Karol Węgrzycki‡

Abstract

We revisit the classic task of finding the shortest tour of n points in d -dimensional Euclidean space, for any fixed constant $d \geq 2$. We determine the optimal dependence on ε in the running time of an algorithm that computes a $(1 + \varepsilon)$ -approximate tour, under a plausible assumption. Specifically, we give an algorithm that runs in $2^{\mathcal{O}(1/\varepsilon^{d-1})} n \log n$ time. This improves the previously smallest dependence on ε in the running time $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon^{d-1})} n \log n$ of the algorithm by Rao and Smith (STOC 1998). We also show that a $2^{\mathcal{O}(1/\varepsilon^{d-1})} \text{poly}(n)$ algorithm would violate the Gap-Exponential Time Hypothesis (Gap-ETH).

Our new algorithm builds upon the celebrated quadtree-based methods initially proposed by Arora (J. ACM 1998), but it adds a new idea that we call *sparsity-sensitive patching*. On a high level this lets the granularity with which we simplify the tour depend on how sparse it is locally. We demonstrate that our technique extends to other problems, by showing that for Steiner Tree and Rectilinear Steiner Tree it yields the same running time. We complement our results with a matching Gap-ETH lower bound for Rectilinear Steiner Tree.

1 Introduction

The Euclidean Traveling Salesman Problem (EUCLIDEAN TSP) is to find a round trip of minimum length for a given set of n points in d -dimensional Euclidean space. Its simple statement and clear applicability make the problem very attractive, and work on it has been immensely influential and inspirational. In particular, the Gödel-prize-winning approximation schemes due to Arora [1] and Mitchell [48] are among the most prominent results in approximation algorithms. Because of their elegance, they serve as evergreens in graduate algorithms courses, textbooks on approximation algorithms or optimization [57, 58, 40], and more specialized textbooks [34, 49].

After the publication of these results, an entire research program with many strong results consisting of improvements, generalizations and different applications of the methods from [1, 48] was conducted by many authors (see e.g., the survey [2]). The technique is now known to be useful for a whole host of geometric optimization problems (see the related work paragraph).

The most natural goal within this research direction is to improve the running times to be *optimal*, i.e. to improve and/or provide evidence that further (significant) improvements do not exist. In the last 25 years, only two such results were obtained in \mathbb{R}^d :

1. Rao and Smith [52] used geometric spanners to improve the $n(\log n)^{\mathcal{O}(1/\varepsilon)^{d-1}}$ time approximation scheme of Arora [1] to run in only $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon)^{d-1}} \cdot n \log n$ time.¹
2. Bartal and Gottlieb [7] gave a $2^{(1/\varepsilon)^{\mathcal{O}(d)}} \cdot n$ time algorithm in the real-RAM model with atomic floor or mod operators. They give a truly linear algorithm in terms of n , however the dependence on ε is worse than the algorithm of Rao and Smith [52].

While these results determine the optimal² dependence on n , they do not yet settle the much faster growing exponential dependence on ε . This is in contrast with the status of our knowledge of the complexity of many other optimization problems: In the last decade a powerful toolbox for determining (conditionally) optimal exponential running times has been developed.

In the context of TSP in d -dimensional Euclidean space (henceforth denoted by \mathbb{R}^d), this modern research direction culminated in an exact algorithm with a running time of $2^{\mathcal{O}(n^{1-1/d})}$, which was matched by a lower bound of $2^{\Omega(n^{1-1/d})}$ [20] under the Exponential Time Hypothesis (ETH).

In the context of approximation schemes for TSP, Klein [38] improved algorithms for the unweighted planar case from [30, 3] with a $2^{\mathcal{O}(1/\varepsilon)}n$ time approximation scheme. Subsequently, Marx [47] showed that the dependence on ε in Klein’s algorithm is conditionally near-optimal. The tight exponential dependency of ε in approximation schemes was also obtained in a plethora of other problems, such as MAXIMUM INDEPENDENT SET in planar graphs [6] and a scheduling problem [15] (see, e.g., [26] for a survey).

Given the modern trend of fine-grained algorithm research and the prominence of the discussed approximation schemes for EUCLIDEAN TSP, our goal suggests itself:

Goal: Conclude the research on approximation schemes for Euclidean TSP with a conditionally optimal algorithm.

¹For dimension d , [52] claimed $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon)^{d-1}} n + T_{\text{spanner}}(n, \varepsilon)$ time, where $T_{\text{spanner}}(n, \varepsilon)$ is the spanner computation time. See [49, Chapter 19] for a more detailed description of an $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon^{d^2})} n \log n$ time algorithm.

²Depending on the model of computation $\Omega(n \log n)$ time is required [19].

1.1 Our contribution

In this work, we achieve this goal for EUCLIDEAN TSP and (RECTILINEAR) STEINER TREE in \mathbb{R}^d and give algorithms with a Gap-ETH-tight dependence on ε . Our main result reads as follows.

Theorem 1.1 (Main result). *For any integer $d \geq 2$, there is a randomized $(1 + \varepsilon)$ -approximation scheme for EUCLIDEAN TSP in \mathbb{R}^d that runs in $2^{\mathcal{O}(1/\varepsilon^{d-1})}n + \text{poly}(1/\varepsilon)n \log(n)$ time. Moreover, this cannot be improved to a $2^{o(1/\varepsilon^{d-1})} \cdot \text{poly}(n)$ time algorithm, unless Gap-ETH fails.*

Thus, we improve the previously best $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon^{d-1})}$ dependence of ε in the running time of [52] to $2^{\mathcal{O}(1/\varepsilon^{d-1})}$. Note that here and in the sequel, our big- \mathcal{O} notation hides factors that depend only on d since it is assumed to be constant. Our running times are double exponential in the dimension d , which is expected because of Trevisan’s lower bound [55].

Theorem 1.1 improves the running time dependence on ε all the way to conditional optimality: we show that an EPTAS with an asymptotically better dependence on ε in the exponent is not possible under Gap-ETH, for constant dimension d . Note that our algorithms can be derandomized at the cost of an extra n^d factor in the running time, which maintains conditional optimality in terms of ε .

Our lower bound for EUCLIDEAN TSP is derived from a construction for HAMILTONIAN CYCLE in grid graphs [21], in combination with Gap-ETH [23, 46] (see Section 6).

Our new algorithmic techniques enable us to improve approximation schemes for another fundamental geometric optimization problem: the RECTILINEAR STEINER TREE and EUCLIDEAN STEINER TREE problems.

Theorem 1.2. *For any integer $d \geq 2$, there is a randomized $(1 + \varepsilon)$ -approximation scheme for EUCLIDEAN STEINER TREE and RECTILINEAR STEINER TREE in \mathbb{R}^d that runs in $2^{\mathcal{O}(1/\varepsilon^{d-1})}n + \text{poly}(1/\varepsilon)n \log(n)$ time. Moreover, the algorithm for RECTILINEAR STEINER TREE cannot be improved to a $2^{o(1/\varepsilon^{d-1})} \cdot \text{poly}(n)$ time algorithm, unless Gap-ETH fails.*

This directly improves state-of-the-art algorithms by Rao and Smith [52] and Bartal and Gottlieb [29] in all regimes of parameters n and ε .

The lower bound for RECTILINEAR STEINER TREE requires new ideas since there is no known ETH-based lower bound for the exact version of the problem. Our construction is based on a reduction from GRID EMBEDDED CONNECTED VERTEX COVER from [21] and a combination of gadgets proposed by [28] (see Section 6). We leave it as an open problem to give a matching lower bound on our algorithm for EUCLIDEAN STEINER TREE.

1.2 The existing approximation schemes and their limitations

The approximation scheme from Arora [1] serves as the basis of our algorithm, and we assume that the reader is familiar with its basics (see [58, 57] for a comprehensive introduction to the approximation scheme). In this section, we consider $d = 2$ for simplicity.

In a nutshell, Arora’s strategy in the plane is first to move the points to the nearest grid points in an $L \times L$ grid where $L = \mathcal{O}(n/\varepsilon)$. This grid is subdivided using a hierarchical decomposition into smaller squares (*a quadtree*, see definition in Section 2), where on each side of a square $\mathcal{O}((\log n)/\varepsilon)$ equidistant *portals* are placed. Arora proves a *structure theorem*, which states that there is a tour of length at most $(1 + \varepsilon)$ times the optimal tour length that crosses each square boundary $\mathcal{O}(1/\varepsilon)$ times and only through portals. This structure theorem is based on a *patching procedure*, which iterates through the cells of the quadtree (starting at the smallest cells) and patches the tour such that the resulting tour crosses all cell boundaries only $\mathcal{O}(1/\varepsilon)$ times and only at portals, and it does it in

such a way that the new tour is only slightly longer. While such a promised slightly longer tour does not necessarily exist for a fixed quadtree, a randomly shifted quadtree works with high probability. The algorithm thus proceeds by picking a randomly shifted quadtree and by performing a dynamic programming algorithm on progressively larger squares and the bounded set of possibilities in it to find a patched tour.

The first improvement to Arora’s algorithm was achieved by Rao and Smith [52] (see [49, Chapter 16] for a modern description of their methods). Recall that Arora placed equidistant portals. Rao and Smith’s idea is to use *light spanners* to "guide" the approximate TSP tour and select portals on the boundary not uniformly. They show that it is sufficient to look for the shortest tour within a spanner, or more precisely, they patch the given spanner such that the resulting graph has $1/\varepsilon^{\mathcal{O}(1)}$ crossings with each quadtree cell, while still containing a $(1 + \varepsilon)$ -approximate tour. Similarly to Arora’s algorithm, it is sufficient to consider tours that cross each square boundary $\mathcal{O}(1/\varepsilon)$ times, but now the number of portals is $(1/\varepsilon)^{\mathcal{O}(1)}$. Consequently, the algorithm of Rao and Smith needs only $((1/\varepsilon)^{\mathcal{O}(1)})^{\mathcal{O}(1/\varepsilon)} = 2^{\mathcal{O}((1/\varepsilon)\cdot\log(1/\varepsilon))}$ subsets of portals to consider for each square in their corresponding dynamic programming algorithm.

Why do known techniques fail to get a better running time? To get the dependence on ε in the running time down to $2^{\mathcal{O}(1/\varepsilon)}$, the bottleneck is to get the number of candidate sets of where the tour crosses a cell boundary down to $2^{\mathcal{O}(1/\varepsilon)}$.³

One could hope to improve Arora’s algorithm by decreasing the number of portals from $\mathcal{O}(\log n/\varepsilon)$ to $\mathcal{O}(1/\varepsilon)$, but this is not possible: the structure theorem would fail even if the optimal tour is a rotated square with equally distributed points on its sides.

Another potential approach would be to improve the spanners and the spanner modification technique of Rao and Smith to get a graph that contains a $(1 + \varepsilon)$ -approximate tour, while having only $\mathcal{O}(1/\varepsilon)$ crossings on each side of each square. Such an improvement seems difficult to accomplish as even with Euclidean spanners [43] of optimal lightness or the more general *Euclidean Steiner spanners* [44], one cannot get the required guarantee. Le and Solomon [43] gave a lower bound of $\Omega(1/\varepsilon)$ on the lightness of Euclidean Steiner Spanners in $d = 2$, which was matched very recently by Bhore and Tóth [9]. Even with that optimal Steiner spanner, the patching method of Rao and Smith yields a guarantee of only $\tilde{\mathcal{O}}(1/\varepsilon^2)$ crossings per square and it is not clear if one can even get $\mathcal{O}(1/\varepsilon^{1.99})$ potential crossings per square.

1.3 Our technique: Sparsity-Sensitive Patching

We introduce a new patching procedure. Slightly oversimplifying and still focusing on 2 dimensions, it iterates over the cells of the quadtree and processes a cell boundary as follows:

Sparsity-Sensitive Patching: For a cell boundary that is crossed by a tour at $1 < k \leq \mathcal{O}(1/\varepsilon)$ crossings, modify the tour by mapping each crossing to the nearest portal from the set of g equidistant portals. Here g is a granularity parameter *that depends on k* as $g = \Theta(1/(\varepsilon^2 k))$.

See Figure 1 for an illustration. This can be used in combination with dynamic programming to prove the algorithmic part of Theorem 1.1 since it produces a tour for which the number of possibilities for the set of crossings of the tour with a cell boundary is $\sum_k \binom{\mathcal{O}(1/(\varepsilon^2 k))}{k} = 2^{\mathcal{O}(1/\varepsilon)}$ (see Claim 3.4).

³To properly solve all required subproblems, the dynamic programming algorithm also needs to consider all matchings on such a candidate set, but this can be circumvented by invoking the rank-based approach from [10] that allows one to restrict attention to only $2^{\mathcal{O}(1/\varepsilon)}$ matchings as long as the candidate set has cardinality $\mathcal{O}(1/\varepsilon)$.

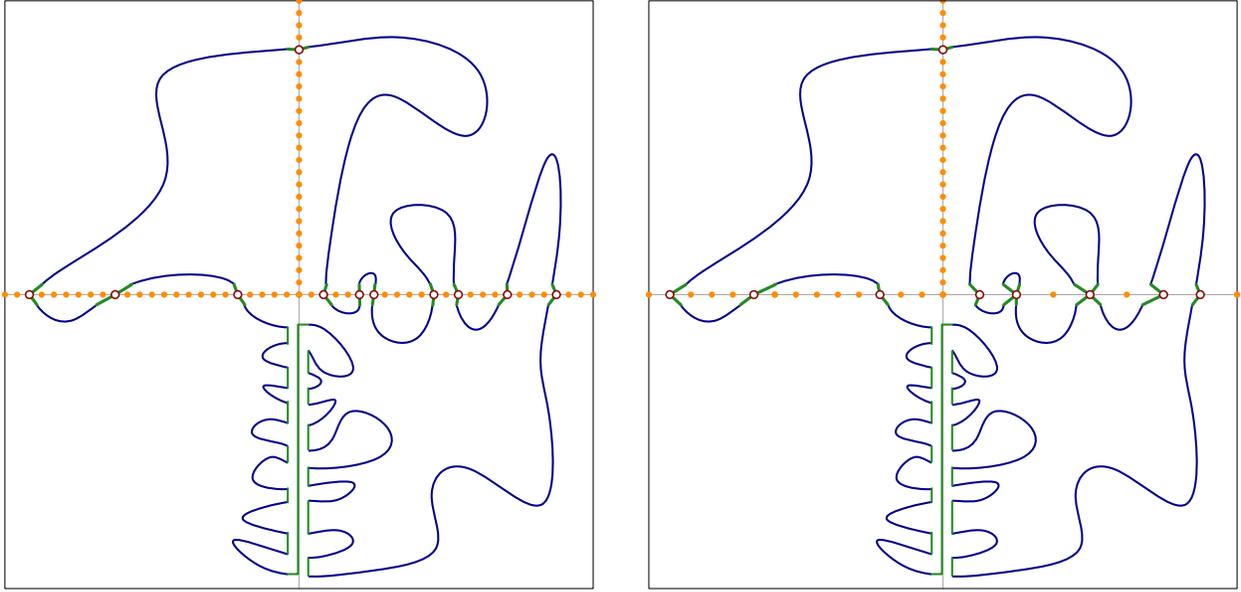

Figure 1: On neighboring cells of the quadtree, one must ensure that the tour crosses at most $1/\varepsilon$ times, chosen from a limited set of portals. Left: Arora’s structure theorem snaps the tour to one of $\mathcal{O}(\frac{\log n}{\varepsilon})$ equally spaced portals. Right: The number of possible portal locations depends on the number of crossings; the fewer portals are used, the more precisely they are chosen. Both techniques use the *Patching Lemma* between the bottom two cells as their shared boundary is crossed more than $1/\varepsilon$ times.

One notable aspect of our technique is that it allows to get running times faster than the ones of Arora [2], but without the use of spanners, see Remark 4.7.

Bounding the patching cost. Our Sparsity-Sensitive procedure may seem quite similar to Arora’s patching procedure, so one may wonder why previous improvements to Arora’s procedure overlooked it. The reason is that our procedure is slightly counter-intuitive, as it increases precision when the tour is already sparse, and it requires a subtle analysis of the patching cost. This proof is the main contribution of this paper.

We will informally describe how we achieve this next. Similar to the patching cost analysis of Arora’s patching procedure, our starting point is that the total number of crossings that an optimal tour π will have with all horizontal and vertical lines aligned at integer coordinates is proportional to the total weight of the tour (Lemma 2.1). Since we can afford an additional cost of $\varepsilon \cdot \text{wt}(\pi)$, it is sufficient to show that each crossing incurs, in an amortized sense, at most $\mathcal{O}(\varepsilon)$ patching cost.

