
On the probability of finding a nonphysical solution through shadowing

Nisha Chandramoorthy and Qiqi Wang

June 2020

Abstract Based on the shadowing property of dynamical systems, we expect that numerical solutions of governing equations lie close to a true solution – a shadowing solution – of the governing equation. This is used to justify, even when the governing equation is chaotic, that numerical solutions represent a true solution. However, shadowing solutions can be *nonphysical*: they may not represent the long-term statistical behavior of an ensemble of true solutions. That is, the probability distribution of a shadowing solution can differ, often dramatically, from that of a solution starting from almost every initial condition. In this paper, we construct analytical examples of chaotic systems in which shadowing solutions are nonphysical. These examples also illustrate that the probability of finding a nonphysical shadowing solution can be 1. Through several analytical constructions, we note that the incorrect assumption of the physicality of shadowing raises questions on the trustworthiness of numerical solutions, and shadowing-based sensitivity analysis of chaotic systems.

1 Shadowing and some applications

Shadowing refers to the relationship between a pair of solutions to slightly different governing equations. The difference between the governing equations can be due to parameter perturbation or numerical error. The solution to one governing equation is said to shadow a solution to a second, slightly different equation if the first solution stays close to the second solution for some amount of time.

The existence of arbitrarily long shadowing solutions for sufficiently similar governing equations has been proven for invertible hyperbolic maps by Anosov

Center for Computational Science and Engineering, MIT, Cambridge, MA 02139, USA.

[1] and Bowen [4]. For non-hyperbolic systems, it is often possible to estimate the length of time for which shadowing solutions exist [8][9].

The existence of shadowing trajectories underlies many applications. Numerical simulations of turbulent flows have been widely used to study its statistical behavior. It is argued, based on shadowing, that such numerical simulations of chaotic dynamical systems can be useful, despite the butterfly effect. Consider a numerical solution to a deterministic chaotic system with an initial condition x . Because of numerical and modeling errors, there will typically be a small difference between the true governing physics and the equations solved on a computer. As the system is evolved forward in time, this difference will be amplified exponentially due to the chaotic nature of the system. The question therefore arises as to whether or not numerical solutions to chaotic systems, such as turbulent flows, represent the true physics. The existence of shadowing solutions is used to argue for the usefulness of such numerical solutions. When certain conditions for shadowing theorems are met, the numerical solution would be an approximation to a “true” solution that satisfies the real governing physics.

Shadowing is also used in sensitivity analysis of chaotic dynamical systems. In particular, it is used in computing how long-time-averages in a chaotic system respond to small perturbations in the governing equation [17][14][12]. In this application, derivative of the long-time-averages is computed using a solution to the perturbed governing equation that shadows a solution to the unperturbed equation. The Least Squares Shadowing [17][14] method uses this concept.

There is an implicit assumption in both of these applications. The assumption is that the shadowing trajectory is a “physical” trajectory, a trajectory on which the long-time-average of a quantity is equal to the ensemble average. Not all solutions satisfying the physical governing equation are considered “physical” in this sense. In high-Reynolds number fluid flows, for example, a steady-state, laminar flow solution may satisfy the Navier-Stokes equation. But such a solution would never be observed in reality because it is unstable, and any small perturbation would trip it into turbulence. Unstable steady-state solutions are not the only nonphysical solution. Many chaotic dynamical systems have infinitely many periodic solutions that are, similar to their steady counterpart, unstable. These trajectories can have a probability distribution that is remarkably different from that of a typically observed solution of the governing equation. It is also possible to effect significant change in the statistics of the true governing dynamics by introducing a minor parameter perturbation. Thus, although two trajectories, at slightly different parameters, may shadow each other, the long-time-averages of observables calculated using them, may not be close. As we will see in the next section, even solutions that look “chaotic”, i.e., unsteady and aperiodic, may not be physical.

2 What are physical and nonphysical solutions?

Intuitively, we call a solution to a governing equation “physical” if it represents what one would observe in a physical experiment. In particular, the statistics measured from a physical solution match the statistics observed in an experiment. Not all solutions are physical. A laminar flow solution, despite satisfying the governing equation, does not produce the turbulent statistics one would observe in a high-Reynolds number experiment. Such solutions are thus called nonphysical.

In this section, we first describe what distinguishes, mathematically, a physical and a nonphysical solution. We also explain why it is theoretically unlikely to observe a nonphysical solution in an experiment. We then give a few examples of these almost-never-observed nonphysical solutions.

2.1 Physical solutions

What we typically call “physical” solutions to a governing equation satisfy the following two criteria:

1. Time-averaged quantities converge in the limit of infinite averaging time. Consider $u(t)$ as the solution to a chaotic governing equation, then for a regular observable of interest $J(u(t))$,

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T J(u(t)) dt \quad (1)$$

exists.

2. For almost any small perturbation to the initial condition $u(0) \rightarrow u'(0)$, the perturbed solution $u'(t)$ should have the same statistics, i.e.,

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T J(u(t)) dt = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T J(u'(t)) dt \quad (2)$$

The left column of Figures 1-3 illustrates a physical solution of the Lorenz system,

$$\frac{du}{dt} = \frac{d}{dt} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = \begin{pmatrix} \sigma(u_2 - u_1) \\ u_1(\rho - u_3) - u_2 \\ u_1 u_2 - \beta u_3 \end{pmatrix} \quad (3)$$

where $\sigma = 10$, $\rho = 28$, and $\beta = 8/3$. The solution starts at the initial condition $u(0) = (0.01, 0.01, 28)$. After a long time evolution, we observe that the solution has visited a large portion of the $u_1 - u_3$ plane with a varying, but well-defined, frequency. We can use a probability distribution, μ , to quantify how frequently a physical solution visits portions of the phase space. Specifically, for a subset A of the phase space, $\mu(A)$ measures the fraction of time a very long physical solution spends inside the subset A . With this distribution defined, the infinite-time average of any quantity $J(u)$ can be represented as an average

Fig. 1 L: An ensemble of initial conditions distributed uniformly in the box $u_1 \in [0, 1]$, $u_2 \in [0, 1]$, $u_3 \in [28, 39]$ after 10 time units of evolution, shown on the u_1-u_3 plane. R: distribution of a trajectory of 1000 time units in length. In both plots, the color represent the number of samples in a 2048×2048 uniform grid. The trajectory is sampled every 0.001 time units.

Fig. 2 L: distribution of the same ensemble as in Figure 1 after another 5 time units of evolution. R: distribution of the same trajectory as in Figure 1 evolved for 10,000 time units.

of J over the entire phase space U , weighted by this statistical distribution μ . Mathematically,

$$\frac{1}{T} \int_0^T J(u(t)) dt \xrightarrow{T \rightarrow \infty} \int_U J(u) d\mu(u) \quad (4)$$

Remarkably, the distribution μ not only characterizes the history of a long physical solution, but also describes the settled state of an ensemble of solutions. This is illustrated on the right column of Figures 1–3. We generate these plots by starting from an ensemble of about one billion initial conditions, randomly and uniformly spaced in a small three-dimensional box. All

Fig. 3 L: distribution of the same ensemble as in Figures 1 and 2 after a total of 50 time units of evolution. R: distribution of the same trajectory as in Figures 1 and 2 evolved for 100,000 time units.

these billion solutions are evolved by solving Eq. 3 for 10, 15, and 50 time units, to obtain the plots. We observe that, as time evolves, the ensemble spreads over an increasingly larger portion of the $u_1 - u_3$ plane. After a long time, the ensemble settles into a time-invariant *attractor* that contains the *unstable manifold*, which appears as filaments forming the attractor. The probability distribution of the ensemble on the attractor becomes identical to the distribution of a single, very long physical solution, which is also contained in the attractor (Figure 3).

This remarkable agreement has been thoroughly studied under the subject of ergodic theory. Under surprisingly weak conditions, a solution starting from **almost** any initial condition, chosen randomly from a set enclosing the attractor, is a physical solution [20]. Meanwhile, an ensemble of trajectories starting from any distribution with a finite density also evolves towards the same final distribution, μ . Due to expansion of a volume of solutions tangent to the attractor filaments, a finite density under long-time evolution becomes absolutely continuous on the unstable manifold, i.e., the likelihood of a trajectory visiting any set not intersecting the attractor filaments is zero. The stationary distribution achieved on long-time evolution of the ensemble that has the absolute continuity property is called the Sinai-Ruelle-Bowen (SRB) measure. The absolute continuity property is sufficient to ensure that the SRB measure is the same μ . That is, the SRB measure is physically observed in the sense that physical solutions produce long-time-averages which are expectations with respect to the SRB measure.

