{equation*}
p_{i j}\left(n,\left\{n_{a b}\right\}\right)=\frac{\left(n_{11}+n_{1-1}\right)!\cdot\left(n_{-11}+n_{-1-1}\right)!\cdot\left(n_{11}+n_{-11}\right)!\cdot\left(n_{1-1}+n_{-1-1)}\right)!}{n_{11}!\cdot n_{-11}!\cdot n_{1-1}!\cdot n_{-1-1}!\cdot n!} \tag{G5}
\end{equation*}
$$

In the limit of many samples $n_{a b}=n \cdot p_{i j}(a, b)$ almost
surely, and by Stirling's formula

$$
\begin{align*}
\log p_{i j}(n) & \approx n\left(\left(p_{i j}(1,1)+p_{i j}(1,-1)\right) \log \left(p_{i j}(1,1)+p_{i j}(1,-1)\right)+\left(p_{i j}(-1,1)+p_{i j}(-1,-1)\right) \log \left(p_{i j}(-1,1)+p_{i j}(-1,-1)\right)\right. \\
& +\left(p_{i j}(1,1)+p_{i j}(-1,1)\right) \log \left(p_{i j}(1,1)+p_{i j}(-1,1)\right)+\left(p_{i j}(1,-1)+p_{i j}(-1,-1)\right) \log \left(p_{i j}(1,-1)+f_{i j}(-1,-1)\right) \\
& \left.-p_{i j}(1,1) \log p_{i j}(1,1)-p_{i j}(1,-1) \log p_{i j}(1,-1)-p_{i j}(-1,1) \log p_{i j}(-1,1)-p_{i j}(-1,-1) \log p_{i j}(-1,-1)\right) \tag{G6}
\end{align*}
$$

which is mutual information, up to a factor $-n$. In a more general setting, this result follows from Sanov's

FIG. 7. Links within top-200 PLM scores of the 1st to the 30th samples with phylogenetic randomization. The links located in coding regions are retained in these circos plots. Each phylogenetic sample contains interactions effects with a rank cut-off threshold of 200. Blue shows links with lengths $d_{i j}$ longer than 3 nucleotide. Red shows links with $d_{i j} \leq 3 n t$ for links with rank in top-50s. Black shows links with $d_{i j} \leq 3 n t$ for links with rank in top 51-200.
lemma in Information Theory. For the data we consider we are always in the range of very large $n$, and Fisher's exact test therefore does not give additional information.

## Appendix H: On putative couplings between nsp7 (11843..12091) and nsp8 (12092..12685)

As described above, the set of loci remaining after filtering depends on the percentage of the a major nu-

FIG. 8. Links within top-200 PLM scores of the 31st to 50 th samples with phylogenetic randomization.

TABLE V. Top-10 significant links found by mutual information (MI) analysis in the coding region for the dataset with cut-off date 2020-08-08.

[^1]cleotide $P_{\text {major }}$ used as threshold. As the two viral genes nsp7 and nsp8 are known to interact [85] we looked for epistatic interactions between loci in these two genes. None appear using the threshold $P_{\text {major }}=96.5 \% \mathrm{em}-$ ployed in the main body of the paper. All loci located in nsp7 and nsp8 are deleted during filtering procedure using this threshold. To nevertheless consider possible
epistasis effects within these two regions, we increased the value of $P_{\text {major }}$. As $P_{\text {major }}$ grows more loci remain after filtering, in all regions, which increases the computational burden. To mitigate this effect, we further filtered the MSA matrix by considering the mutation type of each remaining loci. In the following we have filtered out loci where one of the dominant mutation type are

FIG. 9. Top-200 significant pairwise epistasis from the 2020-$08-08$ data-set. Upper: the filtering threshold is $90 \%$ (for a given locus, if the percentage of a certain main nucleotide (A, C, G, T, -, N) exceeds the threshold, this locus will be deleted.); Lower: the threshold value is $95 \%$. Only epistatic links with both terminals located in the coding region and no gaps and 'N's included in mutations are presented here. Colored lines indicate for top 50s, grey for links with ranks in top 50-200s. Red lines show short-distance links ( $\leq 3 \mathrm{bp}$ ) blue lines show links of longer distance.
gaps ('-') or unknown nucleotide ('N').
With these alternative filtering criteria, we tested values of $P_{\text {major }}$ from $97 \%$ to $99.9 \%$ and found that the loci in nsp7 and nsp8 show up when $P_{\text {major }}>99.7 \%$. With $P_{\text {major }}=99,8 \%$, there remains 262 loci and 5,746 unique sequences, from which one locus at position 11916 in nsp7 and two loci at positions 12199 and 12478 in nsp8 are identified. With $P_{\text {major }}=99,9 \%$, there remains 580 loci and 9525 unique sequences, from which two loci at positions 11916 and 12025 in nsp7 are identified and seven closely positioned loci (12199, 12400, 12478, 12503, 12513, 12534, 12550) in nsp8.