Let $\text{PC}(k, \ell)$ be the patching cost of a horizontal quadtree-cell side of length ℓ with k crossings. Since we connect each crossing to a portal that is at most ℓ/g distance away, and the total patching cost is never greater than $\mathcal{O}(\ell)$ (since we can just “buy” an entire line, as illustrated in the bottom of Figure 1), we obtain $\text{PC}(k, \ell) \leq \mathcal{O}(\min\{\ell, k\ell/g\})$. The amortized patching cost per crossing is then

$$\frac{\text{PC}(k, \ell)}{k} = \mathcal{O}\left(\frac{\min\{\ell, k\frac{\ell}{g}\}}{k}\right) = \mathcal{O}\left(\frac{\ell}{k} \min\{1, (k\varepsilon)^2\}\right), \quad (1)$$

and this is maximized when $k = 1/\varepsilon$, for which it is $\varepsilon\ell$.

Because we consider a random shift of the quadtree, a crossing of π with a fixed horizontal line h will end up in a cell side of length $L/2^i$ with probability at most $2^{i-1}/L$, for each $0 \leq i \leq \log L$

(Lemma 2.3). Letting $\alpha_i(x)$ be the (amortized) patching cost due to the crossing x on line h if h has level i , x incurs

$$\sum_{i=0}^{\log L+1} \frac{2^{i-1}}{L} \cdot \alpha_i(x) \tag{2}$$

amortized patching cost in expectation. Naively applying (1) for each i to get $\alpha_i \leq \varepsilon L/2^i$ and putting this bound into (2), gives an undesirably high cost of $\mathcal{O}(\varepsilon \log L)$.

To get this cost down to $\mathcal{O}(\varepsilon)$, we need to use a more refined argument. We exploit the fact that the bound $\alpha_i(x) \leq \varepsilon L/2^i$ is tight only for a single $i = i^*$ in the worst case. Subsequently, we show that for levels above i^* we have a geometrically decreasing series of costs, which will demonstrate that the cost in (2) is bounded by $\mathcal{O}(\varepsilon)$. Since we amortize the cost by the length of the tour inside a cell, we should increase the precision as we move to levels below i^* . Intuitively, for level $i^* + 1$ the number of intersections is halved, while the tour length (which should be proportional to the area of the cell) is divided by four. This suggests that the number of portals should be inversely proportional to the number of crossings.

In our proof we formalize this with a charging scheme based on the distance of the crossing to the next crossing on the horizontal line.

1.4 More related work

The framework of Arora [1] and Mitchell [48] was employed for several other optimization problems in Euclidean space such as STEINER FOREST [11], k -CONNECTIVITY [17], k -MEDIAN [39, 5], SURVIVABLE NETWORK DESIGN [18]. We hope our techniques will also find some applications in them.

The original results from [1, 48] were also applied or generalized to different settings. The state-of-the-art for the TRAVELING SALESMAN PROBLEM in planar graphs is now very similar to the Euclidean case. In [31], the authors gave the first PTAS for TSP in planar graphs, which was later extended by [4] to weighted planar graphs. Klein [38] proposed a $2^{\mathcal{O}(1/\varepsilon)}n$ time approximation scheme for TSP in unweighted planar graphs, which later was proven by Marx [47] to be optimal assuming ETH. Klein [37] also studied a weighted subset version of TSP that generalizes the planar Euclidean case and gave a PTAS for the problem.

The literature then generalized the metrics much further. Without attempting to give a full overview, some prominent examples are the algorithms in minor free graphs [22, 12, 42], algorithms in doubling metrics [8, 13], and algorithms in negatively curved spaces [41], each of which is at least inspired by the result of Arora [1] and Mitchell [48].

Recently, Gottlieb and Bartal [29] gave a PTAS for STEINER TREE in doubling metrics. Moreover, they proposed a $2^{(1/\varepsilon)^{\mathcal{O}(d^2)}} n \log n$ time algorithm for STEINER TREE in d -dimensional Euclidean Space with a novel construction of banyan.

There is also a vast literature concerning Euclidean Spanners (see the book [49] for an overview). Very recently Le and Solomon [43] proved that greedy spanners are optimal and in [44] they gave a novel construction of light Euclidean Spanners with Steiner points. Many such results mention approximation schemes for EUCLIDEAN TSP as a major motivation.

1.5 Organization

This paper is organized as follows. In Section 2 we define the building blocks of Arora’s approach that we use. Section 3 proves the Structure Theorem, and in Section 4 we show how to use it in combination with dynamic programming to establish the algorithmic part of Theorem 1.1. Section 5

extends these techniques to prove the algorithmic results of Theorem 1.2. In Section 6 the matching lower bounds are presented, and in Section 7 we conclude the paper.

2 Preliminaries

Throughout this paper, \log denotes the logarithm of base 2. We use standard graph notation, and the set $\{1, \dots, k\}$ is denoted by $[k]$.

For a given set of points $S \subseteq \mathbb{R}^d$, a *tour* is defined to be a cycle $\pi = (s_1, \dots, s_n, s_1)$ with vertex (multi)set S , which visits each point and returns to its starting point. Note that in this definition, we allow points to be visited multiple times. The length (sometimes called *weight*) $\text{wt}(\pi)$ of a tour $\pi = (s_1, \dots, s_n, s_1)$ is defined as $\sum_{i=1}^n \text{dist}(s_i, s_{i+1})$, where $s_{n+1} = s_1$. Hence, a tour π consists of a sequence of segments that share endpoints consecutively. A *geometric graph* is an embedding of a graph in \mathbb{R}^d where vertices are points and edges are segments that connect the corresponding points. For technical reasons, we allow both the vertices and edges of a geometric graph to be a multiset of points, i.e., we allow vertices and edges to coincide in the geometric sense. For example a tour can be regarded as a connected geometric graph where the corresponding graph is a cycle. Occasionally, we will also think of embedded graphs where the edges are represented by a path of segments rather than a single segment.

A *salesman tour* of the point set $P \subseteq \mathbb{R}^d$ is a tour of some points $S \supseteq P$ (hence, a salesman tour is a closed polyline that passes through each point in P and is allowed to make some digressions). In the EUCLIDEAN TRAVELING SALESMAN PROBLEM (Euclidean TSP), one needs to return the length of the minimum salesman tour of given points. If π^* is an optimal TSP tour, the standard $(1 + \varepsilon)$ -approximation scheme of the problem reports a length in the range $[\text{wt}(\pi^*), (1 + \varepsilon)\text{wt}(\pi^*)]$ (throughout the paper, we assume that ε is a real number with $0 < \varepsilon < 1$).

A *Steiner tree* of a point set $P \subseteq \mathbb{R}^d$ is a connected geometric graph that contains P as vertices. In a *rectilinear Steiner tree* we additionally require that each edge of the graph is axis-parallel. In the EUCLIDEAN (resp. RECTILINEAR) STEINER TREE problem, for a given $P \subset \mathbb{R}^d$ the goal is to find a Steiner tree (resp., rectilinear Steiner tree) of P with minimum total weight.

In the following we assume an instance of EUCLIDEAN TSP is given by a set P of n points in \mathbb{R}^d . By preprocessing the input instance in $\mathcal{O}(n \log(n/\varepsilon))$ time⁴ (see e.g. [49, Section 19.2]), we may assume that $P \subseteq \{0, \dots, L\}^d$ for some integer $L = \mathcal{O}(n\sqrt{d}/\varepsilon)$ that is a power of 2.

Hyperplanes and crossings For a hyperplane h we say that point $p \in h \cap \pi$ is a *crossing* of the tour $\pi = (s_1, \dots, s_n, s_1)$ if there exist $i \in [n]$ such that $p \in s_i s_{i+1}$ (where $s_{n+1} = s_1$) and the endpoints s_i and s_{i+1} are separated by h .

A *grid hyperplane* is a point set of the form $\{(x_1, \dots, x_d) \in \mathbb{R}^d \mid x_i = 1/2 + k\}$ for some integer $i \in [d]$ and $k \in \mathbb{Z}$. For a set of line segments, tour, or geometric graph S we define $I(S, h)$ (respectively, $I(\pi, h)$) the set of intersection points of the segments of S and h . We remark that the tour π may cross a given point of h several times, but we still think of $I(\pi, h)$ as a set rather than a multiset. Similarly, we will often refer to the set of crossing points with a closed $(d-1)$ -dimensional hypercube F as $\pi \cap F$, and $|\pi \cap F|$ does not count the multiplicity of these crossings.

The following simple lemma relates the number of crossings with grid hyperplanes with the total length of the line segments.

⁴By using a different computational model, this is counted as $\mathcal{O}(n)$ time in [7].

Lemma 2.1 (c.f., Lemma 19.4.1 in [49]). *If S is a set of line segments with endpoints in \mathbb{Z}^d , then*

$$\sum_{h \text{ is a grid hyperplane}} |I(S, h)| \leq \sqrt{d} \cdot \text{wt}(S).$$

The following folklore lemma is typically used to reduce the number of ways a salesman tour can cross a given hyperplane:

Lemma 2.2 (Patching Lemma [1]). *Let h be a hyperplane, π be a tour or Steiner tree, and let $I(\pi, h)$ be the set of intersections of π with h . Assume that h does not contain any endpoints of segments that define π . Let T be a tree on the hyperplane h that spans $I(\pi, h)$. Then, for any point p in T there exist line segments contained in h whose total length is at most $\mathcal{O}(\text{wt}(T))$ and whose addition to π changes it into a tour (resp. Steiner tree) π' that crosses h at most twice and only at p .*

We refer to [49, Section 19.6] for a proof of Lemma 2.2. Note that in typical presentations, the resulting patched tour will contain two copies of T , each infinitesimally close to h but outside it; in our variant we allow overlapping segments inside h which allows the patching to happen in h . See also our definition of dissection-aligned multigraphs Definition 3.6.

Dissection and Quadtree. Now, we introduce a commonly used hierarchy to decompose \mathbb{R}^d that will be instrumental to guide our algorithm. Pick $a_1, \dots, a_d \in \{1, \dots, L\}$ independently and uniformly at random and define $\mathbf{a} := (a_1, \dots, a_d)$. Consider the hypercube

$$C(\mathbf{a}) := \prod_{i=1}^d [-a_i + 1/2, 2L - a_i + 1/2].$$

Note that $C(\mathbf{a})$ has side length $2L$ and each point from P is contained in $C(\mathbf{a})$ by the assumption $P \subseteq \{0, \dots, L\}^d$.

For a cutoff parameter $\mu \in \mathbb{Z}$ let the *dissection* $D(\mathbf{a})$ of $C(\mathbf{a})$ to be a rooted tree that is recursively defined as follows. With each vertex of the tree we associate a hypercube in \mathbb{R}^d . For the root this is $C(\mathbf{a})$ and for the leaves of the tree this is a hypercube of side length 2^μ . Typically we will have $\mu = 0$ and unit side-length cubes associated with the leaves. Each non-leaf vertex v of the tree with associated closed hypercube $\times_{i=1}^d [l_i, u_i]$ has 2^d children with which we associate $\times_{i=1}^d I_i$, where I_i is either $[l_i, (l_i + u_i)/2]$ or $[(l_i + u_i)/2, u_i]$. We refer to such a hypercube that is associated with a vertex in the dissection as a *cell* of the dissection. The level of a cell is the distance from the corresponding vertex to the root of the tree.

The *quadtree* $QT(P, \mathbf{a})$ is obtained from $D(\mathbf{a})$ by terminating the subdivision whenever a cell has at most 1 point from the input point set P . This way, every cell is either a leaf that contains 0 or 1 input points, or it is an internal vertex of the tree with 2^d children, and the corresponding cell contains at least 2 input points. We say that a cell $C \in QT(P, \mathbf{a})$ is *redundant* if it has a child that contains the same set of input points as the parent of C . A redundant path is a maximal ancestor-descendant path in the tree whose internal vertices are redundant. The *compressed quadtree* $CQT(P, \mathbf{a})$ is obtained from $QT(P, \mathbf{a})$ by removing all the empty children of redundant cells, and replacing the redundant paths with single edges. In the resulting tree some internal cells may have a single child; we call these *compressed cells*. It is well-known and easy to check that compressed quadtrees have $\mathcal{O}(n)$ vertices (note that compressed quadtrees can be computed even in $\mathcal{O}(n)$ time on a word RAM model [14]).

For every face F of a cell in $D(\mathbf{a})$ there exists a unique grid hyperplane that contains F . For a grid hyperplane h we define the *level* of h to be the smallest integer i such that $D(\mathbf{a})$ contains a cell with sides of length $2L/2^i$, one of whose faces is contained in h .

We say that two distinct cells of a dissection or quadtree with the same side-length are *neighboring* if they share a facet, and they are *siblings* if they also have the same parent cell.

Lemma 2.3 (Lemma 19.4.3 [49]). *Let h be a grid hyperplane, and let i be an integer satisfying $0 \leq i \leq 1 + \log L$. Then the probability that the level of h is equal to i is at most $2^{i-1}/L$.*

Building blocks of Arora's technique We now briefly describe the building blocks from [1] that we will use.

Definition 2.4 (m -regular set). *An m -regular set of portals on a d -dimensional hypercube C is an orthogonal lattice grid(C, m) of m points in the cube. If the cube has side length ℓ , then the spacing between the portals is set to $\ell/(m^{1/d} - 1)$.*

We will normally have m be chosen as k^d for some integer $k \geq 2$, and as a consequence, grid(C, m) will always contain the corners of C .

Definition 2.5 (r -light). *A set of line segments S is r -light with respect to the dissection $D(\mathbf{a})$ if it crosses each face of each cell of $D(\mathbf{a})$ at most r times.*

Theorem 2.6 (Arora's Structure Theorem). *Let $P \subseteq \{0, \dots, L\}^d$, and let $\text{wt}(OPT)$ be the minimum length of a salesman tour visiting P . Let the shift vector \mathbf{a} be picked randomly. Then with probability at least $1/2$, there is a salesman tour of cost at most $(1 + \varepsilon)\text{wt}(OPT)$ that is r -light with respect to $D(\mathbf{a})$ such that it crosses each facet F of a cell of $D(\mathbf{a})$ only at points from grid(F, m), for some $m = (\mathcal{O}((\sqrt{d}/\varepsilon) \log L))^{d-1}$ and $r = (\mathcal{O}(\sqrt{d}/\varepsilon))^{d-1}$.*

3 Structure Theorem

Now we present and discuss the main structure theorem that allows us to prove the algorithmic part of Theorem 1.1. We state the theorem for a general dimension d .

For a $(d - 1)$ -dimensional hypercube F let F^* denote F without its 2^{d-1} corner points.

Definition 3.1 (r -simple geometric graph). *Let π be a geometric graph in \mathbb{R}^d such that the grid hyperplanes of the dissection $D(\mathbf{a})$ do not contain any edge of π . We say that π is r -simple if for every facet F shared by a pair of sibling cells in $D(\mathbf{a})$:*

- (a) π crosses F^* through at most one point (and some subset of 2^{d-1} corners of F), or
- (b) π crosses F only through the points from grid(F, g) for some $2^{d-1} \leq g \leq r^{2d-2}/|\pi \cap F^*|$.

Moreover, for any point p on a hyperplane h of $D(\mathbf{a})$, π crosses h at most twice via p .

One can see that in case (b) we always have $|\pi \cap F^*| \leq g$ (or when including multiplicities, there are at most $2g$ crossings). Consequently, $|\pi \cap F^*| \leq r^{2d-2}/|\pi \cap F^*|$ and thus $|\pi \cap F^*| \leq r^{d-1}$. Moreover, we recall that grid(F, g) contains all corners of F .

Definition 3.2 (r -simplification). *We say that a geometric graph π' is an r -simplification of π if π' is an r -simple geometric graph, and in each facet F where $|\pi \cap F^*| = 1$, the single non-corner crossing is a point from $\pi \cap F^*$.*

Theorem 3.3 (Structure Theorem). *Let \mathbf{a} be a random shift and let π be a tour or Steiner tree of $P \subseteq \mathbb{R}^d$. Then for any positive integer r there is a tour (resp., Steiner tree) π' of P that is an r -simplification of π such that*

$$\mathbb{E}_{\mathbf{a}}[\text{wt}(\pi') - \text{wt}(\pi)] \leq \mathcal{O}(d^{5/2} \cdot \text{wt}(\pi)/r).$$

Theorem 3.3 is the main contribution of this paper.