Note that almost any, not any, initial condition leads to a physical solution. A set of special initial conditions contained in a neighborhood of the attractor may exist starting from which physical solutions are not generated. These initial conditions do not produce the same statistics as the physical solutions.

Fig. 4 Periodic solutions of the Lorenz equation, overlaid on top of its SRB distribution. The solid line, dashed line, and dotted line represent three distinct periodic solutions.

This special set of initial conditions is Lebesgue measure zero – one has zero chance of finding such an initial condition by randomly sampling. Nonphysical solutions thus take an effort to find. Nevertheless, they turn out to be important when discussing shadowing, the topic of this paper. We first introduce a type of obviously nonphysical solutions in the next subsection, before discussing a less obvious type in section 2.4.

2.2 Nonphysical solutions Type I: Periodic Solutions

A periodic solution is nonphysical because it does not visit as much of the phase space as a physical solution does. Figure 4 shows a few periodic solutions of the Lorenz equation. Comparing these solutions to the physical solution visualized in Figures 1–3, we see that the periodic solutions are significantly more limited in their extent of exploration.

Because periodic solutions have a more limited extent in the phase space, their statistics are different from physical solutions. Here we illustrate the difference using the mean of two quantities of interest

$$J_1(u) = u_3, \quad J_2(u) = e^{-\frac{u_3^2}{2}}. \quad (5)$$

Table 1 shows these quantities of interest averaged over the three periodic solutions shown in Figure 4, compared against those averaged over a physical solution. Here, Periodic #1, #2, and #3 correspond to the solid, dashed, and dotted lines, respectively. We observe from the table that the mean of J_1 over the periodic solutions are different but comparable to the mean over physical

Fig. 5 L: the Lorenz map. The x-axis is the n -th local maximum of $u_3(t)$ over a long solution; the y-axis is the $(n+1)$ -th local maximum of $u_3(t)$. The intersection of this curve with the dashed line ($y = x$) indicates the initial condition for the solid line in Figure 4. R: the Lorenz map iterated twice. The x-axis is the n -th local maximum of $u_3(t)$; the y-axis is the $(n+2)$ -th maximum. The intersections with the diagonal dashed line indicate the initial conditions for both the dotted and dashed lines in Figure 4.

solutions. The mean of J_2 over the periodic solutions, on the other hand, is orders of magnitude different from that of the physical solutions. These differences disqualify the periodic solutions from being physical.

| | Periodic #1 | Periodic #2 | Periodic #3 | Physical solutions |
|-------|---------------------|---------------------|---------------------|------------------------|
| J_1 | 23.05 | 23.19 | 23.37 | 23.67 |
| J_2 | 4×10^{-35} | 7×10^{-28} | 3×10^{-22} | 1.58×10^{-05} |

Table 1 Comparison of statistics computed from periodic solutions of the Lorenz equation with the statistics computed from physical solutions

While periodic solutions are generally difficult to find, the Lorenz equation has a special feature that makes the task significantly easier. In a typical solution to the Lorenz equation, the $u_3(t)$ component oscillates in a pattern that appears neither regular nor random. Lorenz observed that the height of one peak in the oscillation can predict the height of the next peak. He quantified his observation by the Lorenz map, as shown in Figure 5.

The Lorenz map provides us a tool to find as many periodic solutions as we want. By intersecting the map with a diagonal line, we can find a local maximum of $u_3(t)$ for which the next maximum is almost the same value. We then look up the values of $u_1(t)$ and $u_2(t)$ when $u_3(t)$ achieves this maximum. This gives us an initial condition starting from which the solution is nearly periodic. We can similarly intersect the second iterate of the Lorenz map (right plot of Figure 5), and the third iterate, etc, with a diagonal line, to find increasingly complex periodic solutions.

This Lorenz map is more than a tool to study the Lorenz equation. It is a chaotic dynamical system all by itself. Unlike the Lorenz equation, which is a continuous-time dynamical system in three dimensions, the Lorenz map is a discrete-time dynamical system in one dimension. It exhibits the same sensitivity to initial condition that characterizes the Lorenz equation. One can readily observe in the right plot of Figure 5 that a small perturbation in the x-axis can lead to a large change in the y-axis. This sensitivity grows exponentially for iterates of this map. A solution to the Lorenz map can be obtained by extracting the consecutive local maxima of a solution to the Lorenz equation. If we extract from a physical solution to the Lorenz equation, we obtain a physical solution of the Lorenz map. It will visit the interval between 29 and 49 with varying, well-defined frequencies. By contrast, if one extracts a solution to the Lorenz map from a periodic solution to the Lorenz equation, the solution will visit only a discrete set of points. It is thus a periodic, nonphysical solution. What we learned about the Lorenz equation could have all been learned from the Lorenz map.

Having discussed periodic solutions in this section, we move to a second type of nonphysical solutions. This type is more difficult to find and study than the periodic solutions. To make it easier, we switch our example to a one-dimensional, discrete time dynamical systems like the Lorenz map. Because the Lorenz map lacks a closed form, we construct, in the next subsection, a one-dimensional discrete-time dynamical system with a closed form, one that qualitatively resembles the Lorenz map. This map will help us, in section 2.4, to study a more insidious type of nonphysical solutions that hides in shadowing solutions.

2.3 Tent map: periodic and physical solutions

The tent map has been widely studied [6][19]. It is qualitatively similar to the Lorenz map and has a simple analytical form:

$$\varphi(x) := \begin{cases} 2x & x < 1 \\ 4 - 2x & 2 \geq x \geq 1 \end{cases} \quad (6)$$

Figure 6 shows the tent map.

The tent map φ is chaotic because a trajectory x_0, x_1, \dots satisfying $x_{i+1} = \varphi(x_i)$ exhibits exponential sensitivity to initial condition. An infinitesimal perturbation of absolute value δx , applied to an initial condition x_0 , generates a trajectory that is $2\delta x$ away from x_1 , $4\delta x$ from x_2 , $8\delta x$ from x_3 and so on. This exponential divergence of two trajectories that start infinitesimally apart is the butterfly effect that characterizes chaotic dynamics.

It is easy to find periodic solutions for the tent map. $\frac{4}{3}$ maps to itself; $\frac{4}{5}$ and $\frac{8}{5}$ map to each other; $\frac{4}{7}$, $\frac{8}{7}$, and $\frac{12}{7}$ map circularly. In fact, any rational number evolves into periodic solutions that visit only a finite set of rational numbers with the same denominator. This is compatible with ergodic theory because all

Fig. 6 The tent map φ .

rational numbers in $[0, 2]$ comprise a subset of Lebesgue measure zero. That is, we would have zero likelihood of getting a rational number if we sampled the Lebesgue measure (the uniform distribution) on $[0, 2]$. Instead, with a 100% probability, one would get an irrational number that, when iterated under the tent map, leads to a physical trajectory that distributes uniformly on the interval $[0, 2]$.

To understand why a physical solution visits the interval $[0, 2]$ at a uniform frequency, it is helpful to view the tent map from a different perspective. For a randomly chosen $x_0 \in [0, 2]$, we can represent it in binary form:

$$x_0 = \sum_{j=0}^{\infty} \frac{x_{0,j}}{2^j} \quad (7)$$

where $x_{0,0} \in \{0, 1\}$ is the integer component of x_0 and $x_{0,j} \in \{0, 1\}$ is the j th bit after the binary point. Let $x_{i+1} = \varphi(x_i)$, then it is straightforward to verify from the definition of the map that its binary representation

$$x_i = \sum_{j=0}^{\infty} \frac{x_{i,j}}{2^j} \quad (8)$$

satisfies

$$x_{i+1,j} = x_{i,0} \vee x_{i,j+1} \quad (9)$$

where \vee is the xor operator. To see why, note that multiplication by 2 is a left-shift operator in binary, and subtraction from 4 flips every bit after the binary point. If x_0 is chosen uniformly in $[0, 2]$, then each bit $x_{0,j}, j = 0, 1, \dots$ of x_0 has equal probability of being 0 or 1, and each bit is independent of other bits. It follows from Eq. 9 that each bit $x_{i,j}, j = 0, 1, \dots$ of $x_i, i = 1, 2, \dots$ has equal probability of being 0 or 1, and each bit is still independent of the other bits. As the map iterates starting from almost any x_0 , a physical solution explores the entire interval $[0, 2]$ uniformly.