With $P_{\text {major }}=99.8 \%$, there are 34,191 inferred pairwise epistatic links in total. With $P_{\text {major }}=99.9 \%$, the

FIG. 10. Distribution of Mutual information (MI) between pairwise loci for the original data-set with cut-off date 2020-$08-08$. The score pointed by the red arrow corresponds to the link with most significant score ( 1059 to 25563 ) by PLM analysis.
number of inferred links is 167,910 . The epistasis analysis results provided by PLM procedure are summarized in Table VI. Some significant links with high ranks are included for comparison. Both ranks and PLM scores show that the epistasis effects between nsp7 and nsp8 are much weaker than the significant ones. The ranks for the listed links in Table VI are obtained without considering gaps '-' and not recognized notation 'N'. However, they fit well with the results that including the effects of gaps and 'N's, at least for the links with the rank of top-50s. In summary, links between loci in genes nsp7 and nsp8 only appear using much more permissive filtering criteria and with much lower rank than the top-200 listed in Table $\square$ in the main body of the paper.

## Appendix I: On putative couplings between nsp10

 (13025..13441) and nsp14 (18040..19620)As the two viral genes nsp10 and nsp14 are also known to interact [86, 87] we looked for epistatic interactions between loci in these two genes, applying the same procedure as above. With $P_{\text {major }}=99.8 \%$ and $P_{\text {major }}=$ $99.9 \%$, we show three links between loci located in nsp10 and nsp14 that show up in the filtering MSAs with both values of threshold. The corresponding PLM scores and the rank are given in Table VII Similarly to the links between loci in nsp7 and nsp8, it has very low rank, as well as low PLM score. In the main body of the paper, where filtering criterion $P_{\text {major }}=96.5 \%$ is used, these loci are filtered out and do not appear.

## Appendix J: On putative couplings involving loci in Spike

D614G in Spike is a well known mutation 88 of SARS-CoV-2, and has become the most prevalent form in the

TABLE VI. Links between loci in genes nsp7 and nsp8 obtained after the modified filtering procedure applied to the 2020-08-08 data set. Loci without gaps '-', without not recognized ' N ' and satisfying permissive threshold criterion $P_{\text {major }}=99.8 \%$ and $P_{\text {major }}=99.9 \%$ have been retained and reported here.

global pandemic COVID19. This mutation is at position of 23403 with respect to the reference genomic sequence (Wuhan-Hu-1). Through PLM procedure on the whole genomic sequences, we observed two pairwise couplings 3037-23403 and 14408-23403 in top-50 PLM scores. These two pairwise links however showed fairly often in phylogeny randomization tests, and have therefore been interpreted as effects of shared inheritance (phylogeny). In above we show all PLM links involving loci in Spike up to rank 5000 , all of them significantly below top-200. A notable observation as shown in Table VIII is that the locus 23403 appears in all these links. As the epistatic inference is built on retaining the links with highest PLM scores that also do not also appear after randomization, none of the entries in Table VIII are retained as predicted epistatic interactions in Table III of the main body of the paper.

## Appendix K: Potential drugs for proteins in Table III of the main body of the paper

There are eight proteins listed in Table III in main body of the paper. Except ORF3a, all these viral proteins have potential drugs listed in [74, sorted by human interactors of these proteins, see Table IX. As indicated in the table, several of these drugs are approved, for different purposes listed in [74], while some are still in preclinical or clinical trials.

## Appendix L: Results from data set until 20200502

As more data accumulates the predictions obtained from DCA may change. In the main body of the paper we show in Fig. 4 that the leading predictions are stable using four different cut-off dates: (April 1, April 8, May 2, August 8).

TABLE VIII. Links involving loci in Spike protein obtained after the filtering procedure described in the main context applied to the 2020-08-08 data set with $P_{\text {major }}=96.5 \%$.