3.1 Sketch for the 2-dimensional case

Before we present the proof of Theorem 3.3, let us informally describe the construction of the tour π' of Theorem 3.3 for $d = 2$ and how it can be used give a $2^{\mathcal{O}(1/\varepsilon)}n \text{polylog}(n)$ algorithm for EUCLIDEAN TSP when $d = 2$. The full proof of Theorem 3.3 will start at Section 3.2.

Sketch of the algorithm We set $r = \mathcal{O}(1/\varepsilon)$. If we find an r -simple tour of lowest weight, then property (i) of Theorem 3.3 guarantees that this tour is a $(1 + \varepsilon)$ -approximation of an optimal salesman tour. Similarly to Arora [1] we can use dynamic programming to find such a tour. The number of possible ways in which the tour can enter and leave a cell of the quadtree is at most $\binom{\mathcal{O}(1/(\varepsilon^2 m))}{m} 2^{\mathcal{O}(m)} \cdot \text{poly}(n)$,⁵ since there are at most $\text{poly}(n)$ possibilities for the location of crossing if there is at most one crossing. The number of table entries can then be upper bounded with $2^{\mathcal{O}(1/\varepsilon)} \text{poly}(n)$ via the following claim:

Claim 3.4. *For every $1 \leq a \leq b$, it holds that $\binom{b/a}{a} \leq e\sqrt{b/e}$.*

Proof. If $a > \sqrt{b}$, then $\binom{b/a}{a} = 0$ and the inequality follows. If $a \leq \sqrt{b}$, then by the standard upper bound $\binom{n}{k} \leq \left(\frac{n \cdot e}{k}\right)^k$ we have that $\binom{b/a}{a} \leq \left(\frac{b \cdot e}{a^2}\right)^a$. In the interval $a \in [1, \sqrt{b}]$, the latter expression is maximized for $a = \sqrt{b/e}$, where it equals $e\sqrt{b/e}$. \square

To get the $\text{poly}(n)$ factor in the running time down to $\text{polylog}(n)$, note that we can first apply Theorem 2.6 with smaller ε to ensure there are $\log^{\mathcal{O}(1)}(n)$ possibilities for the case where the tour crosses a cell edge at a single point.

Sketch of the patching The proof of Theorem 3.3 uses a so-called *patching procedure* that modifies an (optimal) tour to a tour with the desired properties, but without increasing the length by too much. Here, we sketch the procedure for the case of $d = 2$, hence for simplicity assume that h is a horizontal line, and $c_1 < c_2 < \dots < c_k$ are the x -coordinates of the $k = |I(G, h)|$ crossings. We define the *proximity* of the j -th crossing as $\text{pro}(c_j) = c_j - c_{j-1}$ (for $j = 1$, use $c_0 = -\infty$).⁶

Our Sparsity-Sensitive Patching considers each cell C of the dissection and each side F of C with at least two crossings, and connects each crossing x on F as follows (see Figure 2).

1. Let N be the set of “near” crossings, that is, N is the set of crossings of π and F satisfying $\text{pro}(x) \leq \frac{L}{2^i r}$, where i is the level of the line of F in the dissection.
2. Let G be the set of remaining crossings of π with F .
3. Create a set of line segments PF_F (the *patching forest* of F) by connecting each vertex from N to its successor and, if $|G| > 1$, connecting each vertex from G to the closest point in $\text{grid}(F, r^2/|G|)$.

⁵This uses the well-known fact that the number of non-crossing matchings on r endpoints is at most $2^{\mathcal{O}(r)}$.

⁶In the later formal proof that also handles $d > 2$ we use a more complicated version of *proximity* defined in terms of the *base-line tree*.

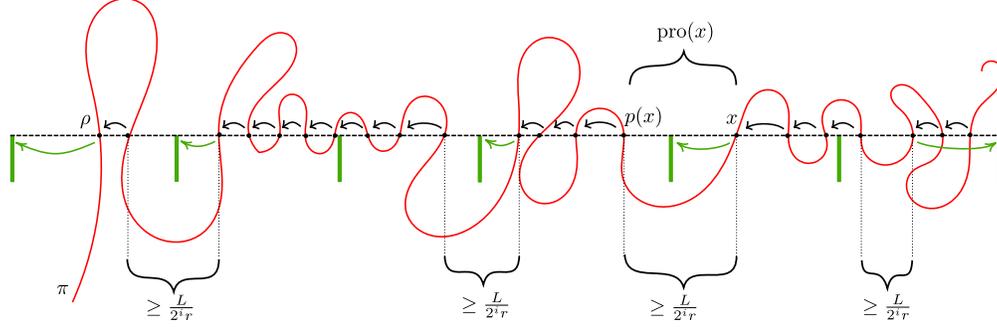

Figure 2: Construction of a set of line segments PF_F in $d = 2$. The tour π is colored red. Green portals denote the points in $\text{grid}(F, r^2/|G|)$. The leftmost point and the points with $\text{pro}(x) > L/(2^i/r)$ form the set G and are connected to the closest portal from the grid by a green arrow. Points with $\text{pro}(x) \leq L/(2^i r)$ form the set N and they are connected to their parent with black arrows. The set of line segments PF_F is indicated with a collection of black and green arrows.

4. Apply Lemma 2.2 to each set of touching line segments of PF_F to obtain a new tour π' that crosses F only at $|G|$ points of $\text{grid}(F, r^2/|G|)$, and at most twice at each of these points.

Remark 3.5. One difference between Arora's and our patching procedure is that each line (or in higher dimensions, each hyperplane) is patched only once. In other words, we only do patching between neighboring sibling cells. Arora's algorithm uses bottom-up patching, that is, it first patches along the shared boundary of neighboring leaf cells of the quadtree. (These leaves need not be siblings.) The procedure then goes up one level, and a patching may happen again if the number of crossings in the new (and larger) facet exceeds some threshold. Thus, Arora's patching procedure is iterative, and several patching steps may occur on any given cell boundary. In contrast, our patching is not iterative and it is done independently in each hyperplane (or on each cell boundary) only once.

The rest of this section is dedicated to the proof of the Structure Theorem in d -dimensional Euclidean space. Before we prove it, we first show the existence of a certain *base-line tree* in d -dimensional Euclidean space. This tree will be a subset of a hyperplane, and parts of it will be used via the invocation of the patching routine from Lemma 2.2 to reduce the number of crossings of the tour with the hyperplane. In \mathbb{R}^2 , this tree is just an entire line segment and the construction of the base-line tree in Subsection 3.2 and the analysis of using it for patching the tour in Subsection 3.3 can be skipped over by readers only interested in a proof sketch for $d = 2$. Trees similar to the base-line tree were also used for the case $d > 2$ by a previous algorithm (see [52, 49]), but we need a more delicate construction. Crucially, our base-line tree determines the proximities (i.e., the amortized patching costs) of the crossings and whether a given crossing point will be connected to a point from a grid or not. It will also play a crucial role in avoiding a large number of new crossings in perpendicular hyperplanes that could arise as a result of patching.

3.2 The base-line tree

In order to construct a good base-line tree we will need to align it with a fixed dissection.

Definition 3.6 (Dissection-aligned geometric graph). *A graph G is a $D(\mathbf{a})$ -aligned geometric graph if the following hold:*

- the vertices and edges of G are represented by a multiset of points and segments in \mathbb{R}^d , respectively,

- each vertex of G is assigned to a unique cell containing the point representing this vertex,
- every edge of positive length connects two vertices of the same cell, and
- every edge of length 0 is connecting a pair of vertices that are assigned to a cell and its child cell, respectively.

We say that an edge of a dissection-aligned geometric multigraph forms a *crossing* of a cell C if it has one end vertex assigned to C and the other end-vertex assigned to the parent of C . Note that by the above definition, a crossing edge is always of length 0, and its geometric location is at the location of the edge.

The following lemma is based on [49, Lemma 19.5.1], but there are two important differences. First, we do not need an efficient construction and only need to prove the existence of such a tree T . Second, [49, Lemma 19.5.1] does not guarantee our Property (c) in Lemma 3.7.

Lemma 3.7. *Let $d \geq 1$ be a constant and let $K \subseteq \mathbb{R}^d$ and let $D(\mathbf{a})$ be a dissection in \mathbb{R}^d where each bottom-level cell contains at most two vertices of K . Then there exists a rooted tree T spanning K that is a $D(\mathbf{a})$ -aligned multigraph with the following properties.*

- (a) T is 1-light, i.e., each cell has at most one crossing edge, which leads to a parent cell.
- (b) Each cell C has its crossing vertex at a designated corner $\text{cor}(C)$ of C , and
- (c) For each cell C of $D(\mathbf{a})$ with side length ℓ and $Q \subseteq K \cap C$, it holds that the minimum subtree T' of T that spans Q satisfies $\text{wt}(T') \leq 8d\ell|Q|^{1-1/d}$.

Proof. We construct a $D(\mathbf{a})$ -aligned geometric tree as follows. The *skeleton* of a cell C of $D(\mathbf{a})$ is the graph whose vertex set consists of the 2^d corners of C and whose edge set consists of all $d2^{d-1}$ edges of the hypercube C (i.e. each pair of corners of C that differ in one coordinate shares an edge). If C is the top-level cell of the dissection, then we define $\text{cor}(C)$ to be the corner of C at which all coordinates are the smallest possible, that is, the lexicographically minimum corner. If C is the child cell of C^* , then let $\text{cor}(C)$ be the unique vertex of C that is also a vertex of C^* . We construct a tree T_0 that only crosses each cell C of the dissection at $\text{cor}(C)$. To do so, for each cell C we add a spanning tree of the skeleton of C rooted at $\text{cor}(C)$ with depth at most d ; this tree is denoted by T_C , see Figure 3. Such a tree could be constructed for example by breadth-first-search on the edges of the hypercube; note that the diameter of the edge graph is d thus the resulting BFS tree has depth d . Observe that trees T_C in different cells C have some shared vertices, but no shared edges, although edges can have overlaps: if C' is a child of C , then C'_τ and C_τ will have edges that are intervals of the same line. For each parent and child cell pair C and C' , let $e_{CC'}$ be an edge of length 0 connecting the vertex of C' located at $\text{cor}(C')$ to the vertex of C located at the same place $\text{cor}(C)$. Now let T_0 be the union of all the trees T_C (with vertices assigned to C) and edges $e_{CC'}$ for each cell C and for each parent-child cell pair C, C' of $D(\mathbf{a})$, respectively.

Now let T be the tree T_0 plus the edge that connects each point $x \in K$ to the vertex of C at $\text{cor}(C)$ where C is the bottom-level cell of the dissection (of side length 2^μ) that contains x . Naturally, the vertex at x is assigned to C . The tree T remains $D(\mathbf{a})$ -aligned and 1-light. It is thus enough to show that it satisfies property (c).

To prove (c) we introduce an auxiliary tree DT as follows. The set of vertices of DT is the multiset defined by $\{\text{cor}(C) \mid C \text{ is a cell of } D(\mathbf{a})\} \cup K$. Recall that a cell C of the dissection has a well-defined level $\text{lvl}_C \in \{1, \dots, \ell\}$. For each vertex $v \in V(DT)$ we say that v has level $\ell + 1$ if $v \in K$ or has level i if the corresponding cell C has level i . Note that when C has level ℓ , then the only vertex of T_0 that was assigned to C and has been added to DT is $\text{cor}(C)$.

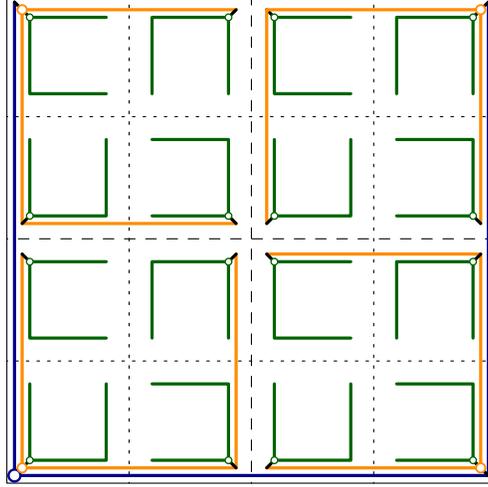

Figure 3: Constructing the tree T_0 . The spanning tree of the skeleton of a cell C is connected to a vertex of its parent's spanning tree with a length-0 edge at $\text{cor}(C)$ (denoted by a circles). The spanning trees at levels 1,2 and 3 are drawn in blue, orange and green, respectively.

Finally, we add edges between $\text{cor}(C)$ and $\text{cor}(C')$ of weight $2 \cdot Ld/2^i$ if C' is a child of C . Moreover, each vertex $x \in K$ is connected to $\text{cor}(C)$ with an edge of weight $2 \cdot Ld/2^{\ell+1}$, where C is a cell at the bottom level that contains x . Notice that when C is at the bottom level, then $|K \cap C| \leq 2$ implies that $\text{cor}(C)$ has at most $2 \leq 2^d$ children in DT .

Now we show that the length of each subtree of DT is at least the length of the corresponding subtree (i.e., the subtree spanned by the same vertex set) of T .

Note that in DT the weight of an edge between $\text{cor}(C)$ and $\text{cor}(C')$ from level i to level $i - 1$ is exactly $2 \cdot Ld/2^i$. Consider the corresponding path between these vertices in T . Notice that $\text{cor}(C)$ and $\text{cor}(C')$ are both in the skeleton of C and their distance in T is at most $Ld/2^i$. For vertices $x \in K$, the distance between x and $\text{cor}(C)$, where C is the bottom-level cell containing x is at most $\sqrt{d} \cdot L/2^\ell < 2 \cdot Ld/2^{\ell+1}$.

The lemma is now a consequence of applying the following claim on general weighted trees to the subtree T' of DT rooted at $\text{cor}(C)$.

Claim 3.8. *Let T' be a rooted tree in which each vertex has at most 2^d children and each edge from level $i - 1$ to level i has weight at most $1/2^i$. Then for any set of vertices Q , the minimum subtree of T' that spans Q has weight at most $4 \cdot |Q|^{1-1/d}$.*

Proof. Let k be the integer such that

$$2^k \leq |Q|^{1/d} < 2^{k+1}.$$

From level $i - 1$ to level i we have at most 2^{di} edges and each such edge has weight $1/2^i$. We have that the total weight of all edges from level 0 to k is at most:

$$\sum_{i=1}^k \frac{2^{di}}{2^i} \leq 2 \cdot 2^{k(d-1)} \leq 2 \cdot (|Q|^{1/d})^{d-1} = 2 \cdot |Q|^{1-1/d}.$$

On the other hand, the length of a path from a vertex $q \in Q$ that has a level at least k to its ancestor at level k is at most $\sum_{i=k+1}^{\infty} 1/2^i = 1/2^k$. Thus, the total length of all such paths is at most $|Q|/2^k < 2|Q|^{1-1/d}$. Therefore, the weight of the subtree is less than $4|Q|^{1-1/d}$ in total. \square

This concludes the proof of Lemma 3.7. □

With Lemma 3.7 in hand, we are ready to start the proof of Theorem 3.3. We start with describing the desired traveling salesman tour π' .

3.3 Constructing the patched tour π' and analyzing its crossings

In the proof of our structure theorem (Theorem 3.3), we may assume without loss of generality that $r \geq 128d$, as otherwise the claim can be satisfied by any known constant-approximation. We will call π a tour; the proof is analogous when π is a Steiner tree.

We construct the tour π' by iteratively processing all crossings per grid hyperplane. For a grid hyperplane h let $I(\pi, h)$ be the set of intersections of π with h .

Now fix a grid hyperplane h and suppose that h fixes the j -th coordinate (so $h = \{(x_1, \dots, x_d) : x_j = 1/2 + z_h\}$ for some integer z_h). Without loss of generality, we assume that $j = 1$. Let a_1 be the first coordinate of \mathbf{a} . Let \mathbf{a}' be obtained from \mathbf{a} by omitting the first coordinate. Therefore $\mathbf{a} = (a_1, \mathbf{a}')$.

Remark 3.9. The level of a hyperplane perpendicular to the first axis depends only⁷ on a_1 .

Suppose that h has level i , and let us fix a facet F of a cell at level i in $D(\mathbf{a})$ (with cutoff $\mu = 0$) where $F \subset h$. Note that F is a $(d-1)$ -dimensional hypercube, so F is actually a *cell* in the dissection $D(\mathbf{a}')$. The side length of F is $L/2^i$. Next, we will change π so that the resulting tour satisfies Definition 3.1 on F : If the tour already satisfies (a) we do not have to do anything, so let us assume for now that it does not satisfy (a) for the facet F .