2.4 Nonphysical solutions Type II: Quasi-physical Solutions

The simplicity of the tent map, as well as its binary form (Eq. 9), enables us to study nonphysical solutions that are not periodic. As in the last section, consider an

$$x_0 = \sum_{j=0}^{\infty} \frac{x_{0,j}}{2^j} \quad (10)$$

in which the bits $x_{0,j}$ are not independent of each other. Instead, suppose each bit is more likely to be identical to the previous bit than to be different. That is, $x_{0,j+1} = x_{0,j}$ with probability $p > \frac{1}{2}$ for $j = 0, 1, 2, \dots$. Then, by Eq. 9, the bits of every $x_i, i = 1, 2, \dots$ follow the same pattern, namely, each bit repeats the previous bit with probability p . Moreover, consider Eq. 9 for $j = 0$ and any i :

$$x_{i+1,0} = x_{i,0} \vee x_{i,1}. \quad (11)$$

Because $x_{i,0} = x_{i,1}$ with probability $p > \frac{1}{2}$, $x_{i+1,0} = 0$ with probability $p > \frac{1}{2}$. Starting from x_1 , this solution visits $[0, 1]$ with probability $p > \frac{1}{2}$. Instead of visiting $[0, 1]$ and $[1, 2]$ with equal probability, as a physical solution does, this solution favors $[0, 1]$. Since it provably visits the interval $[0, 2]$ with a different frequency from that of a physical solution, this is a nonphysical solution.

If $p = 1$, the bits of x_0 are either all zeros or all ones, which is the same as all zeros in mod 2 arithmetic. So, all further iterates when x_0 is 0, are 0, and this is a trivial nonphysical solution of type 1. Now when $p > \frac{1}{2}$ but strictly less than 1, the solutions we just constructed are both nonphysical and aperiodic. The bits of x_0 , though correlated with each other, still can exhibit an infinite variety of patterns. This implies that the solution may not eventually converge to any fixed point, nor show any repetitive patterns. As the map iterates, these patterns shift towards more significant digits, and the solution visits an infinite set of points. Nevertheless, the solutions observed along a trajectory also do not conform to a uniform distribution on $[0, 2]$ since they preferentially visit the first half of this interval. We call such aperiodic nonphysical solutions “quasi-physical” solutions.

Figure 7 shows the empirical density functions of four such quasi-physical solutions. When $p = 0.5001$, the statistical distribution of the quasi-physical solution is approximately uniform. Recall that a physical solution explores $[0, 2]$ uniformly. In this case, the quasi-physical solution has very similar statistical behavior as a physical solution. When $p = 0.51$, the empirical distribution becomes “hairy”. An apparently fractal pattern emerges. This fractal pattern further amplifies when $p = 0.55$. Meanwhile, the density on the left side, $[0, 1]$, becomes obviously higher than the density on the right side, $[1, 2]$. This is consistent with our theoretical analysis at the beginning of this subsection. When $p = 0.9$, the fractal pattern is so intensified that most of the solution seems to concentrate in a collection of tiny intervals. These plots expose the diversity of quasi-physical solutions. Their statistical distribution can be either very similar or completely different from that of physical solutions.

Fig. 7 Empirical probability distribution of long solutions (a billion steps) starting from four points whose binary digits have probability p of repeating the previous digit. The solution shown in the top-left plot starts from a point with $p = 0.5001$; top-right: $p = 0.51$; bottom-left: $p = 0.55$; bottom-right: $p = 0.9$.

So far we have constructed one class of quasi-physical solutions. It is noteworthy that there are infinite ways to construct quasi-physical solutions. In the binary representation of the initial condition x_0 , any statistical deviation from equal probability of 0 or 1, or any statistical dependence among digits would lead to quasi-physical solutions. One could, for example, construct an x_0 in which a bit is more likely to be 1 than 0 only if it follows two consecutive 0's. Such an x_0 would lead to a nonphysical solution. Its statistical distribution would differ from any of the plots in Figure 7. Nevertheless, as can be observed in Figure 8, it shows a remarkable resemblance in its “hairiness”; some kind of

Fig. 8 Empirical distribution function of other quasi-physical solutions. The solution shown in the left plot starts from an initial condition whose bits are independent and have probability 0.6 of being 0. The solution shown in the right plot starts from an initial condition whose bits have a probability of 0.6 of being 1 only following two consecutive 1's; otherwise a bit is 0 or 1 with equal probability.

fractal pattern emerges from the distribution. A fractal distribution appears to be a signature of quasi-physical solutions.

We have only seen quasi-physical solutions for the tent map. It is difficult to analytically construct quasi-physical solutions to the Lorenz equation and other, more complex, governing equations which typically produce chaotic solutions. Nevertheless, the similarity between the tent map and the Lorenz map [19], shown in Figure 5, suggests that quasi-physical solutions may exist for the Lorenz map, and by extension, the Lorenz equation. It is then natural to conjecture that such aperiodic, nonphysical, quasi-physical solutions exist in general for chaotic dynamical systems.

These quasi-physical solutions raise doubts over the usefulness of shadowing in some applications. For example, even if a numerical solution is shadowed by a solution to the true governing physics, is the shadowing solution physical or quasi-physical? At first glance, this may seem to be a nonissue because almost all solutions are physical. It seems reasonable to argue that because the set of all nonphysical solutions is Lebesgue measure-zero, the probability of finding a nonphysical solution through shadowing is zero percent. Such an argument, as we show in the next section, is wrong. The probability of finding a nonphysical solution through shadowing can be, instead of zero percent, one hundred percent.

Fig. 9 L: The scaled tent map $\hat{\varphi}_s$ at different values of s between 0 and 1. R: sensitivity to small perturbation in the governing equation. The y-axis shows the absolute value of the difference between two solutions, one satisfying Eq. 12, one for $s = 0$ and the other for $s = 10^{-5}$. The x-axis shows the iteration number. The initial condition is at $x_0 = \pi/2$.

3 Are shadowing solutions physical?

3.1 Example of a shadowing solution for the tent map

To illustrate the concept of shadowing, consider the tent map, defined in Eq. 6, and a scaled version of the map, defined by

$$\hat{\varphi}_s(x) := \begin{cases} 2x & x < 1 + s \\ 4(1 + s) - 2x & x \geq 1 + s \end{cases} \quad (12)$$

where $s \ll 1$. Note that a small change in s can lead to drastic differences between solutions starting from the same initial condition. As demonstrated in Figure 9, this sensitivity to small perturbations reflects the chaotic nature of the governing equation.

We can avoid this sensitivity to the governing equation using a coordinated perturbation to the initial condition. Consider two solutions satisfying Eq. 12 at different values of s . Instead of starting from the same initial condition, these two solutions start from $x_0(1 + s)$ with the same x_0 but their respective values of s . It can be shown that the solution of these two equations would be $x_i(1 + s)$, $i = 0, 1, \dots$ with their respective values of s , where $x_{i+1} = \varphi(x_i)$ satisfies the original tent map (Eq. 6). When the values of s are similar between the two solutions, this pair of solutions stays uniformly close to each other forever. Such a true solution of the governing equation that stays close to a given perturbed solution over a long time, is known as a *shadowing* solution. In this example, the perturbed solution satisfies a slightly different governing equation.