TABLE IX. Potential drugs for interactors of proteins in Table III] as listed in [74]. Approved drugs for any purpose in boldface.

| Bait | Interactor(s) | Drug | Status |
| :---: | :---: | :---: | :---: |
| nsp2 | FKBP15 | Rapamycin ${ }^{\text {b }}$ | Approved |
|  | EIF4E2/H | Zotatifin ${ }^{\text {b }}$ | Clinical trials |
| ORF3a | None in 74 | - | - |
| nsp4 | NUPs RAE1 | Selinexor ${ }^{\text {b }}$ | Approved |
| ORF8 | DNMT1 | Azacitidine ${ }^{\text {a }}$ | Approved |
|  | LOX | CCT $365623^{\text {a }}$ | Pre-clinical |
|  | FKBP7/10 | Rapamycin ${ }^{\text {b }}$ | Approved |
|  | FKBP7, FKBP10 | FK-506 ${ }^{\text {b }}$ | Approved |
|  | PLOD1/2 | Minoxidil ${ }^{\text {b }}$ | Approved |
| nsp14 | IMPDH2 | Merimepodib ${ }^{\text {a }}$ | Clinical Trial |
|  | GLA | Migalastat ${ }^{\text {a }}$ | Approved |
|  | IMPDH2 | Mycophenolic acid ${ }^{\text {a }}$ | Approved |
|  | IMPDH2 | Ribavirin ${ }^{\text {a }}$ | Approved |
|  | IMPDH2 | Sanglifehrin A ${ }^{\text {b }}$ | Pre-clinical |
| nsp12 | RIPK1 | Ponatinib ${ }^{\text {a }}$ | Approved |
| nsp13 | PRKACA | H-89 ${ }^{\text {a }}$ | Pre-clinical |
|  | MARK3,TBK1 | ZINC95559591 ${ }^{\text {a }}$ | Pre-clinical |
|  | CEP250 | WDB002 ${ }^{\text {b }}$ | Clinical Trial |
| nsp6 | ATP6AP1 | Bafilomycin A1 ${ }^{\text {a }}$ | Pre-clinical |
|  | SIGMAR1 | E-52862 ${ }^{\text {a }}$ | Clinical trials |
|  | SIGMAR1 | PD-144418 ${ }^{\text {a }}$ | Pre-clinical |
|  | SIGMAR1 | RS-PPCC ${ }^{\text {a }}$ | Pre-clinical |
|  | SIGMAR1 | PB28 ${ }^{\text {a }}$ | Pre-clinical |
|  | SIGMAR1 | Haloperidol ${ }^{\text {a }}$ | Approved |
|  | SLC6A15 | Loratadine ${ }^{\text {a }}$ | Approved |
|  | SIGMAR1 | Chloroquine ${ }^{\text {b }}$ | Approved |

[^2]Here we show as a further robustness test the other figures and tables of the main body of the paper, but for the second largest data set (cut-off date May 2, 2020).

Table X presents the top-50 significant links for the 20200502 data set, all of them appear in Table $\Pi$ in the main context for the 20200808 data set. Table XI shows the top 10 significant links provided by the correlation
analysis for the 20200502 data, which could be compared with Table $\overline{I V}$ in the main body of the paper. The Fig. 11 shows the histogram of PLM scores for the original MSAs (Fig.11(a)) as well as that for phylogeny (Fig.11(b)) and profile (Fig. 11(c)) randomization respectively. This plot can be compared with the Fig. 2 in the main context.

FIG. 11. Histograms of PLM scores for (a) 2020-05-02 dataset, (b) a phylogeny randomized sample and (c) a profile randomized sample. The blue bars for all scores while the red ones for top-50 largest scores. Red arrows in (a) indicate links listed in Table III, with the 29th link almost overlapping with the 22 nd . The largest PLM score is pointed to by red arrows for random samples in (b) and (c). None of them is located inside a coding region, and none of them appear in Table X and Table III in the main context.

TABLE X. Top-50 significant epistatic links between loci for the 2020-05-02 data-set. To be compared to Table $\begin{aligned} & \text { in main body }\end{aligned}$ of paper.

| Rank ${ }^{\text {a }}$ | Locus 1 - b protein | $\begin{aligned} & \hline \begin{array}{l} \text { mutation- } \\ \text { type } \end{array} \end{aligned}$ | Locus 2 protein | mutationtype | PLM score |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 8782-nsp4 | C\|T-syn. | 28144-ORF8 | T\|C-non. | 2.0649 |
| 2 | 1059-nsp2 | C\|T-non. | 25563-ORF3a | G\|T-non. | 1.9480 |