We apply the $(d-1)$ -dimensional version of Lemma 3.7 to the set of crossings $I(\pi, h) \subseteq h$ with dissection $D(\mathbf{a}')$ with cutoff ν where ν is the largest integer such that $2^\nu < \frac{1}{r \cdot 2^{d-2}}$ and all vertices of $I(\pi, h)$ fall in different cells of $D(\mathbf{a}')$. (We reiterate that during this proof of the structure theorem is not intended to be algorithmically efficient.) We obtain a rooted tree T_0 that spans $I(\pi, h)$ and that is 1-light with respect to $D(\mathbf{a}')$. Let ρ denote the root vertex of T_0 . Let T be the tree whose vertices are the leaves and branching points of T_0 , and its edges are the maximal paths of T_0 whose internal vertices have degree 2. (That is, the drawing of T and T_0 consists of the same set of segments.) Let X be the set of vertices in T ; note that $X \supset I(\pi, h)$ and $|X| \leq 2|I(\pi, h)| - 2$. We orient every edge in T away from ρ . Hence ρ is an ancestor of every vertex in X and leaves of T have only themselves as descendants.

Remark 3.10. The tree T and the set X depend only on \mathbf{a}' and $I(\pi, h)$.

For a point $x \in X$ let $\text{cdc}(x)$ denote the *closest descendant crossing* of x , that is, the closest vertex among $I(\pi, h)$ in the subtree of x in T , where the distance is measured along the edges of T . In particular, if $x \in I(\pi, h)$ then $\text{cdc}(x) = x$. Notice moreover that the leaves of T are all vertices of $I(\pi, h)$ and therefore $\text{cdc}(\cdot)$ assigns leaves to themselves. See Figure 4.

⁷The orthogonality expressed in Remarks 3.9 and 3.10 are crucial to the success of our analysis. This orthogonality will be instrumental to the swapping of sums in (6). We observe that the same orthogonality is used in an analogous manner in the proof of Arora's structure theorem: it is required to be able to swap two similar sums.

The iterative patching of Arora raises a related problem. Consider the variable $c_{\ell, j}$ in [1], and the sentence stating that $c_{\ell, j}$ is independent of i above formula (3) on page 766 of [1] (due to orthogonality). Strictly speaking this is not true: $c_{\ell, j}$ is undefined when $j < i$ (or it could be set to 0). Thus in lines 6 and 7 of page 767 of [1] the swapping of the sums over i and j is formally incorrect. This inaccuracy can be easily fixed by setting $c_{\ell, j}$ based on the case $i = 1$, thus making it independent from i , and treating $c_{\ell, j}$ as an upper bound on the true crossing count $c_{\ell, i, j}$ at stage $j \geq i$, where $c_{\ell, i, j}$ is set to 0 when $j < i$. We note furthermore that the sums are swapped without the mention of orthogonality on page 770 of [1]. The same inaccuracy appears in almost all published proofs of Arora's structure theorem: see page 460 of [49], page 268 of [58]. The only full analysis that the authors are aware of which manages to avoid this matter is by Har-Peled [34] for $d = 2$.

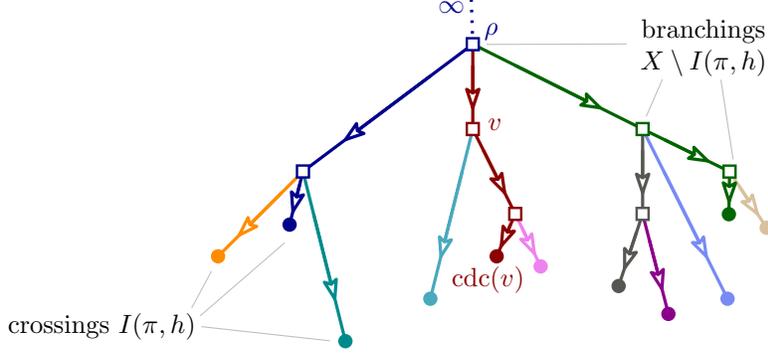

Figure 4: Closest descendant crossings ($\text{cdc}(\cdot)$) and proximity in T , where crossing nodes are denoted by disks. The closest descendant crossing of each node $x \in X$ (be it a crossing or a branching) is the crossing node of the same color. The proximity of a crossing node $v \in I(\pi, h)$ is the total length of the tree path of the same color, i.e., the total length of the arcs entering $\text{cdc}^{-1}(v)$, except for the dark blue crossing $\text{cdc}(\rho)$ whose proximity is ∞ .

Construction of PF_F . For a point $x \in I(\pi, h) \setminus \{\text{cdc}(\rho)\}$ we define the *proximity* of x , denoted by $\text{pro}_{\mathbf{a}'}(x)$, to be the sum of arc lengths in T whose targets are in $\text{cdc}^{-1}(x)$. We set $\text{pro}_{\mathbf{a}'}(\text{cdc}(\rho)) = \infty$. We note that $\text{pro}_{\mathbf{a}'}$ is positive, and we will occasionally use $1/\text{pro}_{\mathbf{a}'}(\text{cdc}(\rho)) = 0$. By Remark 3.10 we have that $\text{pro}_{\mathbf{a}'}(x)$ depends only on \mathbf{a}' and it is independent of a_1 . Let T_F be the subtree of T induced by $F \cap X$, and let ρ_F denote the root of T_F . We remark that we are using the 1-lightness of T here: it guarantees that $F \cap X$ induces a subtree in T which is *contained* in F . We define $G \subset I(\pi, h) \cap F$ to include a set of (intuitively distant) vertices whose proximity is large: we add $\text{cdc}(\rho_F)$ to G as well as the vertices $x \in I(\pi, h) \cap F \setminus \{\text{cdc}(\rho_F)\}$ such that $\text{pro}_{\mathbf{a}'}(x) > L/(2^i r)$. Let $G' := G \setminus \{\text{cdc}(\rho_F)\}$.

Lemma 3.11. *Let T_F^G be the minimum subtree of T spanned by G . Then $\sum_{z \in G'} \text{pro}_{\mathbf{a}'}(z) \leq \text{wt}(T_F^G)$.*

Proof. For $z \in G$ the arcs ending in $\text{cdc}^{-1}(z)$ form a directed path inside T_F ; let P_z be this path. Notice that these paths are edge-disjoint. Let ρ_F^G denote the root of T_F^G . The path $P_{\text{cdc}(\rho_F)}$ contains the arc with target ρ_F as well as the arc with target ρ_F^G . By the disjointness of the paths P_z for $z \in G$, we have that every other path stays in F and under ρ_F^G . Consequently, each path P_z for $z \in G'$ is contained in T_F^G . Thus we have that $\sum_{z \in G'} \text{pro}_{\mathbf{a}'}(z) = \sum_{z \in G'} \text{wt}(P_z) \leq \text{wt}(T_F^G)$. \square

If $|G| = 1$, that is, when $G = \{\text{cdc}(\rho_F)\}$, we set $\text{PF}_F^* = T_F$. When $|G| \geq 2$, then we change T_F to get a forest PF_F^* as follows. We say that an arc (u, v) of T_F , where v is a child of u , is *bad* if $\text{cdc}(u) \neq \text{cdc}(v)$ and $\text{cdc}(v) \in G$. Delete every bad edge from T_F , and for any rooted tree in the remaining forest, iteratively remove a root if it has degree one and it is not in $I(\pi, h)$. The resulting forest PF_F^* has exactly $|G|$ connected components, and for each component the root is either in $I(\pi, h)$ or it has at least two children. Finally, we will connect each vertex of G to a point of a grid as follows. To define the grid, let q be a positive integer such that $(q-1)^{d-1} < (r/2)^{2d-2}/|G| \leq q^{d-1}$, and let $g = q^{d-1}$ (since $r \geq 128d$ such q exists). Thus

$$\frac{(r/2)^{2d-2}}{|G|} \leq g < \frac{r^{2d-2}}{|G|}, \quad (3)$$

where the second inequality follows, since we assumed $r \geq 128d$.

Claim 3.12. $|G| < (16dr)^{d-1}$ and $g > \left(\frac{r}{64d}\right)^{d-1}$, in particular, $g > 2^{d-1}$.

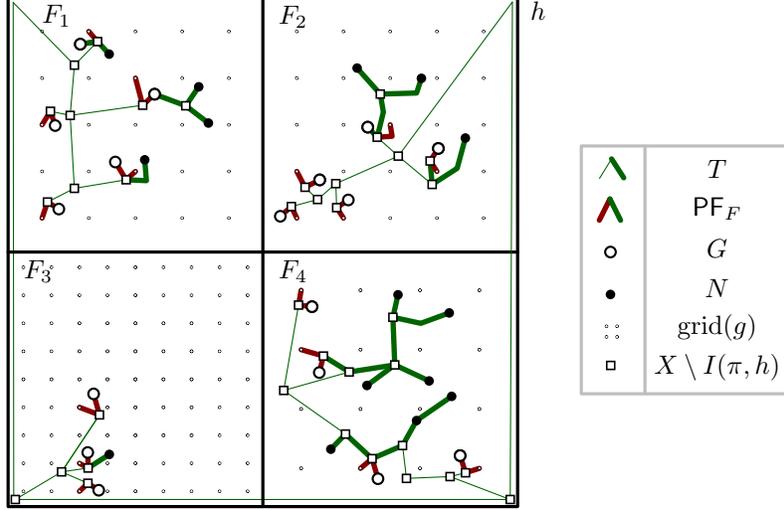

Figure 5: Construction of the forests PF_F in four faces in a plane h of level 1 in the quadtree. The green (thin and thick) edges are a schematic picture of T (note that the actual edges consist only of axis-parallel segments), and the thick (red and green) edges indicate the forests PF_F .

Proof. Recall from Lemma 3.11 that T_F^G is the subtree of T spanned by G . By Lemma 3.7(c) in T with $Q = G$ gives $\text{wt}(T_F^G) \leq \frac{8dL}{2^i} |G|^{1-1/(d-1)}$. Lemma 3.11 implies that $\sum_{z \in G'} \text{pro}_{\mathbf{a}'}(z) \leq \frac{8dL}{2^i} |G|^{1-1/(d-1)}$. By the definition of G , we have that for any $z \in G'$ the proximity $\text{pro}_{\mathbf{a}'}(z) > \frac{L}{2^i r}$. Thus we get

$$(|G| - 1) \frac{L}{2^i r} < \frac{8dL}{2^i} |G|^{1-1/(d-1)}. \quad (4)$$

For the second inequality, if $|G| = 1$ then (3) implies that $g \geq (r/2)^{2d-2} > \left(\frac{r}{64d}\right)^{d-1}$ as $r \geq 8$. Assuming $|G| \geq 2$, we have $2(|G| - 1) \geq |G|$, thus after simplifying (4) we get

$$|G|^{1/(d-1)} < 16dr \quad \Rightarrow \quad |G| < (16dr)^{d-1}.$$

Using (3) we get $g > \frac{(r/2)^{2d-2}}{(16dr)^{d-1}} = \left(\frac{r}{64d}\right)^{d-1}$. Since $r \geq 128d$, this directly implies $g > 2^{d-1}$. \square

Consider now the grid $\text{grid}(F, g)$ in F . Let $T_{\text{grid}(F, g)}$ be the subtree of T induced by all of its vertices in F plus a new edge from each point x of $\text{grid}(F, g)$ to $\text{cor}(C_x) \in V(T_{\text{grid}(F, g)})$ where C_x is the bottom level cell of side length 2^ν containing x . Observe that our setting of the cutoff ν ensures that each cell of $D(\mathbf{a}')$ contains at most two vertices from $\text{grid}(F, g) \cup I(\pi, h)$. Notice that $T_{\text{grid}(F, g)}$ is a supergraph of T_F and it is 1-light with respect to $D(\mathbf{a})$, as it is the tree one gets by applying Lemma 3.7 for the set $I(\pi, h) \cup \text{grid}(F, g)$ on the subdivision $D(\mathbf{a}')$.

For a vertex $x \in G$ let C_x be the smallest cell of $D(\mathbf{a}')$ that contains x and at least one point y from $\text{grid}(F, g)$. We connect x and y along the tree path in $T_{\text{grid}(F, g)}$. Let PF_F be the resulting forest. See Figure 5 for a schematic illustration of the construction for $d = 3$.

Lemma 3.13. *The length of the path connecting $x \in G$ to the point y in $\text{grid}(F, g)$ along $T_{\text{grid}(F, g)}$ is less than $\frac{128dL|G|^{1/(d-1)}}{r^2 2^i}$.*

Proof. For a vertex $x \in G$ consider the cell C_x that is the smallest cell of $D(\mathbf{a}')$ that contains x and at least one point y from $\text{grid}(F, g)$. Recall that $\text{grid}(F, g)$ is a grid with minimum point distance $s := \frac{L}{(g^{1/(d-1)} - 1)2^i}$. Then the side length of C_x is at most $2s$. Claim 3.12 implies that $g > 2^{d-1}$, thus

$g^{1/(d-1)} - 1 \geq g^{1/(d-1)}/2$, so $s \leq \frac{2L}{g^{1/(d-1)}2^i}$. By Lemma 3.7 with $Q = (x, y)$ in the tree $T_{\text{grid}(F,g)}$, we have that the distance of x and y in $T_{\text{grid}(F,g)}$ is at most

$$8ds \cdot 2^{1-1/d} < \frac{32dL}{g^{1/(d-1)}2^i} \leq \frac{128dL|G|^{1/(d-1)}}{r^22^i},$$

by the first inequality in (3). □

Patching along PF_F . Next, we change the salesman tour π by applying Lemma 2.2 on each connected component of PF_F that has a vertex from $I(\pi, h)$. This restricts the tour to cross the hyperplane h only at some vertex of $I(\pi, h) \cap F$ when $G = \{\text{cdc}(\rho_F)\}$ or in at most $|G|$ points from $\text{grid}(F, g)$. Additionally, if there is a point $p \in h$ and the patched tour crosses h more than twice at p , we apply Lemma 2.2 with $X = T = \{p\}$ and reduce the number of crossings at p to at most two without increasing the length of the tour. This finishes the description of the construction of π' promised by the theorem. We note that the cost of the patching in F is at most $\mathcal{O}(\text{wt}(\text{PF}_F))$ by Lemma 2.2. After processing F the resulting tour restricted to F is a $\text{D}(\mathbf{a}')$ -aligned geometric multigraph, as each vertex in the relative interior of F is assigned to the level of F , and we can add length-0 edges at crossings of the relative boundary of F .

Observe that this patching can introduce new crossings in hyperplanes perpendicular to h . Let C be a cell with face F . New crossings can only be introduced between two descendants of C that are incident to F . Recall that the patching of F occurs along some subforest of the $\text{D}(\mathbf{a}')$ -aligned base-line tree, so in particular we have the following.

Claim 3.14. *Let C_1, C_2 be a pair of d -dimensional sibling cells in $\text{D}(\mathbf{a})$ that are descendants of C and there is a new crossing introduced between them by PF_F . Then, this crossing is in a shared corner of C_1 and C_2 .*

Proof. Let x be a point of $T_{\text{grid}(F,g)}$ that gives an intersection between C_1 and C_2 on the shared boundary hyperplane h' of C_1 and C_2 . Observe that the level of h' is more than i , therefore C_1 and C_2 also have level more than i , and they are thus descendants of C . The point $x \in F \cap h'$ is a point of PF_F , thus Lemma 3.7(b) implies that x is a shared corner of the cells $C_1 \cap F$ and $C_2 \cap F$ of the dissection $\text{D}(\mathbf{a}')$. This corner is also a shared corner of C_1 and C_2 . □

To construct the patched tour π' , apply the above patching on π in each hyperplane of the dissection $\text{D}(\mathbf{a})$. We emphasize that the patching is not iterative, it is always applied on the original tour π .

We note that π' may in fact have edges within grid hyperplanes due to the patching. We make infinitesimal perturbations to π' to ensure that any positive-length edge assigned to a cell is shifted to the interior of the cell. As a result, the intersections of π' with any grid hyperplane is a set of points.

To see that the obtained tour π' is an r -simplification of π , note that if π' crosses a facet F outside a grid⁸, then $|G| = 1$ and the crossing of π must have happened at some point of $I(\pi, h) \cap F = \pi \cap F$. Otherwise π' crosses in at most $|G|$ non-corner points from $\text{grid}(F, g)$. The inequality chain (3) gives $g < r^{2d-2}/|G|$, thus $g < r^{2d-2}/|G| \leq r^{2d-2}/|\pi' \cap F^*|$. Finally, if some point of $\pi' \cap F^*$ appears more than 3 times along π , then we can use Lemma 2.2 at this single point to get a new tour of the same length whose multiplicity at this point is reduced to at most 2. Thus π' is an r -simplification of π .