For every solution $\hat{x}_i, i = 0, \dots$ satisfying Eq. 12, there is a shadowing solution satisfying Eq. 6: $x_i := \hat{x}_i/(1+s)$. The map,

$$\hat{h}_s(x) := x/(1+s) \quad (13)$$

is known as a *conjugacy* between the two maps φ and $\hat{\varphi}_s$ because it satisfies

$$\varphi(\hat{h}_s(x)) = \hat{h}_s(\hat{\varphi}_s(x)), \quad \forall x \quad (14)$$

or equivalently, $\varphi \circ \hat{h}_s \equiv \hat{h}_s \circ \hat{\varphi}_s$. Such conjugacy maps can generally help us construct shadowing solutions. For every solution satisfying $\hat{\varphi}_s$, \hat{h}_s maps it to a shadowing solution satisfying φ because iterating Eq. 14, we get $\varphi^n \circ \hat{h}_s(x) = \hat{h}_s \circ \hat{\varphi}_s^n(x)$, for $n = 1, 2, 3, \dots$, where f^n stands for the function composition of f n -times.

Is the shadowing solution a physical solution? In this example, the answer is almost surely positive. We can demonstrate that almost any solution of the scaled tent map (Eq. 12) is uniformly distributed in $[0, 2(1+s)]$ – we can repeat our analysis in section 2.3 but represent our initial condition as $x_0 = (1+s) \sum_{j=0}^{\infty} x_{0,j}/2^j$. Its shadowing solution, which satisfies the original tent map (Eq. 6), can be obtained through the conjugacy (Eq. 13). Thus, the distribution of the shadowing solution can be obtained by mapping a uniform distribution in $[0, 2(1+s)]$ through the conjugacy map. This leads to a uniform distribution in $[0, 2]$, which is precisely the distribution of a physical solution of the tent map.

This simple example is useful in illustrating the concept of shadowing and the utility of the conjugacy map. But it is rather special in that the shadowing solution is almost always physical. Our next example introduces a tilted version of the tent map. Although the tilting perturbation to the tent map seems as simple as the scaling perturbation, the shadowing solution, as we will see, is almost always a quasi-physical solution.

3.2 An example of quasi-physical shadowing solution

The tilted tent map is defined as

$$\tilde{\varphi}_s(x) := \begin{cases} \frac{2}{1+s}x & x < 1+s \\ \frac{2}{1-s}(2-x) & x \geq 1+s \end{cases} \quad (15)$$

When $s = 0$, this map is identical to the tent map (Eq. 6). Let $\tilde{x}_{i+1} = \tilde{\varphi}_s(\tilde{x}_i), i = 0, 1, \dots$ be a solution of $\tilde{\varphi}_s$ that is also a perturbed solution of φ . As we explained in the previous subsection, the corresponding shadowing solution, which solves φ , can be found through a conjugacy map \tilde{h}_s that connects the solutions of φ and $\tilde{\varphi}_s$. If $\varphi \circ \tilde{h}_s \equiv \tilde{h}_s \circ \tilde{\varphi}_s$, then $x_i = \tilde{h}_s(\tilde{x}_i), i = 0, 1, \dots$ is the shadowing solution that satisfies $x_{i+1} = \varphi(x_i)$, corresponding to the perturbed solution $\tilde{x}_i, i = 0, 1, \dots$.

Fig. 10 L: the tilted tent map Eq. 15 for $s = 0, 0.1, 0.2, 0.3, 0.4,$ and 0.5 . R: the conjugacy \tilde{h}_s between the tent map (Eq. 6) and the tilted tent map (Eq. 15), evaluated using Eq. 16-17, for the same set of s as the left plot.

The conjugacy map, although more complex than the one in the last subsection, has the following closed form:

$$\tilde{h}_s(x) = \sum_{j=0}^{\infty} \frac{\xi_{s,j}(x)}{2^j}, \quad (16)$$

where

$$\xi_{s,j}(x) := \begin{cases} 0 & j = 0, x < 1 + s \\ 1 & j = 0, x \geq 1 + s \\ \xi_{s,j-1}(x) & j > 0, \tilde{\varphi}_s^j(x) < 1 + s \\ 1 - \xi_{s,j-1}(x) & j > 0, \tilde{\varphi}_s^j(x) \geq 1 + s. \end{cases} \quad (17)$$

In the above expression, $\tilde{\varphi}_s^j$ refers to the j -time composition of $\tilde{\varphi}_s$. That is, if $\tilde{x}_{j+1} = \tilde{\varphi}_s(\tilde{x}_j), j = 0, 1, \dots$, is a solution, $\tilde{\varphi}_s^i(\tilde{x}_j) = \tilde{x}_{j+i}, i, j = 0, 1, \dots$. To see why \tilde{h}_s constructed in Eq. 16 satisfies the definition of a conjugacy map $\tilde{h}_s(\tilde{\varphi}_s(x)) = \varphi(\tilde{h}_s(x))$ for all x – we need to analyze two cases: $x < 1 + s$ and $x \geq 1 + s$. When $x < 1 + s$, $\xi_{s,0}(x) = 0$; thus $\tilde{h}_s(x) = \sum_{j=1}^{\infty} \frac{\xi_{s,j}(x)}{2^j}$. Inside this infinite series, $\xi_{s,1}(x) = \xi_{s,0}(x) = 0$ if $\tilde{\varphi}_s(x) < 1 + s$, or $\xi_{s,1}(x) = 1 - \xi_{s,0}(x) = 1$ if $\tilde{\varphi}_s(x) \geq 1 + s$. Thus, $\xi_{s,1}(x) = \xi_{s,0}(\tilde{\varphi}_s(x))$ according to the definition of $\xi_{s,0}$. Using this as the base case, one can inductively verify that $\xi_{s,j+1}(x) = \xi_{s,j}(\tilde{\varphi}_s(x))$ for all $j > 0$, using just the definitions of $\xi_{s,j}$ and $\xi_{s,j+1}$. Therefore, $\tilde{h}_s(x) = \frac{1}{2} \sum_{j=0}^{\infty} \frac{\xi_{s,j}(\tilde{\varphi}_s(x))}{2^j} = \frac{1}{2} \tilde{h}_s(\tilde{\varphi}_s(x))$. On the other hand, because $\tilde{h}_s(x) = \sum_{j=1}^{\infty} \frac{\xi_{s,j}(x)}{2^j} \leq 1$, $\varphi(\tilde{h}_s(x)) = 2\tilde{h}_s(x)$ according to the definition of φ . Thus, $\varphi(\tilde{h}_s(x)) = \tilde{h}_s(\tilde{\varphi}_s(x))$ holds when $x < 1 + s$.

When $x \geq 1 + s$, $\xi_{s,0}(x) = 1$; thus $\tilde{h}_s(x) = 1 + \sum_{j=1}^{\infty} \frac{\xi_{s,j}(x)}{2^j} = 2 - \sum_{j=1}^{\infty} \frac{1 - \xi_{s,j}(x)}{2^j}$. Inside this infinite series, $1 - \xi_{s,1}(x) = 1 - \xi_{s,0}(x) = 0$ if $\tilde{\varphi}_s(x) < 1 + s$, or $1 - \xi_{s,1}(x) = \xi_{s,0}(x) = 1$ if $\tilde{\varphi}_s(x) \geq 1 + s$. Thus, $1 - \xi_{s,1}(x) =$

Fig. 11 L: the density of a trajectory satisfying Eq. 6 that shadows a random trajectory satisfying Eq. 15 for $s = 0.1$. R: the density of a trajectory satisfying Eq. 6 that shadows a random trajectory satisfying Eq. 15 for $s = 0.5$.

$\xi_{s,0}(\tilde{\varphi}_s(x))$ according to the definition of $\xi_{s,0}$. Using this as the base case, one can inductively verify that $1 - \xi_{s,j+1}(x) = \xi_{s,j}(\tilde{\varphi}_s(x))$ for all $j > 0$, using just the definitions of $\xi_{s,j}$ and $\xi_{s,j+1}$. Therefore, $\tilde{h}_s(x) = 2 - \frac{1}{2} \sum_{j=0}^{\infty} \frac{\xi_{s,j}(\tilde{\varphi}_s(x))}{2^j} = 2 - \frac{1}{2} \tilde{h}_s(\tilde{\varphi}_s(x))$. On the other hand, because $\tilde{h}_s(x) = 1 + \sum_{j=1}^{\infty} \frac{\xi_{s,j}(x)}{2^j} \geq 1$, $\varphi(\tilde{h}_s(x)) = 4 - 2\tilde{h}_s(x)$ according to the definition of φ . Thus, $\varphi(\tilde{h}_s(x)) = \tilde{h}_s(\tilde{\varphi}_s(x))$ also holds when $x \geq 1 + s$.

Figure 11 shows how fractal the conjugacy map is. This fractal conjugacy map transforms a uniform distribution in $[0, 2]$ into a fractal distribution similar to the ones plotted in section 2.4. In fact, we will show that the fractal distribution obtained by mapping a uniform distribution through \tilde{h}_s is exactly the family of distributions shown in Figure 7. We will also show that a physical solution of the tilted tent map (Eq. 15) is uniformly distributed in $[0, 2]$. Thus, for almost any physical solution of the tilted tent map, a shadowing solution of the original tent map, obtained through the conjugate map \tilde{h}_s , has a fractal distribution. Such a shadowing solution is therefore a quasi-physical solution of the tent map.

We first show that a physical solution of the tilted tent map (15) is uniformly distributed in $[0, 2]$, for any $0 \leq s < 1$. According to the ergodic theory and the properties of the SRB measure of one-dimensional chaotic systems ([20]), we only need to show that the uniform distribution is stationary under the tilted tent map. The function $\tilde{\varphi}_s$ stretches an infinitesimal region around each x by the absolute value of the derivative at x ; hence, a uniform density on an infinitesimal region around $\tilde{\varphi}_s(x)$ is reduced by the same factor. In other words, let $\tilde{\rho}(x)$ be the map of a uniform density on $[0, 2]$, through $\tilde{\varphi}_s$. Then, $\tilde{\rho}(\tilde{\varphi}_s(x)) = 0.5/|\tilde{\varphi}'_s(x)| + 0.5/|\tilde{\varphi}'_s(2-x)|$, where the two terms express the conservation of probability from the two pre-images of $\tilde{\varphi}_s$. Substituting the

piecewise constant derivative of $\tilde{\varphi}_s$ on the two intervals, $[0, 1+s)$ and $[1+s, 2]$, we have $\tilde{\rho}(\tilde{\varphi}_s(x)) = 0.25(1+s) + 0.25(1-s) = 0.5$, at all x . Hence, a uniform density of 0.5 is unaltered by mapping through $\tilde{\varphi}_s(x)$.

We now show that the conjugacy \tilde{h}_s maps a uniform distribution to a fractal. Here we use the closed forms Eqs. 16-17. If x is a random number drawn uniformly in $[0, 2]$, it has $\frac{1+s}{2}$ probability of being less than $1+s$. Thus, $\xi_{s,0}(x) = 0$ with probability $\frac{1+s}{2}$. This means, according to Eq. 16, $\tilde{h}_s(x) < 1$ with probability $\frac{1+s}{2}$: $\tilde{h}_s(x)$ is more likely to lie in the left half of the domain $[0, 2]$. Furthermore, for $j \geq 0$, $\xi_{s,j+1}(x) = \xi_{s,j}(x)$ with probability $\frac{1+s}{2}$ since each $\tilde{\varphi}_s^j(x)$ is sampled from the uniform distribution on $[0, 2]$. This probability has direct implication on $\tilde{h}_s(x)$ since, again by Eq. (16), $\xi_{s,j}$ is the j th bit in the binary representation of \tilde{h}_s – each bit repeats the previous one with probability $\frac{1+s}{2}$. For a uniformly random x , $\tilde{h}_s(x)$ is exactly the kind of initial condition we used to construct the quasi-physical solution in section 2.4, with $p = \frac{1+s}{2}$. Since this analysis holds for any x sampled uniformly on $[0, 2]$, we can conclude that the shadowing solution is almost surely nonphysical. Let $x_{s,i}, i = 0, 1, \dots$ be a solution to the tilted tent map $\tilde{\varphi}_s$ with $x_{s,0}$ chosen randomly in $[0, 1+s]$. Then, with a hundred percent probability, it is a physical solution that uniformly visits the domain $[0, 2]$. Its shadowing solution $\tilde{h}_s(x_{s,i}), i = 0, 1, \dots$, however, is a quasi-physical solution, also with a hundred percent probability. It explores $[0, 2]$ at a nonuniform frequency with a fractal probability distribution.

3.3 Are general shadowing solutions physical?

In the previous subsection, we examined a tilting perturbation to the tent map. We derived the fractal conjugacy map, and showed that a typical shadowing trajectory is exactly the quasi-physical solution we analyzed in section 2.4. This example contrasts with section 3.1, in which the shadowing solutions of a different perturbation, the scaling perturbation, are physical solutions. Which situation is more typical? When we make other types of perturbations, do we expect to observe physical or nonphysical shadowing solutions?

This section attempts to answer this question by investigating several other perturbations, the first of which scales the height, but not the width, of the tent map. The resulting “squashed” tent map, illustrated in Figure 12, has the closed form

$$\hat{\varphi}_s^{\text{sq}}(x) := \begin{cases} (2-s)x & x < 1 \\ (2-s)(2-x) & x \geq 1 \end{cases} \quad (18)$$

In Figure 13, we show side-by-side the probability distributions generated by observing a long solution (of length 10 billion) of $\hat{\varphi}_s^{\text{sq}}$ (left) and its corresponding shadowing solution (right) at two different values of s . The left column showing the probability distribution of the shadowing solution is reminiscent of the hairy probability distributions of the quasi-solutions of the tent map in section 2.4. The reader is referred to the Supplementary Material section 5.2 for a note on the computation of the shadowing solution. Note that,

Fig. 12 The “squashed” tent map (Eq. 18) for $s = 0.01, 0.05, 0.2$, and 0.5 .

unlike the tilted tent maps, the family of squashed tent maps do not have the uniform distribution as their SRB distribution, as indicated on the right column. However, the SRB distributions are not fractal. That is, the physical solutions of the squashed tent map are distributed according to a regular probability density (right column of Figure 13). But the shadowing solution, which is a true orbit of the original tent map, is distributed neither like a physical solution of the original tent map nor of the squashed tent map, as suggested by its fractal-like probability distribution.

Next we consider a second perturbation of the tent map, the *pinched* tent map, which has the following closed form

$$\hat{\varphi}_s^p(x) = \begin{cases} \frac{4x}{1 + s + \sqrt{(1 + s)^2 - 4sx}}, & x < 1 \\ \frac{4(2 - x)}{1 + s + \sqrt{(1 + s)^2 - 4s(2 - x)}}, & 2 \leq x \leq 1. \end{cases} \quad (19)$$

Again, at $s = 0$, the original tent map is recovered, and other values of s , the tent map is “pinched” by perturbations that are symmetric around $x = 1$, and zero at the end points. Figure 14 shows the pinched tent map at different s values. In Figure 15, we show the corresponding plots of the physical and shadowing distributions for the pinched tent map. From the right column, which shows the probability density of a long physical solution, we can see that the pinching perturbation changes the uniform density of the original tent map to a linearly varying density. The more pronounced the perturbation – the higher the value of s – the steeper decline in the density from left to the right. The shadowing distribution, in this case as well, appears fractal. Once again, with probability one – or, for any randomly chosen initial condition of the solution of the pinched tent map – any physical solution is shadowed by a quasi-physical solution. We consider yet another perturbation of the tent map

Fig. 13 The left column shows the empirical probability distribution of the shadowing solution for the squashed tent map at $s = 0.01$ (top) and at $s = 0.2$ (bottom). The right column shows the empirical probability distribution of a physical solution at the same two values of $s = 0.01$ (top) and $s = 0.2$ (bottom).

with the closed form

$$\hat{\varphi}_s^w(x) = \begin{cases} \frac{4x}{1 + s + \sqrt{(1+s)^2 - 4sx}}, & x < 1 \\ \frac{4(2-x)}{1 - s + \sqrt{(1-s)^2 - 4s(2-x)}}, & 2 \leq x \leq 1. \end{cases} \quad (20)$$

The above map, called the wave tent map, is illustrated in Figure 16. To construct the pinched tent map (Eq. 19), we perturbed the original tent map in such a way that the perturbations on the two halves of the interval $[0, 2]$ are mirror images of each other about the $x = 1$ line. In the wave tent map,

Fig. 14 The pinched tent map (Eq. 19) for $s = 0.01, 0.05, 0.2,$ and 0.5 .

the perturbations on the two halves are a reflection of each other about the x -axis. The wave perturbation does not noticeably alter the SRB density of the original tent map. As we show in Figure 17 (right), a solution of the wave tent map, starting from almost any point on $[0, 2]$ – a physical solution – has a density that looks almost identical to a uniform density of 0.5. On the left column of Figure 17, we observe that the distributions of the shadowing solutions corresponding to the physical solutions on the right, once again appear fractal. Hence, we can once again conclude that almost every solution, which is physical, has a corresponding shadowing solution, that is nonphysical. In this section, we have shown that the same conclusion holds for several different perturbations of the tent map. The physical solutions were distributed nonuniformly and differently from one another. However, we observed a commonality in the different perturbations: the shadowing solutions corresponding to almost every physical solution had a fractal-like probability distribution that did not resemble the distributions of the physical solutions in any case. Thus, we have shown significant evidence, through analytical constructions of perturbed tent maps in this section and section 2.4 that shadowing solutions can almost surely be nonphysical.