⁸Recall that the corners of F are included in grids of each possible granularity.

3.4 Analysis of the expected length of π'

Let $\text{cost}(h)$ denote the increase of the salesman tour during the iteration corresponding to the hyperplane h . Our main effort will lie in proving that $\mathbb{E}[\text{cost}(h)] \leq \mathcal{O}(\frac{d^2}{r} \cdot |I(\pi, h)|)$. This would be sufficient to prove the theorem since it allows us to conclude that

$$\sum_{h:\text{grid hyperplane}} \mathbb{E}[\text{cost}(h)] \leq \sum_{h:\text{grid hyperplane}} \mathcal{O}\left(d^2 \cdot \frac{|I(\pi, h)|}{r}\right) = \mathcal{O}(d^{5/2} \cdot \text{wt}(\pi)/r), \quad (5)$$

where the second inequality is by Lemma 2.1.

We note here that in case of $d = 2$ the following analysis can be simplified. First, the patching forest PF_F is a line segment, and the proximity of a point is $\text{pro}_{\mathbf{a}'}$ is independent of the shift, i.e., one could omit the subscript \mathbf{a}' . The set X is equal to the set $I(\pi, h)$ of crossings in h . Finally, the function $\text{cdc}(\cdot)$ is the identity function.

Amortized patching costs. By Remark 3.9, we have that the level $i = i_{a_1}$ of h depends only on a_1 and it is independent of \mathbf{a}' . With each $x \in I(\pi, h)$ we associate the following coefficients $\alpha_{i, \mathbf{a}'}(x)$ that represent the *amortized expected patching cost* due to x if the level of h is i :

$$\alpha_{i, \mathbf{a}'}(x) = \begin{cases} \text{pro}_{\mathbf{a}'}(x) \cdot 2^i / L, & \text{if } \text{pro}_{\mathbf{a}'}(x) \leq L/(2^i r), \\ \frac{d^2 L}{\text{pro}_{\mathbf{a}'}(x) \cdot 2^i r^2}, & \text{if } L/(2^i r) < \text{pro}_{\mathbf{a}'}(x) \leq L/2^i, \\ 0, & \text{if } L/2^i < \text{pro}_{\mathbf{a}'}(x). \end{cases}$$

In case of $d = 2$, we note that $\alpha_{i, \mathbf{a}'}(x)$ is independent of \mathbf{a}' and could simply be written as $\alpha_i(x)$.

Next, we will show that the expected cost of patching from Lemma 2.2 for a fixed cell F whose hyperplane has level i is at most $\mathcal{O}(\frac{L}{2^i} \cdot \sum_{x \in F \cap X} \alpha_{i, \mathbf{a}'}(x))$.

The weight of PF_F . Now we use the special properties of T guaranteed by Lemma 3.7 to show the following.

Lemma 3.15. *It holds that:*

$$\text{wt}(\text{PF}_F) = \mathcal{O}\left(\frac{L}{2^i} \cdot \sum_{x \in F \cap I(\pi, h)} \alpha_{i, \mathbf{a}'}(x)\right).$$

Proof. Let ρ_F be the root of T_F . Consider the following subset of $F \cap X$:

$$N := \left\{x \in F \cap I(\pi, h) : \text{pro}_{\mathbf{a}'}(x) \leq \frac{L}{2^i r}\right\} \setminus \{\text{cdc}(\rho_F)\}.$$

Therefore N is a set of (near) vertices with *small proximity*. As G consists of vertices with large proximity (i.e., it consists of $\text{cdc}(\rho_F)$ and all vertices in $z \in I(\pi, h) \cap F$ that satisfy $\text{pro}_{\mathbf{a}'}(z) > L/(2^i r)$) we have that $I(\pi, h) \cap F = N \cup G$.

Claim 3.16.

$$\text{wt}(\text{PF}_F) \leq \begin{cases} 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y) & \text{if } |G| = 1 \\ 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y) + |G|^{d/(d-1)} \cdot \frac{128dL}{r^2 2^i} & \text{otherwise.} \end{cases}$$

Proof. If $d = 2$, then each component of PF_F consists of a segment connecting the crossings whose length is $\sum_{y \in N} \text{pro}(y)$, and a segment connecting an endpoint of this segment to the nearest grid point, which is of length at most $\frac{L|G|}{r^2 2^i}$. If $|G| = 1$, then this latter connection to the grid is not made. When $|G| \geq 2$, then the total cost of these grid connections is therefore $|G|^2 \frac{L}{r^2 2^i}$. This concludes the proof for $d = 2$.

For general d , recall that PF_F consists of two types of edges, those that connect vertices of G to points of $\text{grid}(F, g)$ and the edges of PF_F^* . To bound $\text{wt}(\text{PF}_F^*)$, let T_x be the tree of PF_F^* containing a given $x \in G$, and let ρ_x be the root of the subtree T_x . We claim that $\text{wt}(T_x[\rho_x, x]) + \sum_{y \in V(T_x) \cap N} \text{pro}_{\mathbf{a}'}(y) = \text{wt}(T_x)$, where $T_x[\rho_x, x]$ is the path in T_x connecting ρ_x to x . To see this, notice that all vertices of T_x are covered by $\bigcup_{y \in N \cap V(T_x)} \text{cdc}^{-1}(y)$ except those in $V(T_x[\rho_x, x])$, as $V(T_x[\rho_x, x]) \subseteq \text{cdc}^{-1}(x)$. Thus by the definition of $\text{pro}_{\mathbf{a}'}(\cdot)$ we have that arcs whose lengths are included in the sum $\sum_{y \in V(T_x) \cap I(\pi, h)} \text{pro}_{\mathbf{a}'}(y)$ include each arc of $E(T_x) \setminus E(T_x[\rho_x, x])$.

Notice that x is the vertex among $V(T_x) \cap I(\pi, h)$ that is closest to ρ_x in T_x , and $\text{pro}_{\mathbf{a}'}(x)$ is an upper bound on this distance.

We claim that $\text{wt}(T_x) \leq 2 \cdot \sum_{y \in N \cap V(T_x)} \text{pro}_{\mathbf{a}'}(y)$. This trivially holds when $N \cap V(T_x) = \emptyset$ since that implies that T_x is a single-vertex tree.

Suppose now that $N \cap V(T_x) \neq \emptyset$. It is sufficient to show that $\text{wt}(T_x[\rho_x, x]) \leq \max_y \text{pro}_{\mathbf{a}'}(y)$. This is immediate when $\rho_x = x$ because then $\text{wt}(T_x[\rho_x, x]) = 0$. Otherwise, the definition of PF_F^* implies that ρ_x has a child z such that $z \notin T_x[\rho_x, x]$. Then $\text{pro}_{\mathbf{a}'}(\text{cdc}(z)) = \text{wt}(T_x[\rho_x, z])$, and by the definition of $\text{cdc}(\cdot)$, we have $T_x[\rho_x, x] \leq \text{wt}(T_x[\rho_x, z])$. Consequently, $\text{wt}(T_x[\rho_x, x]) \leq \max_y \text{pro}_{\mathbf{a}'}(y)$ holds, as the right hand side includes the term for $\text{cdc}(z) \in N \cap V(T_x)$, and thus $\text{wt}(T_x) \leq 2 \cdot \sum_{y \in N \cap V(T_x)} \text{pro}_{\mathbf{a}'}(y)$ holds. Summing over each tree T_x of PF_F^* , we get

$$\text{wt}(\text{PF}_F^*) \leq 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y).$$

To bound the connections of G to the grid points, recall that no connections are made when $|G| = 1$. When $|G| \geq 2$, then 3.13 implies that each connection is of length less than $\frac{128dL|G|^{1/(d-1)}}{r^2 2^i}$, so the total length of these connections is less than $|G|^{d/(d-1)} \cdot \frac{128dL}{r^2 2^i}$, which concludes the proof of our claim. \square

We consider the case $|G| = 1$ (so $G = \{\text{cdc}(\rho_F)\}$). By Claim 3.16 we have

$$\text{wt}(\text{PF}_F) \leq 2 \sum_{x \in N} \text{pro}_{\mathbf{a}'}(x) = 2 \cdot \frac{L}{2^i} \sum_{x \in N} \alpha_{i, \mathbf{a}'}(x),$$

and the lemma follows. Thus, from now we assume $|G| \geq 2$.

Next, we upper bound the size of G .

Claim 3.17. *If $|G| \geq 2$, then*

$$|G|^{d/(d-1)} \leq 32 \frac{dL}{2^i} \sum_{z \in G} \frac{1}{\text{pro}_{\mathbf{a}'}(z)}.$$

Proof. Recall that T_F^G is the smallest subtree of T that contains G and $G' := G \setminus \{\text{cdc}(\rho_F)\}$. By property (c) of Lemma 3.7 of T with set $Q := G$ and cell F , we have that $\text{wt}(T_F^G) \leq \frac{8dL}{2^i} |G|^{1-1/(d-1)}$. Thus by Lemma 3.11 we have that $\sum_{z \in G'} \text{pro}_{\mathbf{a}'}(z) \leq \text{wt}(T_F^G) \leq \frac{4dL}{2^i} |G|^{1-1/(d-1)}$. Next, we apply the

Cauchy-Schwartz inequality to the vectors $(\sqrt{\text{pro}_{\mathbf{a}'}(z)})_{z \in G'}$ and $(\sqrt{1/\text{pro}_{\mathbf{a}'}(z)})_{z \in G'}$, which gives

$$|G'|^2 \leq \left(\sum_{z \in G'} \text{pro}_{\mathbf{a}'}(z) \right) \cdot \left(\sum_{z \in G'} \frac{1}{\text{pro}_{\mathbf{a}'}(z)} \right) \leq \frac{8dL}{2^i} |G'|^{1-\frac{1}{d-1}} \cdot \left(\sum_{z \in G'} \frac{1}{\text{pro}_{\mathbf{a}'}(z)} \right).$$

Since $|G| \geq 2$, we have that $|G|^2 = (|G'| + 1)^2 \leq 4|G'|^2$ and conclude the proof of the claim. \square

Now, we can upper bound $\text{wt}(\text{PF}_F)$ by bounding the weight of each the edge from x to the parent of x in PF_F as follows:

$$\begin{aligned} \text{wt}(\text{PF}_F) &\leq 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y) + \sum_{z \in G} \frac{128dL}{2^i r^2} \cdot |G|^{1/(d-1)} && \text{(by Claim 3.16)} \\ &= 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y) + \frac{128dL}{2^i r^2} \cdot |G|^{\frac{d}{d-1}} \\ &\leq 2 \cdot \sum_{y \in N} \text{pro}_{\mathbf{a}'}(y) + 2^{12} d^2 \left(\frac{L}{2^i r} \right)^2 \sum_{z \in G} \frac{1}{\text{pro}_{\mathbf{a}'}(z)} && \text{(by Claim 3.17)} \\ &= \frac{L}{2^i} \cdot \mathcal{O} \left(\left(\sum_{y \in N} \frac{2^i}{L} \cdot \text{pro}_{\mathbf{a}'}(y) \right) + \left(\sum_{z \in G} \frac{d^2 L}{r^2 2^i} \frac{1}{\text{pro}_{\mathbf{a}'}(z)} \right) \right) \\ &= \mathcal{O} \left(\frac{L}{2^i} \sum_{x \in I(\pi, h) \cap F} \alpha_{i, \mathbf{a}'}(x) \right). \end{aligned} \quad \square$$

Expected patching cost analysis. Recall that by Lemma 2.3, the hyperplane h gets level i with probability $2^{i-1}/L$, where $i = i(a_1)$ is the level of h . Thus we have the following.

$$\begin{aligned} \mathbb{E}[\text{cost}(h)] &= \frac{1}{L^d} \sum_{\mathbf{a} \in [L]^d} \text{cost}_{\mathbf{a}}(h) \\ &= \frac{1}{L^d} \sum_{a_1 \in [L]} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{\substack{F \text{ is facet of } C \text{ in } h, \\ \text{level of } C \text{ is } i=i(a_1)}} \text{wt}(\text{PF}_F) \\ &= \frac{1}{L^d} \sum_{a_1 \in [L]} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{\substack{F \text{ is facet of } C \text{ in } h, \\ \text{level of } C \text{ is } i=i(a_1)}} \mathcal{O} \left(\frac{L}{2^i} \sum_{x \in I(\pi, h) \cap F} \alpha_{i, \mathbf{a}'}(x) \right) && (6) \\ &= \mathcal{O} \left(\frac{1}{L^d} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{a_1 \in [L]} \frac{L}{2^i} \sum_{\substack{F \text{ is facet of } C \text{ in } h, \\ \text{level of } C \text{ is } i=i(a_1)}} \left(\sum_{x \in I(\pi, h) \cap F} \alpha_{i, \mathbf{a}'}(x) \right) \right) \\ &= \mathcal{O} \left(\frac{1}{L^d} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{a_1 \in [L]} \frac{L}{2^i} \sum_{x \in I(\pi, h)} \alpha_{i, \mathbf{a}'}(x) \right) \end{aligned}$$

Notice that for any fixed \mathbf{a}' , the value of $\alpha_{i,\mathbf{a}'}$ depends only on the level $i = i(a_1)$ of h , and there are 2^j values of a_1 where $i = j$. Thus, we can write

$$\begin{aligned}\mathbb{E}[\text{cost}(h)] &= \mathcal{O}\left(\frac{1}{L^d} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{a_1 \in [L]} \frac{L}{2^i} \sum_{x \in I(\pi, h)} \alpha_{i,\mathbf{a}'}(x)\right) \\ &= \mathcal{O}\left(\frac{1}{L^d} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{j=0}^{1+\log L} 2^j \frac{L}{2^j} \sum_{x \in I(\pi, h)} \alpha_{j,\mathbf{a}'}(x)\right) \\ &= \mathcal{O}\left(\frac{1}{L^{d-1}} \sum_{\mathbf{a}' \in [L]^{d-1}} \sum_{x \in I(\pi, h)} \sum_{j=0}^{1+\log L} \alpha_{j,\mathbf{a}'}(x)\right)\end{aligned}$$

In the innermost sum, for a fixed \mathbf{a}' and x we have that

$$\sum_{j=0}^{1+\log L} \alpha_{j,\mathbf{a}'}(x) = \sum_{j=0}^{\theta_1} \alpha_{j,\mathbf{a}'}(x) + \sum_{j=\theta_1+1}^{\theta_2} \alpha_{j,\mathbf{a}'}(x) \leq \frac{2}{r} + \frac{2d^2}{r} < \frac{3d^2}{r},$$

where we have set $\theta_1 := \log\left(\frac{L}{\text{pro}_{\mathbf{a}'}(x) \cdot r}\right)$ and $\theta_2 := \log\left(\frac{L}{\text{pro}_{\mathbf{a}'}(x)}\right)$, and used the bound on the sum of both geometric series. Consequently, $\mathbb{E}[\text{cost}(h)] = \mathcal{O}\left(\frac{d^2 |I(\pi, h)|}{r}\right)$. We can now conclude the proof of Theorem 3.3 with (5).

4 Approximate TSP in \mathbb{R}^d

In this section we prove the algorithmic part of Theorem 1.1. The first few steps of the algorithm are the same as in Arora's algorithm [1], as outlined in Section 2.

In *Step 1*, we perturb points and assume that $P \subseteq [L]^d$ for some integer $L = \mathcal{O}(n\sqrt{d}/\varepsilon)$ that is a power of 2. Then in *Step 2* we pick a uniform random shift $\mathbf{a} \in \{0, \dots, L\}^d$ and construct a compressed quadtree.

In *Step 3* we use the following result by Rao and Smith [52] (the result can also be obtained by applying the procedure PATCH from [49] to the graph obtained from [49, Lemma 19.3.2]).

Lemma 4.1 ([52], see also [49]). *Let $P \subset \mathbb{R}^d$ be a set of n points and let \mathbf{a} be a random shift. There is a $\text{poly}(1/\varepsilon)n \log(n)$ time algorithm that, given P and \mathbf{a} , computes a set of line segments S such that*

1. $\mathbb{E}_{\mathbf{a}}[\text{wt}(\pi^S) - \text{wt}(\pi)] = \mathcal{O}(\varepsilon \cdot \text{wt}(\pi))$, where π is a shortest tour of P and π^S is a shortest tour of P among the tours that use only edges from S .
2. S is $1/\varepsilon^{\mathcal{O}(d)}$ -light with respect to $\mathbf{D}(\mathbf{a})$.