3.4 What about the Lorenz equation?

In order to analyze the behavior of the shadowing solutions of the Lorenz'63 system of equations, we first make a closed form approximation of the Lorenz map (see section 5.1 of the supplementary material). The reason is that except at rare parameter values, the Lorenz system does not have solutions that shadow perturbed orbits for all time, but rather only for a finite time [11]. Hence, the Lorenz map also does not have infinitely long shadowing solutions. This implies that a numerical solution of the Lorenz map approximates a true solution, as accurately as desired, only for a finite time.

Fig. 15 The left column shows the empirical distribution of the shadowing solution for the pinched tent map at $s = 0.05$ (top) and at $s = 0.2$ (bottom). The right column shows the probability distribution of a physical solution at the same two values of $s = 0.05$ (top) and $s = 0.2$ (bottom).

A closed form approximation is constructed by regression performed using long solutions of the Lorenz map (see Figure 5). The Lorenz map approximation obtained this way is illustrated in Figure 18, for variations of the parameters around their standard values of $\rho = 28, \sigma = 10, \beta = 8/3$. For a range of parameter values, it is numerically verified that the approximate Lorenz map qualitatively reproduces the behavior of the true Lorenz map. Using the approximate Lorenz map, we calculate next the shadowing solutions. The empirical densities computed from long shadowing solutions, of length 10 billion, are shown in the left column of Figure 19 at three different sets of parameter values, which are also different from the standard values of $\rho = 28, \sigma = 10,$

Fig. 16 The wave tent map (Eq. 20) for $s = 0.01, 0.05, 0.2,$ and 0.5 .

and $\beta = 8/3$. In the top and middle row, $\rho = 29$ and $\rho = 30$ are used, respectively, while the other two parameters are retained at their standard values. In the bottom row, only the parameter β is perturbed from the standard values; $\beta = 10/3$ is used. On the right column, we plot the densities of physical solutions, the SRB distribution, at the set of parameters corresponding to each row. We again notice that, while the physical distributions are smooth, the shadowing solutions have a rough distribution that appears to have hair-like patterns. Thus, we draw the same conclusion in the Lorenz map as in the various perturbations of the tent map treated in section 3.3: shadowing solutions do not have the same distribution as a typically observed solution of the governing equation. In other words, shadowing solutions may be nonphysical.

4 Discussion and outlook

Through a rigorous counter-example, we show that shadowing can lead to non-physical solutions. This has a troubling implication for numerical simulations of chaotic governing equations. Through the examples in this paper, it is clear that a numerical solution, satisfying a governing equation perturbed due to numerics, is not expected to be shadowed by a physical solution of the real governing physics. What is, if any, the relation of a numerical solution, such as DNS of turbulent flows, to the true physics? For an $\mathcal{O}(10^{-18})$ perturbation (due to numerical error), we may get completely different statistics from a true, physical solution. How then can we trust numerical solutions when they are not guaranteed to share the long-term statistical behavior of the governing equation? We conclude with an example that illustrates a counterintuitive feature of some chaotic systems: a small perturbation to the governing equation can significantly change the statistics/long-term behavior of its physical solutions. We construct yet another perturbed tent map – the *plucked* tent map – in which an oscillatory perturbation is introduced (see Supplementary

Fig. 17 The left column shows the empirical distribution of the shadowing solution for the wave tent map (Eq. 20) at $s = 0.05$ (top) and at $s = 0.2$ (bottom). The right column shows the probability distribution of a physical solution at the same two values of $s = 0.05$ (top) and $s = 0.2$ (bottom).

Material section 5.3 for the map equation). In Figure 20, we show that the magnitude of the oscillatory perturbation is controlled by parameters s and n , and its frequency is controlled by the parameter n ; at $s = 0$, we recover the original tent map at all n . The stationary probability distributions – computed empirically over a trajectory of length 10 billion – at $s = 0.1$, are shown in Figure 21. On the top-left, $n = 0$, and there is already a marked asymmetry developed in the probability distribution compared to the uniform distribution seen at $s = 0, n = 0$. The figure shows that by increasing n , despite the fact that the magnitude of the perturbation becomes smaller with n , we see a dramatic change in the appearance of the stationary probability distribution:

Fig. 18 The left, center, and right plots show the effect of the parameters σ , ρ , and β on the Lorenz map, respectively. In the left plot, the blue and orange lines represent $\sigma = 10$ and 12 , respectively, while $\rho = 28$ and $\beta = 8/3$. In the center plot, the blue and orange lines represent $\rho = 28$ and 30 , respectively, while $\sigma = 10$ and $\beta = 8/3$. In the right plot, the blue and orange lines represent $\sigma = 8/3$ and $10/3$ respectively, while $\sigma = 10$ and $\rho = 28$.

we observe an apparent fractal distribution reminiscent of that of the quasi-physical solutions in section 3.3. By construction of the map (Supplementary Material section 5.3), the nonuniformities of the probability distribution at $n = 0$ are transferred to smaller and smaller scales, as n is increased. It is worth emphasizing that these remarkable changes in the physical distribution are effected (as shown in the right hand side of Figure 21) with a tiny perturbation – the perturbed map at $n = 10$, and the original tent map appear indiscernible on the bottom-right of Figure 20.

In view of the plucked tent map, we can question further the validity of numerical solutions. Can numerical play the role of the plucking perturbation to the governing equation? That is, can numerical solutions represent slight perturbations to the governing equations that nevertheless exhibit drastically different statistics from that of the ensemble? Uniformly hyperbolic dynamical systems exhibit *linear response* ([15][2]) by which small parameter perturbations lead to small changes in statistics, which can be expanded as Taylor series around the reference parameter value. But, uniform hyperbolicity is a mathematical idealization, and although some physical systems have been observed to behave as if they were uniformly hyperbolic [7], a violation of uniform hyperbolicity is more likely [18][10]. Sauer [16] has shown examples in which numerical error due to computation in double-precision floating point arithmetic causes significant change in the stationary probability distribution on the attractor. The plucked tent map adds to this list of examples by exhibiting a mechanism to produce an extreme non-smooth response (Supplementary Material section 5.3).

Both the nonphysicality of shadowing solutions, and the existence of extremely non-smooth statistical response, undermine the validity of using shadowing for sensitivity analysis of statistics [17][14][12]. When the goal is to compute derivatives of ensemble averages, where the ensemble is distributed according to the physical measure, i.e., the SRB measure, shadowing-based methods can give wrong results. This is because shadowing-based methods compute the sensitivities of ensemble statistics along shadowing solutions, but

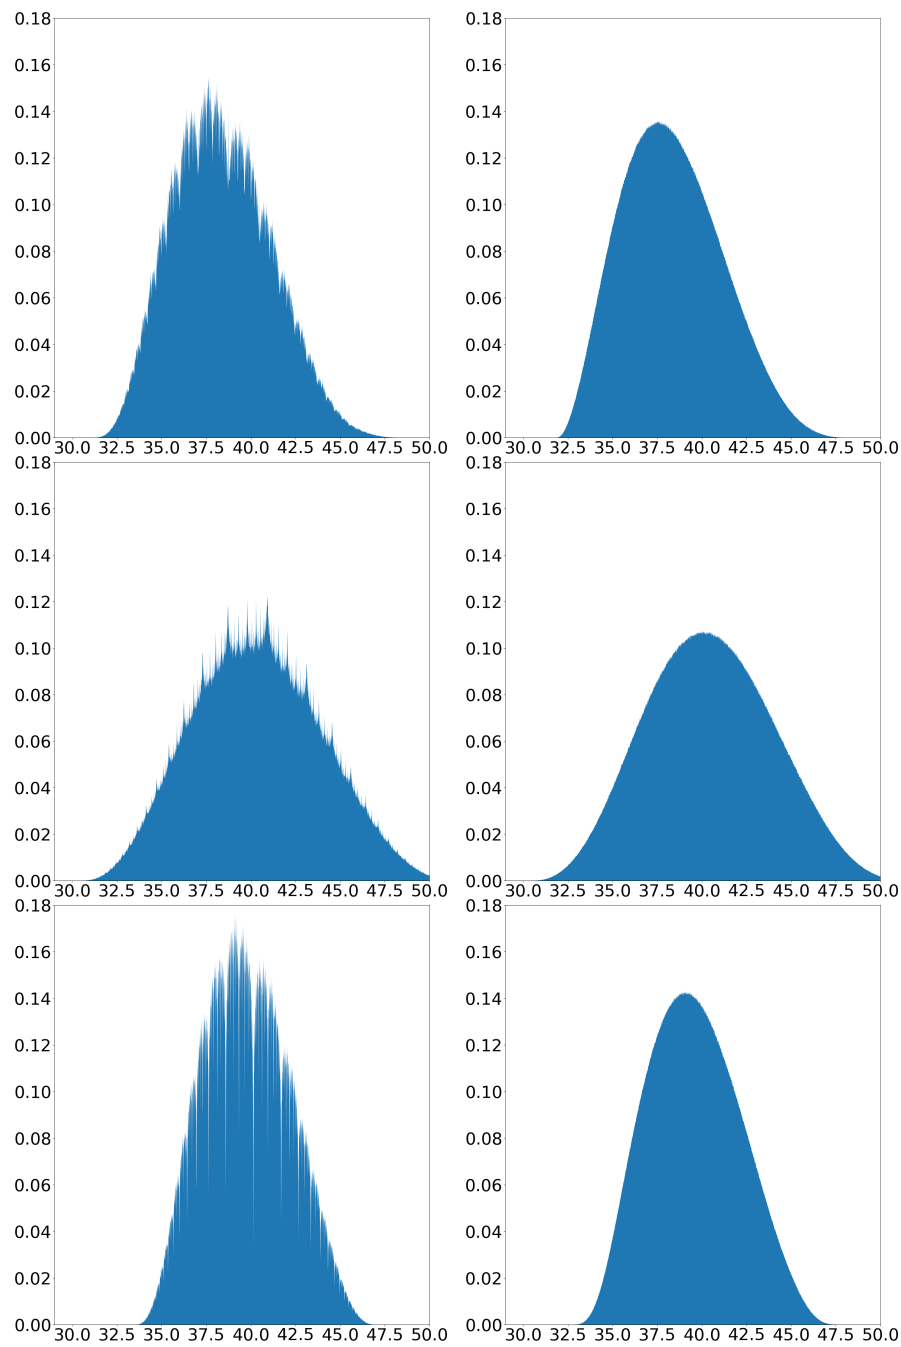

Fig. 19 The left column shows the empirical distribution of the shadowing solution of the Lorenz map at $\rho = 28$ (top row), $\rho = 29$ (middle row), and $\beta = 10/3$ (bottom row). The right column shows the probability distribution of the corresponding physical solution. In each case, the parameters not mentioned are held at their standard values of $\rho = 28$, $\sigma = 10$, $\beta = 8/3$.

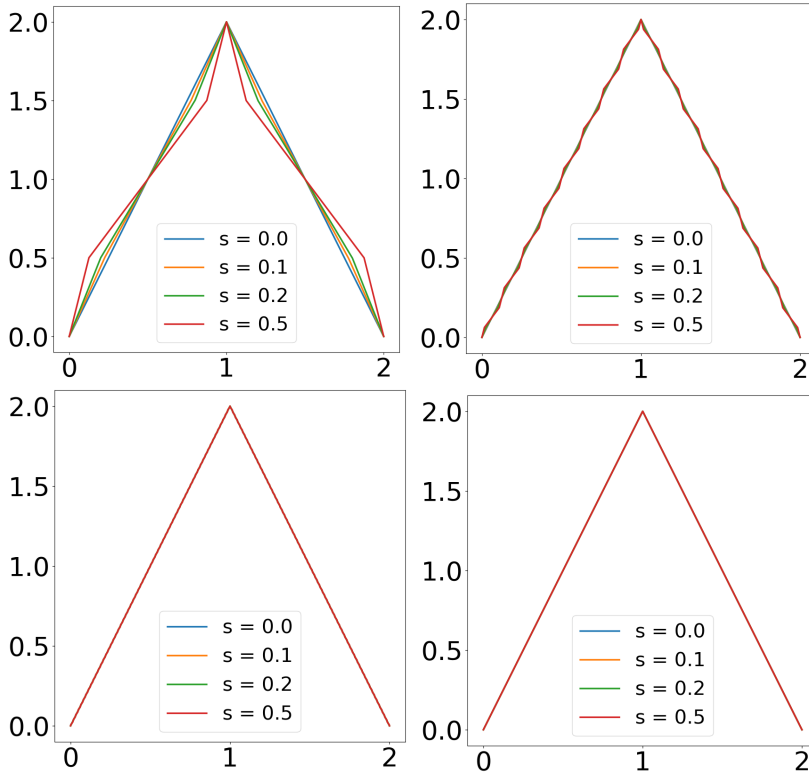

Fig. 20 The plucked tent map shown at different values of s and $n = 0$ (top-left), $n = 3$ (top-right), $n = 6$ (bottom-left), and $n = 10$ (bottom-right). The original tent map is at $s = 0$ on each plot.

these may not be physical solutions that reproduce ensemble statistics. The error in shadowing sensitivities has been observed before and appropriately attributed as “ergodicity breaking error” [3] [13]. Violations of smooth response, like in the plucked tent map, have an immediate implication for shadowing sensitivities as well. In particular, if perturbed solutions are shadowed by physical solutions for all time, the change in the statistics of the perturbed solutions must be small. In other words, the physicality of shadowing predicts that there cannot be a large change in statistics due to small parameter perturbations; the reality is that, as illustrated by the plucked tent map, the effect of small parameter changes on the statistics can be drastic.

In this paper, we have constructed several counterexamples that dispel the notion that shadowing solutions are physical solutions, i.e., that their statistical distribution is the same as that typically observed for almost every solution of a governing equation. The existence of long-time shadowing solutions [8] has historically been used to address the issue of whether numerical simulations, which are perturbed solutions, represent the true physics implied by the governing equation. In light of the evidence in this paper, we must

Fig. 21 The effect of increasing n on the probability distribution associated to the plucked tent map. The stationary probability distribution of the plucked tent map at $s = 0.1$ and $n = 0$ (top-left), $n = 3$ (top-right), $n = 6$ (bottom-left) and $n = 10$ (bottom-right).

reopen this issue. Even when numerical simulations are shadowed by a true solution in that the difference between them is small for a long time, this shadowing solution may not represent the long-term or ensemble behavior of the physical system. The nonphysicality of shadowing solutions also indicates that shadowing-based methods [17] can lead to incorrect values of sensitivities of statistics to parameter changes.