Moreover, in $\text{poly}(1/\varepsilon)n \log n$ time we can store for each facet F of every cell C of $\text{CQT}(P, \mathbf{a})$ all the crossings of S and F .

Let π be the optimum TSP tour on the perturbed point set P . Lemma 4.1 gives us the set S with the property that (i) there exist π^S that uses only edges from S , and (ii) in expectation the extra weight of π^S is only $\mathcal{O}(\varepsilon \cdot \text{wt}(\pi))$, and (iii) π^S crosses every cell of the quadtree at most $1/\varepsilon^{\mathcal{O}(d)}$ times. This summarizes all the steps from previous work that we will use in the algorithm.

We apply Theorem 3.3 to π^S , which guarantees the existence of an r -simple tour that is a good approximation in expectation and has the property that quadtree facets that are crossed only once outside the corners will be crossed at the same place as in π^S . In *Step 4*, which we describe in full detail in the next section, we find the optimal r -simplification of π^S with this property. Similar to Arora’s algorithm and the description in Section 2, we use a dynamic programming algorithm for this. However, there are two crucial changes. First, we cannot bound the number of matchings in $d > 2$ the same way as we did for $d = 2$ since we used the non-crossing property for this. For this reason, we combine the dynamic programming with the rank-based approach [10]. In order to achieve a more efficient $\mathcal{O}(n \log n)$ running time dependence on n , we use a portal set consisting of all crossings with the cell boundary and the set of line segments S from Lemma 4.1 when the tour has only one crossing point in a given facet.

4.1 Dynamic Programming

We use a dynamic programming algorithm to find an $\mathcal{O}(1/\varepsilon)$ -simple salesman tour with respect to the shifted quadtree (in a similar fashion to Arora [1]). With high probability, this salesman tour has weight $(1 + \varepsilon) \cdot \text{wt}(\text{OPT})$. The running time of this step is $2^{\mathcal{O}(1/\varepsilon^{d-1})}n$.

For a given quadtree cell C let ∂C denote its boundary. Our Structure Theorem, (Theorem 3.3) guarantees the existence of some set of active portals $B \subseteq \partial C$ that will be traversed by the tour. Technically, each portal may be used at most twice: for the sake of convenient set notation, we will think of each portal as having two copies that are infinitesimally close, and selecting a subset of these modified portals. In our subproblem we will fix such a set B and we are also given a perfect matching M on B . We say that a collection $\mathcal{P} := \{\pi_1, \dots, \pi_{|B|/2}\}$ of paths *realizes* M on B if for each $(p, q) \in M$ there is a path $\pi_i \in \mathcal{P}$ with p and q as endpoints.

For each facet F there is a unique maximum facet $\text{ex}(F)$ that is the boundary of a cell in the compressed quadtree that contains F . Note that when considering the cell C and one of its facets F , we will place the portals according to the grids of $\text{ex}(F)$, or potentially at some point in $F \cap S$. We say that B is *fine* with respect to S if for all facets F of C we have that either (i) $B \cap F^* = \{p\}$ and $p \in S \cap F$, or (ii) B contains each point of $F \subset \text{grid}(\text{ex}(F), r^{2d-2}/m_F)$ at most twice, where $|B \cap F^*| \leq 2m_F \leq 2r^{d-1}$. Note that the first option is needed because in Definition 3.1 we often need a perfect precision on faces that are crossed at exactly one point apart from their corners.

The subproblems are defined as follows (cf., r -multipath problem in Arora [1]).

r -Multipath Problem

Input: A nonempty cell C in the shifted quadtree, a portal set $B \subseteq \partial C$ that is fine with S , and a perfect matching M on B .

Task: Find an r -simple path collection $\mathcal{P}_{B,M}$ of minimum total length that satisfies the following properties.

- The paths in $\mathcal{P}_{B,M}$ visit all input points inside C .
- $\mathcal{P}_{B,M}$ crosses ∂C only through portals from B .
- $\mathcal{P}_{B,M}$ realizes the matching M on B .

Arora [1] defined the multipath problem in a similar way. The main difference is that he considers all $B \subseteq \bigcup_F \text{grid}(\text{ex}(F), (r \log n)^{d-1})$, while our structural Lemma enables us to select B from $\bigcup_F \text{grid}(\text{ex}(F), r^{2d-2}/m_F)$ of size at most $2 \sum_F m_F$ apart from the special case with 1 crossing on F^* . (In this comparison and the subsequent sketch we ignore the corner crossings.) Arora [1] showed how to use dynamic programming to solve the r -Multipath problem in time $\mathcal{O}(n \cdot m^{\mathcal{O}(r)})$

(for $d = 2$) which is already too expensive in our case for $m, r = \mathcal{O}(1/\varepsilon)$. Here and below, the union is taken over all facets F of the given cell C .

Before we explain our approach in detail, let us first discuss the natural dynamic programming algorithm for the $d = 2$ case and why it is not fast enough for $d > 2$. The dynamic programming builds a lookup table that contains the costs of all instances of the multipath problem that arise in the quadtree, which is exactly the same as in Arora [1]. When the table is built, it is enough to output the entry that corresponds to the root of the quadtree. The number of non-empty cells in the compressed quadtree is $\mathcal{O}(n)$. For each facet F of the cell C , we guess an integer $m_F \leq 1/\varepsilon^{d-1}$ that is the number of times the $\mathcal{O}(1/\varepsilon^{d-1})$ -simple salesman tour crosses $\text{ex}(F^*)$. Then, we select a set B of size at most $2m$ by choosing from $\bigcup_F \text{grid}(\text{ex}(F), r^{2d-2}/m_F)$, where $\sum_F m_F = m$. There are at most

$$\prod_{F \text{ facet of } C} \sum_{m_F=2}^{r^{d-1}} \left(3^{m_F} \cdot \binom{r^{2d-2}/m_F}{m_F} \right) \leq 2^{\mathcal{O}(r^{d-1})}$$

possible choices for the set of active portals B by Claim 3.4, since the number of facets F of C is only $2d$. Unfortunately, the number of perfect matchings on the m points is $2^{\mathcal{O}(m \log m)}$. Since $m = \mathcal{O}(r^{d-1}) = \mathcal{O}(1/\varepsilon^{d-1})$, this would lead to a running time of $2^{\mathcal{O}(1/\varepsilon^{d-1} \log(1/\varepsilon))}$, which has an extra $\log(1/\varepsilon)$ factor in the exponent compared to our goal. If $d = 2$ we could use the fact that an optimal TSP tour is crossing-free, which allows one to look for “crossing-free matchings” (and their number is at most $2^{\mathcal{O}(m)}$). To reduce the number of possible matchings in $d > 2$, we will use the *rank-based approach*.

Rank-based approach Now we describe how the rank-based approach [10, 16] can be applied in this setting. We will heavily build upon the methodology and terminology from [10], and describe the basics here for the unfamiliar reader. We follow the notation from [20].

Let C be the cell of the quadtree and let $B \subseteq \partial C$ be the set of portals on its boundary with $|B| = m$ (note that m is even). We define the *weight* of a perfect matching M of B to be the total length of the solution to the multipath problem on (C, B, M) , and denote it by $\text{wt}(M)$. A weighted matching on B is then a pair $(M, \text{wt}(M))$ for some perfect matching M . Let $\mathcal{M}(B)$ denote the set of all weighted matchings on B .

We say that two perfect matchings M_1, M_2 *fit* if their union is a Hamiltonian Cycle on B . For some set $\mathcal{R}[B] \subseteq \mathcal{M}(B)$ of weighted matchings and a fixed perfect matching M we define

$$\text{opt}(M, \mathcal{R}[B]) := \min \{ \text{weight}(M') : (M', \text{weight}(M')) \in \mathcal{R}[B] \text{ and } M' \text{ fits } M \}$$

Finally, we say that the set $\mathcal{R}[B] \subseteq \mathcal{M}(B)$ is *representative* if for any matching M , we have $\text{opt}(M, \mathcal{R}[B]) = \text{opt}(M, \mathcal{M}(B))$. The following result is the crucial theorem behind the rank-based approach.

Lemma 4.2 (Theorem 3.7 in [10]). *There exists a set $\mathcal{R}^*[B]$ of $2^{|B|/2-1}$ weighted matchings that is representative of $\mathcal{M}(B)$. There is an algorithm **Reduce** that given some representative set $\mathcal{R}[B]$ of $\mathcal{M}(B)$ computes a set \mathcal{R}^* in $|\mathcal{R}^*[B]| \cdot 2^{\mathcal{O}(|B|)}$ time.*

In the following, $\mathcal{R} := \bigcup_B \{\mathcal{R}[B]\}$ for $B \subseteq \partial C$ that are fine with S . For convenience, we say that the family \mathcal{R} is representative if every $\mathcal{R}[B] \in \mathcal{R}$ is representative.

Now, we are ready to describe the solution to the r -Multipath problem (see Algorithm 2 for global pseudocode). The algorithm is given a quadtree cell C and a set of line segments S . The task is to output the union of sets $\mathcal{R}^*[B]$ for every $B \subseteq \partial C$, where B has size m and it is fine with

S , and $\mathcal{R}^*[B]$ is representative of $\mathcal{M}(B)$. We start the description of the algorithm with a case distinction based on the type of the given cell in the quadtree.

In the *base case*, we consider a cell that has one or zero points. Next, we consider another special case, i.e., the *compressed case*, when the given cell has only one child in the compressed quadtree. After that, we show how to combine 2^d children in the *non-compressed non-leaf case* paragraph.

Base case We start with the base case, where the cell C is a leaf of the quadtree and contains at most one input point. Consider all possible sets B that are fine with S . This gives an instance of at most $|B| + 1$ points and we can use an exact algorithm to get a set $\mathcal{R}^*[B]$ in time $2^{\mathcal{O}(|B|)}$. We can achieve that with a standard dynamic programming procedure: Let us fix B and let p be the only input point inside C (if it exists). For every $X \subseteq B$ we will compute a table $\text{BC}[X]$ that represents $\mathcal{M}(X)$ for every $X \subseteq B$. Initially $\text{BC}[\emptyset] = \{(\emptyset, 0)\}$ and if p exists, then for every $a, b \in B$ let $\text{BC}[a, b] := \{ \{(a, b)\}, \text{dist}(a, p) + \text{dist}(p, b) \}$, which means that p is connected to the portals $a, b \in B$. Next, we compute $\text{BC}[X]$ for every $X \subseteq B$ with the following dynamic programming formula.

$$\text{BC}[X] := \text{reduce} \left(\bigcup_{\substack{u, v \in X \\ u \neq v}} \left\{ (M \cup \{(u, v)\}, \text{wt}(M) + \text{dist}(u, v)) \mid (M, \text{wt}(M)) \in \text{BC}[X \setminus \{u, v\}] \right\} \right)$$

For a fixed B this algorithm runs in $\mathcal{O}(|\mathcal{R}^*[B]| \cdot 2^{\mathcal{O}(|B|)})$ time and correctly computes $\text{BC}[B] = \mathcal{R}^*[B]$ (cf., [10, Theorem 3.8] for details of an analogous dynamic programming subroutine).

Compressed case In this case, we are given a large cell C_{out} and its only child C_{in} . From the dynamic programming algorithm, we know the solution to C_{in} for all relevant $B_{\text{in}} \subseteq \partial C_{\text{in}}$, and the task is to connect these portals to the portals $B_{\text{out}} \subseteq C_{\text{out}}$. We do dynamic programming similar to the one seen in the base case. We say that a pair $B_{\text{in}}, B_{\text{out}}$ where $B_{\text{out}} \subset \partial C_{\text{out}}$ and $B_{\text{in}} \subset \partial C_{\text{in}}$ are fine with S if they are individually fine with S , and if $\partial C_{\text{out}} \cap \partial C_{\text{in}} \neq \emptyset$, then $B_{\text{out}} \supset B_{\text{in}} \cap \partial C_{\text{out}}$. For each fixed pair $B_{\text{out}}, B_{\text{in}}$ that are fine with S , we compute a table $\text{DBC}[X]$ (mnemonic for *dummy base case*) that represents $\mathcal{M}(X)$ (where the paths *need not cover* any input points) for every multiset $X \subseteq B_{\text{out}} \uplus B_{\text{in}}$. Note that the cell C_{out} can be regarded as the disjoint union of C_{in} and a *dummy leaf cell* that has region $C_{\text{out}} \setminus C_{\text{in}}$. Initially, we set $\text{DBC}[\emptyset] = \{(\emptyset, 0)\}$. We can then compute the values for the dummy base cases DBC with the same formula as for the base case.

$$\text{DBC}[X] := \text{reduce} \left(\bigcup_{\substack{u, v \in X \\ u \neq v}} \left\{ (M \cup \{(u, v)\}, \text{wt}(M) + \text{dist}(u, v)) \mid (M, \text{wt}(M)) \in \text{DBC}[X \setminus \{u, v\}] \right\} \right)$$

Let \mathcal{R}^* be the table of these sets for all $B_{\text{out}}, B_{\text{in}}$ that are fine with S , i.e., $\mathcal{R}^*[X] = \text{DBC}(X)$ for all $X \subseteq B_{\text{out}} \cup B_{\text{in}}$. In order to get representative sets $\mathcal{R}[B_{\text{out}}]$ of $\mathcal{M}(B_{\text{out}})$ for every $B_{\text{out}} \subset \partial C_{\text{out}}$ that is fine with S , we can combine the representative set $\mathcal{R}_{\text{in}}^*$ of C_{in} and \mathcal{R}^* (see Algorithm 1).

Observe that for a fixed B_{out} and B_{in} this algorithm runs in $\mathcal{O}(|\mathcal{R}^*[B_{\text{out}}]| \cdot |\mathcal{R}^*[B_{\text{in}}]| \cdot 2^{\mathcal{O}(|B_{\text{out}}| + |B_{\text{in}}|)})$ time and correctly computes the distances and matchings for every that are $B_{\text{out}} \subseteq \partial C_{\text{out}}$, $B_{\text{in}} \subseteq \partial C_{\text{in}}$ that are fine with S .

Non-compressed non-leaf case For non-compressed non-leaf cells C we combine the solutions of cells of one level lower. Let C_1, \dots, C_{2^d} be the children of C in the compressed quadtree. Also, let \mathcal{R}_i be the solution to the r -Multipath problem in cell C_i that we get recursively. Next we

```

```

Algorithm 2: Pseudocode of the dynamic programming for the Multipath problem

Next, if the matchings M_1, \dots, M_{2^d} are compatible, we *join* them (join can be thought of as $2^d - 1$ joins of matchings defined in [10]). This operation will give us the matching obtained from $M_1 \cup \dots \cup M_{2^d}$ by contracting degree-two edges if no cycle is created, and gives us matchings on the boundary (i.e., set B) and information about the connection between these points (i.e., a matching M on the set B).

If B is fine with S , then we insert M into $\mathcal{R}[B]$ with weight being the sum of the weights of matchings M_1, \dots, M_{2^d} . At the end, we will use the operation *reduce* to decrease the sizes of all $\mathcal{R}[B]$ and still get a representative set of size $2^{\mathcal{O}(|B|)}$. The corresponding pseudo-code is given in Lines 5 to 13 of Algorithm 2.