5.1 Approximation of the Lorenz Map

The motivation for approximating the Lorenz map is that a closed form expression for the map is necessary for our numerical shadowing procedure. In a small region around the cusp, we approximate the map using an exponential function. The tails on both sides are fitted with a sum of a cubic polynomial and a rational function. Thus, the approximate Lorenz map has the following

Fig. 22 L: the blue and orange lines are the Lorenz map at the standard parameters, and the dotted black lines indicate the approximate Lorenz map (Table 2). R: the regression error is shown as a function of z

closed form expression:

$$\varphi(x) = \begin{cases} z_{\max} - f_R(x - z_{\text{sep}}) & x > z_{\text{sep}} \\ z_{\max} - f_L(z_{\text{sep}} - x) & x \leq z_{\text{sep}} \end{cases} \quad (21)$$

where

$$f_R(y) = \left((1000y)^p + \sum_{n=0}^3 p_{R,n} y^n + \frac{a_{R,0} + a_{R,1}y}{\sum_{n=0}^3 b_{R,n} y^n} \right), \quad (22)$$

and,

$$f_L(y) = \left((1000y)^p + \sum_{n=0}^3 p_{L,n} y^n + \frac{a_{L,0} + a_{L,1}y}{\sum_{n=0}^3 b_{L,n} y^n} \right). \quad (23)$$

The location of the cusp is denoted z_{sep} (in which “sep” stands for *separation*), and the maximum and minimum values encountered in the Lorenz map iterates are denoted z_{\max} and z_{\min} , respectively. The exponent of the cusp is denoted p . The coefficients of the cubic polynomial modelling the left (right) tail are denoted $p_{L,n}, n = 0, 1, 2, 3$ ($p_{R,n}, n = 0, 1, 2, 3$). The coefficients of the numerator and denominator of the rational function modelling the left (right) tail are denoted $a_{L,0}, a_{L,1}$ ($a_{R,0}, a_{R,1}$) and $b_{L,n}, n = 0, 1, 2, 3$ ($b_{R,n}, n = 0, 1, 2, 3$), respectively. The values of these coefficients are obtained by regression on the map at standard parameters are shown in the table below. As shown in Figure 22, the fit obtained matches the Lorenz map closely.

5.2 Computing shadowing solutions

In general, to numerically compute the shadowing solutions, one could use existing methods such as the least squares shadowing method [17]. However, since these maps are all one-dimensional chaotic systems that have in common non-invertibility with two inverse *branches*, we devise a simpler approach. The map φ_s in this section refers to any of the perturbations of the tent map (section 3.3) or the Lorenz map. Suppose we are given a perturbed solution $x_n, n = 0, 1, \dots, N$ that we must compute a shadow of. The shadowing solution, $y_n, n = 0, 1, 2, \dots, N$ must a) satisfy the governing equation: $y_{n+1} = \varphi_s(y_n)$ and b) lie close to the given perturbed solution at all times up to N , i.e., $|x_n - y_n| < \epsilon$, for some $\epsilon > 0$, for all $n \leq N$. Suppose we set $y_0 = x_0$, the difference $y_1 - x_1$ will amplify on further iterations under φ_s for any perturbed solution. On the other hand, backward iteration of the map is contracting, and thus we set $y_N = x_N$ and proceed backward in time to construct a solution of φ_s , noting that any difference that emerges at a given time n will be made smaller starting at $n - 1$. Each point has two pre-images under φ_s , and thus there are two possible choices for y_{N-1} , each lying in one of two fixed sub-intervals separated by the cusp of φ_s . Due to the contraction of errors backward in time, as long as we choose a pre-image in the same subinterval as the perturbed solution, we are guaranteed to approximate a shadowing solution. Marching backward by choosing at each step, the pre-image y_n in the same subinterval as x_n , y_n approximates the shadowing solution better as n decreases. Thus, the procedure to find a shadowing solution simply reduces to solving for a backward trajectory (specifically one among the possible 2^N), starting at a given final condition x_N .

Hence, it is clear that all we need is the inverse of φ_s , which is propagated backward by choosing the same *branch* of the inverse as x_n at time n . This logic is implemented for each map of section 3.3 in the function `shadow` that can be found in the files named for each map (for example, the shadowing solution of the pinched tent map can be found by executing the `shadow` function of `tent_shadow/tent_shadow_pinched.py`). These functions use the analytical inverses of the maps, which are easy to derive for the tent map perturbations

of section 3.3. For the Lorenz map, we use Newton's method to solve for the inverse, and this is implemented in the file `lorenz_map/shadow.py`. Note that we need a closed form expression of the map, for the Newton's method, and this is indeed the reason why we approximate the map, as described in section 5.1.

5.3 The *plucked* tent map

We provide a recursive definition of the plucked tent map, which is illustrated at different values of n and s in Figure 20. First we define a function $f_s(x)$, which creates a bend in the tent map that increases with s , around $((1 - s)/2, 1)$:

$$f_s(x) = \min\left(\frac{2x}{1-s}, 2 - \frac{2(1-x)}{1+s}\right), \quad x < 1 \quad (24)$$

$$(25)$$

Then, we introduce oscillations using repetitions of the above map within the unit interval,

$$o_s(x) = \begin{cases} f_s(2x)/2, & x < 0.5 \\ 2 - f_s(2 - 2x)/2, & x \geq 0.5. \end{cases} \quad (26)$$

We can modulate the frequency or repetitions – proportional to n – of the oscillations through

$$\lambda_{s,n}(x) = \frac{o_s(2^n x - \lfloor 2^n x \rfloor)}{2^n} + 2 \frac{\lfloor 2^n x \rfloor}{2^n}, \quad (27)$$

where $\lfloor x \rfloor$ is the greatest integer less than or equal to x . Finally, the plucked tent map is defined as the above function in the unit interval, and as its reflection about $x = 1$, in the interval $[1, 2)$.

$$\varphi_{s,n}(x) = \min(\lambda_{s,n}(x), \lambda_{s,n}(2 - x)), \quad 0 < x < 2. \quad (28)$$

Recall that our motivation is to construction a slight perturbation of the tent map whose stationary probability distribution is not just non-uniform (e.g. like the other tent map perturbations of section 3.3) but in which the nonuniformity can be controlled, and made skewed as desired. Thus, we choose to construct a base perturbation of the tent map, $\min(o_s(x), o_s(2 - x))$ – which is also obtained by setting $n = 0$ in $\varphi_{s,n}$ – in which an asymmetry is produced in the probability distribution (top-left of Figure 21). Upon repeating, with appropriate scaling, the oscillation o_s , the frequency of which is controlled by n , we obtain $\varphi_{s,n}$, as indicated by Eq. 27-28. Thus, the asymmetric probability distribution, through this process of scaled repetition, acquires an apparent fractal-like structure seen on increasing n , as shown on the bottom row of Figure 21.

One way to see the asymmetry in the probability distribution about $x = 1$, at $n = 0$, is to construct a Markov chain with nodes 00, 01, 10, and 11, that indicate the subintervals $(0, 0.5)$, $[0.5, 1)$, $[1, 1.5)$ and $[1.5, 2)$, respectively. From Eq. 28, we can see that the application of $\varphi_{s,0}$ yields the following transition matrix:

$$\begin{bmatrix} (1-s)/2 & (1+s)/2 & 0 & 0 \\ 0 & 0 & (1+s)/2 & (1-s)/2 \\ 0 & 0 & (1+s)/2 & (1-s)/2 \\ (1-s)/2 & (1+s)/2 & 0 & 0 \end{bmatrix}.$$

The stationary probability distribution of this Markov chain, which is the left eigenvector of the transition matrix corresponding to eigenvalue 1, is $[(1-s)^2/2, (1-s^2)/2, (1+s)^2/2, (1-s^2)/2]^T$. One can verify this is consistent with the top-left of Figure 21 for $\varphi_{0.1,0}$. Clearly, the time spent by an infinitely long physical solution in the second quarter interval, $[0.5, 1]$ is 1.2 times the time spent in the first quarter, $[0, 0.5]$; the time spent in the third quarter $[1, 1.5]$ is 1.5 times that spent in the first quarter. This nonuniformity is more pronounced with increasing s . For instance, at $s = 0.5$, the left subinterval, $[0, 1)$, is three times less likely to be visited by a long trajectory compared to $[1, 2)$.

But, as mentioned in the main text, even a small perturbation – very small s – is sufficient to trigger a remarkable variation in the statistics. This is because this particular construction transfers the nonuniformities in the probability distribution at larger scales to smaller scales, with increasing n . The nonuniformity at the largest scale of half intervals is retained at higher values of n . That is, the probability of visiting the interval $[0, 1]$ is the same: $(1-s)$, at all n . However, with increasing n , the nonuniformity emerges within smaller subintervals, due to the construction of the map that relies on repeating the behavior at larger scales at smaller scales (Eq. 27). This repetitive construction is responsible for the apparent fractal structure of the probability distribution (Figure 21, bottom-right). The scripts that generate the plucked tent map and its stationary probability distributions can be found under `tent_sens_stat`.