Overall Algorithm

Lemma 4.3. *For a cell C and a fixed B that is fine with respect to S , the set $\mathcal{R}[B]$ computed in Algorithm 2 is representative of $\mathcal{M}(B)$.*

Proof. The proof is by induction on $|C \cap P|$. For $|C \cap P| \leq 1$ the lemma follows from the correctness of the base case. Next we assume that $|C \cap P| > 1$ and has some children C_1, \dots, C_{2d} in the quadtree. Let us fix some $B \subseteq \partial C$ of size m that is fine with respect to S , a matching M on B and an optimal solution, i.e., collection of r -simple paths $\text{OPT}(S, B, M, r) = \{\pi_1, \dots, \pi_{|B|/2}\}$ with distinct endpoints in B that realize matching M . Because $\text{OPT}(S, B, M, r)$ is r -simple, there exists $B_1 \subseteq \partial C_1, \dots, B_{2d} \subseteq \partial C_{2d}$ that are fine with respect to S and matchings M_1, \dots, M_{2d} on B_1, \dots, B_{2d} such that $\text{OPT}(S, B, M, r)$ crosses boundaries between C_1, \dots, C_{2d} exactly in B_1, \dots, B_{2d} and the matchings M_1, \dots, M_{2d} are compatible and their join is M . Hence in Line 10, Algorithm 2 finds B and the matching M . Next we will insert it with the weight $\text{wt}(\text{OPT}(S, B, M, r))$ to the set $\mathcal{R}[B]$. Since the join operation preserves representation (see [10, Lemma 3.6]), the set $\mathcal{R}[B]$ is a representative set. Finally, by Lemma 4.2 we assert that the `reduce` algorithm also outputs a representative set. An analogous argument shows that the sets $\mathcal{R}[B]$ computed for compressed cells are also representative. \square

Lemma 4.4. *Algorithm 2 runs in time $\mathcal{O}(n \cdot |\mathcal{R}|^{2^{\mathcal{O}(d)}} \cdot 2^{\mathcal{O}(|B|)})$, where n is the number of points in C .*

Proof. In the algorithm, we use a compressed quadtree, therefore the number of cells to consider is $\mathcal{O}(n)$. Algorithm 2 in the base case runs in time $\sum_B |\mathcal{R}| 2^{\mathcal{O}(|B|)} = |\mathcal{R}|^{\mathcal{O}(1)} 2^{\mathcal{O}(|B|)}$. The for loop in Line 8 of Algorithm 2 has $|\mathcal{R}_1| \cdots |\mathcal{R}_{2d}| = \mathcal{O}(|\mathcal{R}|)^{2d}$ many iterations, and the analogous for loop in the compressed case has $|\mathcal{R}_{\text{in}}| \cdot |\mathcal{R}_{\text{empty}}^*| \cdot 2^{\mathcal{O}(|B|)} = 2^{\mathcal{O}(|B|)} |\mathcal{R}|^{\mathcal{O}(1)}$ iterations. Checking whether matchings M_1, \dots, M_{2d} are compatible and joining them takes $\text{poly}(r, 2^d)$ time. Moreover, checking whether B is fine with respect to the set S can be checked in $r^{\mathcal{O}(d)}$ time because Lemma 4.1 guarantees us that access to these points can be achieved through the lists. The for loop in Line 13 of Algorithm 2 has at most $|\mathcal{R}|$ many iterations. In each iteration, we invoke the `reduce` procedure that takes $|\mathcal{R}| \cdot 2^{\mathcal{O}(|B|)}$ time according to Lemma 4.2. Note that the running times in the compressed case can be bounded the same way. This yields the claimed running time. \square

Lemma 4.5. $|\mathcal{R}| \cdot 2^{\mathcal{O}(|B|)} \leq 2^{\mathcal{O}(r^{d-1})}$

Proof. First, recall that $|B| < 4dr^{d-1} + 2^d = \mathcal{O}(r^{d-1})$ as Definition 3.1 implied that $|B \cap F^*| \leq 2r^{d-1}$ for each of the $2d$ faces. Next, we bound the number of possible sets B . We select sets $B \cap F^*$ of size at most m_F , where the points can be chosen from $\text{grid}(\text{ex}(F), r^{2d-2}/m_F) \cap F^*$, each with multiplicity 0, 1 or 2, so $|B \cap F^*| \leq 2m_F \leq 2r^{d-1}$ or (when some facet F^* is crossed exactly once) it can also be chosen from $S \cap F$ with multiplicity at most 2. Including the choice of some subset of the 2^d corners of C , each of multiplicity at most 2, there are at most

$$3^{2^d} \cdot 3^{2d} \binom{|S \cap \partial C|}{2d} \cdot \prod_F \left(\sum_{m_F=1}^{r^{d-1}} 3^{m_F} \binom{r^{2d-2}/m_F}{m_F} \right)$$

possible choices for B . Recall that there are at most $2d$ possible facets F . Moreover, Lemma 4.1 guarantees that S crosses each face at most $1/\varepsilon^{\mathcal{O}(d)}$ times, hence $|S \cap F| \leq 1/\varepsilon^{\mathcal{O}(d)} = r^{\mathcal{O}(d)}$ and $\binom{|S \cap \partial C|}{2d} \leq r^{\mathcal{O}(d^2)}$. By Claim 3.4, $\binom{r^{2d-2}/m_F}{m_F}$ is bounded by $2^{\mathcal{O}(r^{d-1})}$, and $3^{m_F} = 2^{\mathcal{O}(r^{d-1})}$. Therefore,

the number of possible choices for B is at most

$$3^{2^d} \cdot r^{\mathcal{O}(d^2)} \cdot \prod_F \left(\sum_{m_F=1}^{r^{d-1}} 2^{\mathcal{O}(r^{d-1})} \right) = 2^{\mathcal{O}(r^{d-1})}.$$

Next we bound $\mathcal{R}[B]$ for a fixed B . Note that in Algorithm 2, we always use the subroutine **reduce** to reduce the size of $\mathcal{R}[B]$. Lemma 4.2 guarantees that this procedure outputs a set $\mathcal{R}^*[B]$ of size at most $2^{|B|-1}$. Multiplying all of these factors together gives us the desired property. \square

Combining all of the above observations gives us the following Corollary.

Corollary 4.6. *Suppose we are given a compressed quadtree Q , a point set P with n points, and a set S of segments that cross each facet of Q at most $r^{\mathcal{O}(d)}$ times. Let $\pi^S \subseteq S$ be the shortest salesman tour of P within S . Then, we can find the shortest r -simple salesman tour π' that visits all points in P and, if π^S crosses any facet of Q exactly once, then π' crosses it at the same point, in $n \cdot 2^{\mathcal{O}(r^{d-1})}$ time.*

We can now proceed with the proof of the algorithm's existence from Theorem 1.1.

Proof of the algorithmic part of Theorem 1.1. For the running time observe that Step 1, 2, 3 and 5 take $\text{poly}(1/\varepsilon) \cdot n \log n$ time. In Step 4 we set r to $\mathcal{O}(d^{5/2}/\varepsilon)$ and by Corollary 4.6 we get an extra $n \cdot 2^{\mathcal{O}(d^{5/2}/\varepsilon)^{d-1}}$ factor. Overall, this gives the claimed running time.

For the approximation ratio, assume that π is the optimal solution. Note that Step 1 perturbs the solution by at most $\mathcal{O}(\varepsilon \cdot \text{wt}(\pi))$. In Step 3, by the Lemma 4.1 we are guaranteed that there exists a tour π^S of weight $\mathcal{O}(\varepsilon \cdot \text{wt}(\pi))$ larger than π (in expectation). Next in Step 4, Corollary 4.6 applied to the set S , guarantees that that we find a salesman tour π' that satisfies the condition of Structural Theorem 3.3 for π^S . It means that $\mathbb{E}_{\mathbf{a}}[\text{wt}(\pi') - \text{wt}(\pi^S)] = \mathcal{O}(\varepsilon \cdot \text{wt}(\pi))$ and $\text{wt}(\pi') = (1 + \mathcal{O}(\varepsilon))\text{wt}(\pi)$. Applying Step 5 on π' can only decrease the total weight of π' . This concludes the proof of the algorithmic part of Theorem 1.1. \square

It is easy to see that the algorithm can be derandomized by trying all possibilities for \mathbf{a} .

Remark 4.7. One can swap out the patched spanner of Rao and Smith in *Step 3* with Arora's structure theorem in order to avoid using spanners, which can be beneficial for certain problems. As a result, when the patched tour has a single crossing in a facet, its location would have to be guessed from Arora's portals, which are grid $\left(\text{ex}(F), \mathcal{O}\left(\frac{\log(1/\varepsilon)}{\varepsilon^{1/(d-1)} \log n}\right)\right)$. This results in $\text{poly}(1/\varepsilon) \cdot (\log n)^{d-1}$ potential locations for the crossing in the facet rather than just $\text{poly}(1/\varepsilon)$ as with spanners. For a given cell C , there would be $\prod_F \left(\binom{r^{2d-2}/m_F}{m_F} + (\text{poly}(1/\varepsilon) \log n)^{d-1} \right) = 2^{\mathcal{O}(1/\varepsilon^{d-1})} (\log n)^{(d-1) \cdot 2d}$ options. This results in a spanner-free algorithm with a slightly slower running time of $2^{\mathcal{O}(1/\varepsilon^{d-1})} n (\log n)^{2d-2d} = 2^{\mathcal{O}(1/\varepsilon^{d-1})} n \text{poly}(\log n)$.

5 Algorithm for EUCLIDEAN and RECTILINEAR STEINER TREE

In this subsection, we consider extensions to two variants of STEINER TREE: EUCLIDEAN STEINER TREE and RECTILINEAR STEINER TREE. As most techniques work the same way for these problems, we only sketch the differences compared to our algorithm for EUCLIDEAN TSP.

The notion of spanners for the Steiner tree problems is more complicated (one requires so-called banyans). We summarize this notion at the end of this section. Similarly to how we used spanners

for the algorithm for TSP, here we use banyan to determine a set \tilde{S} of points. This set will consist of $(1/\varepsilon)^{\mathcal{O}(d)}$ portals for each facet that we use in the case of single crossing. Consequently, we say that a portal set $B \subset \partial C$ is *valid* with respect to \tilde{S} if for each facet F of C , we have that either (i) $B \cap F = \{p\}$ and $p \in \tilde{S} \cap F$, or (ii) $B \subset \text{grid}(\text{ex}(F), r^{2d-2}/m_F)$ where $|B \cap F| \leq m_F \leq r^{d-1}$.

Additionally, we need to track connectivity requirements with partitions instead of matchings. A partition M of B is realized by a forest if for any $b, b' \in B$, we have that b and b' are in the same tree of the forest if and only if they are in the same partition class of M . The problem we need to solve in cells is the following.

r-Simple Steiner Forest Problem

Input: A nonempty cell C in the shifted quadtree, a portal set $B \subseteq \partial C$ that is valid with \tilde{S} , and a partition M on B

Task: Find an *r*-simple forest $\mathcal{P}_{B,M}$ of minimum total length that satisfies the following properties.

- The forest $\mathcal{P}_{B,M}$ spans all input points inside C .
- $\mathcal{P}_{B,M}$ crosses ∂C only through portals from B .
- $\mathcal{P}_{B,M}$ realizes the partition M on B .

The rank-based approach [10, 16] was originally conceived with partitions in mind, and therefore we can still use representative sets and the reduce algorithm as before (although the upper bound on $\mathcal{R}^*[B]$ of $2^{|B|/2-1}$ from Lemma 4.2 needs to be increased to $2^{|B|-1}$). The main difference between TSP and Steiner Tree is the handling of leaf and dummy leaf cells (i.e., the base case and the dynamic programming in the compressed case).

Leaves and dummy leaves for RECTILINEAR STEINER TREE. Consider now a point set $Q \subset \mathbb{R}^d$. The *Hanan-grid* of Q is the set of points that can be defined as the intersection of d distinct axis-parallel hyperplanes incident to d (not necessarily distinct) points of Q . By Hanan's and Snyder's results [33, 54], the optimum rectilinear Steiner tree for a given point set Q lies in the Hanan-grid of Q . In particular, in a leaf cell, our task is to find a representative set for a fixed set of $k = \mathcal{O}(1/\varepsilon)^{d-1}$ terminals (which includes the input point in case of a non-empty leaf cell). Note that for each fixed B , this task can be done in the graph G defined by the Hanan-grid of $B \cup (C \cap P)$, where the edge weights correspond to the ℓ_1 distance. The graph G has $\text{poly}(1/\varepsilon)$ vertices and edges. Let H be the set of vertices in the Hanan-grid of B , i.e., the set of possible Steiner points for the terminal set B , where B is the set of portals on the boundary of the cell.

To solve the base case efficiently, we will use a dynamic programming subroutine inspired by the classical Dreyfus-Wagner algorithm [24]. Let $\text{ST}[D, v]$ be the minimum possible weight of a Steiner Tree for $D \cup \{v\}$, for all $D \subseteq B$ and $v \in H$. In the base case $\text{ST}[\{b\}, v] = \|b - v\|_1$. We can compute it efficiently with the following dynamic programming formula:

$$\text{ST}[D, v] := \min_{\substack{u \in H \\ \emptyset \neq D' \subset D}} \left\{ \text{ST}[D', u] + \text{ST}[D \setminus D', u] + \|u - v\|_1 \right\}.$$

This algorithm correctly computes a minimum weight Steiner Tree that connects $D \subseteq B$ and the running time of this algorithm is $2^{\mathcal{O}(|B|)} \cdot \text{poly}(1/\varepsilon)$ (see [24]). Finally, let $\text{ST}[X] := \min_v \text{ST}[X, v]$.

Next, we take care of all partitions of B . This involves a similar dynamic programming as in the base case of TSP. Let $\text{SF}(X)$ be the set $\mathcal{R}^*[X]$ that represents every partition of $X \subseteq B$. Namely, for every Steiner forest F with connected components B_1, \dots, B_k , such that $B_1 \uplus \dots \uplus B_k = X$ there exists $M \in \mathcal{R}^*[X]$, such that the union of F and a forest F_M whose connected components

correspond to M gives a tree that spans X . At the beginning, we set $\text{SF}[\emptyset] = \{\emptyset, 0\}$. Next, we use the following dynamic programming to compute $\text{SF}[X]$ for all $X \subset B$:

$$\text{SF}[X] := \text{reduce} \left(\bigcup_{Y \subset X} \left\{ (M \cup \{Y\}, \text{wt}(M) + \text{ST}[Y]) \mid (M, \text{wt}(M)) \in \text{SF}[X \setminus \{Y\}] \right\} \right)$$

The number of table entries $\text{SF}[X]$ is $2^{|B|}$. To compute each entry we need $2^{\mathcal{O}(|B|)} |\mathcal{R}^*|$ time. Because **reduce** guarantees that $|\mathcal{R}^*| \leq 2^{\mathcal{O}(|B|)}$ we can bound the running time of the dynamic programming algorithm by $2^{\mathcal{O}(|B|)}$. We know that $|B| \leq \mathcal{O}(1/\varepsilon^{d-1})$ and the running time bound for the base case follows. The correctness follows from the correctness of the procedure **reduce** for partitions (see [10]) and the fact that $\text{ST}[Y]$ is an optimal Steiner tree on the terminal set $Y \subseteq B$.

Leaves and dummy leaves for EUCLIDEAN STEINER TREE. In the case of EUCLIDEAN STEINER TREE, we can pursue a similar line of reasoning. First, notice that in leaf and dummy leaf cells, it is sufficient to compute a $(1 + \mathcal{O}(\varepsilon))$ -approximate forest for $\tau' \cap C$, as these forests are a subdivision of τ' . By the grid perturbation argument within C , it is sufficient to consider forests where the Steiner points lie in a regular d -dimensional grid of side length $\mathcal{O}(1/\varepsilon)$. Let V_C be the set of $\mathcal{O}(1/\varepsilon)^d$ grid points obtained this way, and let G be the complete graph on V_C where the edge weights are defined by the ℓ_2 norm. Then the minimum Steiner forest of B for a given partition M is equal to the corresponding forest within G . In particular, it is sufficient to compute the representative set of all partitions of B in G . To achieve that, we use exactly the same dynamic programming as in the base case for rectilinear Steiner Tree. We only need to change the distance in the procedure **ST** to be ℓ_2 distance. Note that **ST** works in $2^{\mathcal{O}(|B|)} \cdot \text{poly}(|V_C|)$ and the running time of the dynamic programming for **SF** is bounded by $2^{\mathcal{O}(|B|)} \cdot \text{poly}(|V_C|)$.

Single crossings and banyans Similarly to *Step 3* in our algorithm for Euclidean TSP, we use the structure theorem based on the results of Rao and Smith [52] and Czumaj et al. [18]. We include the details of the proofs in Appendix A for completeness. Note that this is taken almost verbatim from [18]. We modify their approach to make it work in the required time for both the rectilinear and the Euclidean case. Let $\text{ST}(P; E)$ be the minimum length Steiner tree with terminal set P which is allowed to use only segments from E as edges.

Lemma 5.1. *There is a $\text{poly}(1/\varepsilon)n \log(n)$ time algorithm that, given point set P and the random offset \mathbf{a} of the dissection, computes a set of segments \tilde{S} such that:*

1. $\mathbb{E}_{\mathbf{a}}[\text{wt}(\text{ST}(P; \tilde{S})) - \text{wt}(\text{ST}(P; \mathbb{R}^d \times \mathbb{R}^d))] = \mathcal{O}(\varepsilon \cdot \text{wt}(\text{ST}(P; \mathbb{R}^d \times \mathbb{R}^d)))$.
2. *for every facet F of $D(\mathbf{a})$ it holds that $|F \cap \tilde{S}| = 1/\varepsilon^{\mathcal{O}(d)}$.*

Lemma 5.1 is analogous to Lemma 4.1. It gives us the set \tilde{S} of segments such that (i) there exists a Steiner Tree that uses only edges from \tilde{S} , (ii) in expectation the excess weight of the tree is only $\mathcal{O}(\varepsilon \text{wt}(\text{OPT}))$, and (iii) the segments of \tilde{S} cross every cell of the quadtree at most $(1/\varepsilon)^{\mathcal{O}(d)}$ times. Lemma 5.1 works for both Rectilinear and Euclidean Steiner Tree (see Appendix A).

We use Lemma 5.1 analogously to Lemma 4.1. Namely, when our dynamic programming procedure guesses that an optimum solution of the r -simple Steiner Forest Problem crosses a cell facet F exactly once, then we guess the crossing exactly from $\tilde{S} \cap F$. Lemma 5.1 guarantees that the number of candidates is $(1/\varepsilon)^{\mathcal{O}(d)}$, which is less than $2^{\mathcal{O}(1/\varepsilon)^{d-1}}$.

Putting the above ideas together proves the algorithmic part of Theorem 1.2.

6 Lower bounds

Our starting point is the gap version of the Exponential Time Hypothesis [23, 46], which is normally abbreviated as Gap-ETH. The hypothesis is about the MAX 3SAT problem, where one is given a 3-CNF formula with n variables and m clauses, and the goal is to satisfy the maximum number of clauses.

Gap Exponential Time Hypothesis (Gap-ETH) (Dinur [23], Manurangsi and Raghavendra [46]). *There exist constants $\delta, \gamma > 0$ such that there is no $2^{\gamma m}$ algorithm which, given a 3-CNF formula ϕ on m clauses, can distinguish between the cases where (i) ϕ is satisfiable or (ii) all variable assignments violate at least δm clauses.*

Let MAX-(3,3)SAT be the problem where we want to maximize the number of satisfied clauses in a formula ϕ where each variable occurs at most 3 times and each clause has size at most 3. (Let us call such formulas (3,3)-CNF formulas.) Note that the number of variables and clauses in a (3,3)-CNF formula are within constant factors of each other. Papadimitriou [50, pages 315–318] gives an L -reduction from MAX-3SAT to MAX-(3,3)SAT, which immediately yields the following:

Corollary 6.1. *There exist constants $\delta, \gamma > 0$ such that there is no $2^{\gamma n}$ algorithm that, given a (3,3)-CNF formula ϕ on n variables and m clauses, can distinguish between the cases where (i) ϕ is satisfiable or (ii) all variable assignments violate at least δm clauses, unless Gap-ETH fails.*

6.1 Lower bound for approximating EUCLIDEAN TSP

In this subsection we prove the following Theorem, which will conclude the proof of Theorem 1.1.

Theorem 6.2. *For any d there is a $\gamma > 0$ such that there is no $2^{\gamma/\varepsilon^{d-1}} \text{poly}(n)$ time $(1 + \varepsilon)$ -approximation algorithm for EUCLIDEAN TSP in \mathbb{R}^d , unless Gap-ETH fails.*

We show that the reduction given in [21] from (3,3)-SAT to EUCLIDEAN TSP (see also the equivalent reduction for HAMILTONIAN CYCLE in [36]) can also be regarded as a reduction from MAX-(3,3)SAT, and it gives us the desired bound. We start with the short summary of the construction from [21].

The construction of [21] heavily builds on the construction of [35] for HAMILTONIAN CYCLE in grid graphs and [51] for HAMILTONIAN CYCLE in planar graphs. A basic familiarity with the lower bound framework [21] as well as the reductions in [51] and [35] is recommended for this section.

Overall, the construction of [21] takes a (3,3)-CNF formula ϕ as input, and in polynomial time creates a set of points $P \subset \mathbb{R}^d$ where each point has integer coordinates, and P has a tour of length $|P|$ if and only if ϕ is satisfiable. The set P can be decomposed into *gadgets*, which are certain smaller subsets of P .

We will use a notation proposed by [47] to describe properties of gadgets. We say that a set of walks is a *traversal* if each point of a given gadget is visited by at least one of the walks. Note that for a given gadget a TSP tour induces a traversal simply by taking edges adjacent to the points of a gadget.

Each gadget G has a set of *visible points* $S \cup T \subseteq G$. A *state* q of gadget G with visible points $S \cup T \subseteq G$ is a collection of pairs (s_i^q, t_i^q) for $i \in [k]$ where $s_i^q \in S$ and $t_i^q \in T$. We say that a traversal $\mathcal{W} = \{W_1, \dots, W_k\}$ represents state q if walk W_i starts in s_i^q and ends in t_i^q for each $i \in [k]$. The set of allowed states form the *state space* Q of the gadget. Finally, for a given TSP tour π and a gadget G we say that a traversal induced on G by an (bidirected) tour π has the following *weight*.

$$\text{wt}(T, G) := \sum_{\substack{p \in G, \\ (p, x) \in \pi}} \frac{\|p - x\|_2}{2} - |G|,$$

where (p, x) are ordered pairs, i.e., edges induced by G are counted twice. Hence if a traversal visits all vertices exactly once and all edges are of length 1, then the weight of the traversal is 0. Note that the input/output edges contribute 1/2 to the weight of the traversal.

Recall that in the construction developed in [21], the points are placed on a grid of integral coordinates. The tour that traverses a gadget in a “bad” way (i.e., in a way that does not correspond to a state of the gadget) has to either visit a point more than once or it must use some diagonal edge of length at least $\sqrt{2}$. Hence a weight of a traversal that does not represent any state of the gadget needs to have weight at least $\frac{\sqrt{2}-1}{2}$.

Observation 6.3. *Every gadget G with state space \mathcal{Q} developed in [21] has two properties:*

- (i) *for every state $q \in \mathcal{Q}$ there exists a traversal \mathcal{W}_q of weight 0 that represents q , and*
- (ii) *any traversal \mathcal{W} that does not represent any $q \in \mathcal{Q}$ is of weight at least $\frac{\sqrt{2}-1}{2}$.*

Now, we are ready to describe more concretely the gadgets in [21]. There are size-3 and size-2 clause gadgets with state spaces $\mathcal{Q}_3 = \mathbb{Z}_2^3 \setminus (0, 0, 0)$ and $\mathcal{Q}_2 = \mathbb{Z}_2^2 \setminus (0, 0)$ respectively. Both types of clause gadgets consist of a constant number of points with integer coordinates in $\{0, \dots, c_0\}^d$ (translated appropriately). Clause gadgets are used to encode clauses of the MAX-(3,3)SAT instance. Similarly, [21] developed a *Variable Gadget* for state space $\mathcal{Q} = \mathbb{Z}_2$, that is used to encode the values of variables in the MAX-(3,3)SAT instance.

A *wire* is a constant width grid path with state space \mathbb{Z}_2 . It is used to transfer information from a Variable gadget to a Clause Gadget (note that a wire does have a constant number of points). In the 2-dimensional case [21] define a *crossover gadget* that has state space $\mathbb{Z}_2 \times \mathbb{Z}_2$ that is able to transfer information both horizontally and vertically. It is added in the junction of two crossing wires in order to enable transfer of two independent bits of information. We and [21] do not need crossing gadgets in higher dimensions.

In the reduction of [21] Clause Gadgets are connected with Variable Gadgets by wires. When a gadget and a wire are connected, then they always share a constant number of points. Clauses are connected to Variables in the natural way: Namely, let T_{OPT} be the optimal TSP path. Any clause gadget $\phi = x_1^* \vee x_2^* \vee x_3^*$ where $x_i^* \in \{x_i, \neg x_i\}$ ($i = 1, 2, 3$) is connected by a wire to the variable gadgets x_1, x_2, x_3 . Moreover if a subpath of the optimal tour T_{OPT} goes through a clause gadget ϕ and represents a state (y_1, y_2, y_3) , then the traversal of P inside the wire connecting ϕ with x_i represents state y_i , and the traversal of T_{OPT} inside the gadget of x_i represents state y_i if x_i has a positive literal in this clause and $\neg y_i$ if it has a negative literal there.

The final detail that [21] needs is to place all the gadgets along a cycle. They add a “snake” (a width 2-grid path based on [35]) through variable and clause gadgets (see [36, Figure 8.10] for a schematic picture of construction in 3-dimensions). A snake is used to represent a long graph edge. It has two states, corresponding to the long edge being in the Hamiltonian Cycle or not. Note that every point in the construction is part of one gadget or gadget and a wire or a gadget and a snake, and distinct gadgets have distance more than 1.

We are now ready to prove the lower bound for EUCLIDEAN TSP.

Proof of Theorem 6.2. We use a reduction from MAX-(3,3)SAT. For an input point set P let OPT denote the minimum tour length. Suppose for the sake of contradiction that for every $\gamma > 0$ there is

an algorithm that for any point set P and $\varepsilon > 0$ returns a traveling salesman tour of length at most $(1 + \varepsilon)OPT$ in $2^{\gamma/\varepsilon^{d-1}}$ poly(n) time. Fix some integer $d \geq 2$, and let ϕ be a (3,3)-CNF formula, and apply the construction of [21] to obtain a point set $P \subset \mathbb{R}^d$ satisfying Observation 6.3. Note that P has a TSP tour of length $|P|$ if and only if ϕ is satisfiable. Let c be such that $|P| = cn^{d/(d-1)}$.

Suppose now that P has a TSP tour T_{apx} of length $(1 + \varepsilon)|P|$. We mark a gadget G to be *destroyed* if the traversal of T_{apx} does not represent any state of the gadget. By the properties of the gadget, such a traversal has weight at least $\frac{\sqrt{2}-1}{2}$. Therefore, there can be at most $\frac{4\varepsilon|P|}{\sqrt{2}-1}$ destroyed gadgets (note that 1 edge of T_{apx} can be a part of at most 2 traversals).

For a fixed variable x let V_x be the variable gadget that encodes it. We will mark a variable x “bad” if one of the following conditions holds:

- the gadget V_x is destroyed, or
- any of the wires or snakes connecting to V_x is destroyed, or
- a crossover gadget on one of the wires of V_x is destroyed, or
- any clause that is connected to V_x is destroyed.

Consequently, one destroyed gadget may result in up to 3 variables being marked bad (in case the destroyed gadget corresponds to a size-3 clause). Since there are at most $\frac{4\varepsilon|P|}{\sqrt{2}-1}$ destroyed gadgets, we can have at most $12\frac{\varepsilon|P|}{\sqrt{2}-1} < 30\varepsilon|P|$ bad variables. Therefore, for all variables that have not been marked “bad”, as well as the connected wires, snakes, crossovers, and clause gadgets only have incident edges of length 1. Just as in the original construction, we can use the length 1 edges of the tour in these variable gadgets to define a partial assignment for the non-bad variables. This partial assignment is guaranteed to satisfy all the clauses that contain only non-bad variables. Since each variable occurs in at most 3 clauses, we have at most $90\varepsilon|P|$ clauses that have a bad variable, so the partial assignment for the non-bad variables will satisfy at least $m - 90\varepsilon|P| = \left(1 - 90\varepsilon c \frac{n^{d/(d-1)}}{m}\right) m$ clauses.

We can now set $\varepsilon = \frac{\delta m}{90cn^{d/(d-1)}}$. Since $m = \Theta(n)$, we have that $\varepsilon = \Theta(1/n^{1/(d-1)})$. We can now apply the approximation algorithm for EUCLIDEAN TSP with the above ε on P . As a result, we can distinguish between a satisfiable formula (and thus a tour of length $|P|$) and a formula in which all assignments violate at least δm clauses, where therefore any tour has length more than $(1 + \varepsilon)|P|$. Since the construction time of P is polynomial in n , the total running time of this algorithm is $2^{\gamma/\varepsilon^{d-1}}$ poly(n) = $2^{\gamma c' n}$ for some constant c' . The existence of such algorithms for all $\gamma > 0$ would therefore violate Gap-ETH by Corollary 6.1. \square

6.2 Lower bound for approximating RECTILINEAR STEINER TREE

We will now prove the lower bound of Theorem 1.2, which can be stated as follows.

Theorem 6.4. *For any $d \geq 2$ there is a $\gamma > 0$ such that there is no $(1 + \varepsilon)$ -approximation algorithm for RECTILINEAR STEINER TREE in \mathbb{R}^d that has running time $2^{\gamma/\varepsilon^{d-1}}$ poly(n), unless Gap-ETH fails.*

The proof of Theorem 6.4 has three stages. In the first stage, we give a reduction (in several steps) from MAX-(3,3)SAT, which converts a (3, 3)-CNF formula ϕ to a variant of connected vertex cover on graphs drawn in a d -dimensional grid. In the second stage, given such a connected vertex cover instance, we create a point set $P \subset \mathbb{R}^d$ in polynomial time. A satisfiable formula ϕ will

correspond to a minimum connected vertex cover, which will correspond to minimum rectilinear Steiner tree. The harder direction will be to show that from a $(1 + \varepsilon)$ -approximate rectilinear Steiner tree T we can find a good connected vertex cover and therefore a good assignment to ϕ . Before we can define a connected vertex cover based on the tree T , we need to show that we can *canonize* T , i.e., to modify parts of T in a manner that does not lengthen T , and at the same time makes its structure much simpler. In the final stage, we use the canonized tree T and an argument similar to the one seen for EUCLIDEAN TSP above to wrap up the proof.

6.2.1 From MAX-(3,3)SAT to CONNECTED VERTEX COVER

The construction begins in a slightly different manner for $d = 2$ and for $d \geq 3$, but the resulting constructions will share enough properties so that we will be able to handle $d \geq 2$ in a uniform way in later parts of this proof.

Let ϕ be a fixed (3,3)-CNF formula on n variables, and let G be its *incidence graph*, i.e., G has one vertex for each variable and one vertex for each clause of ϕ , and a variable vertex and clause vertex are connected if and only if the variable occurs in the clause.

A *grid cube of side length ℓ* is a graph with vertex set $[\ell]^d$ where a pair of vertices is connected if and only if their Euclidean distance is 1. We say that a graph is *drawn in a d -dimensional grid cube of side length ℓ* if its vertices are mapped to distinct points of $[\ell]^d$ and its edges are mapped to vertex disjoint paths inside the grid cube.

Given a graph $G = (V, E)$, a vertex subset $S \subset V$ is a *vertex cover* if for any edge $e \in E$ there is a vertex incident to e in S . The set S is a *connected vertex cover* if S is a vertex cover and the subgraph induced by S is connected. The VERTEX COVER problem is to find the minimum vertex cover of a given graph on n vertices, while CONNECTED VERTEX COVER seeks the minimum connected vertex cover. If G is restricted to be in the class of graphs that can be drawn in an $n \times n$ grid, then the corresponding problems are called GRID EMBEDDED VERTEX COVER and GRID EMBEDDED CONNECTED VERTEX COVER. (Note that the graph itself may have up to n^2 vertices in these grid embedded problems.)

Grid embedding in \mathbb{R}^2 Given ϕ , [21] constructs a CNF formula ϕ' on $\mathcal{O}(n^2)$ variables such that the incidence graph G' of ϕ' is planar and it can be drawn in $[cn]^2$ for some constant c , and each variable of ϕ' occurs at most 3 times, and each clause has size at most 4. By introducing a new variable for each clause of size 4, we can replace a clause $(x_1 \vee x_2 \vee x_3 \vee x_4)$ with the clauses $(x_1 \vee x_2 \vee y) \wedge (\neg y \vee x_3 \vee x_4)$, and this corresponds to dilating the original clause vertex and subdividing it with the variable vertex of y in G' . One can then modify the drawing of G' accordingly. (The drawing of G' may need to be *refined*, i.e., scaled up by a factor of 3, while keeping the underlying grid unchanged, to provide enough space for the new vertices.) As a result, we get a (3,3)-CNF formula ϕ_2 whose incidence graph G_2 is planar and has a drawing in the grid $[cn]^2$ for some constant c .

Lemma 6.5. *The formula ϕ is satisfiable if and only if ϕ_2 is satisfiable. If ϕ_2 has an assignment that satisfies all but t clauses, then ϕ has an assignment that satisfies all but $6t$ clauses.*

Proof. The first statement follows from the construction. See also [21, 45]. For the second statement, we simply restrict the assignment to the set of variables that are also present in ϕ ; let us call these original variables. Note that an unsatisfied clause within a crossing gadget of ϕ_2 might make two variables “bad” (see the proof of Theorem 6.2 for a similar argument). Since each variable occurs at most 3 times, this means that up to 6 clauses may become unsatisfied. As all clauses either occur

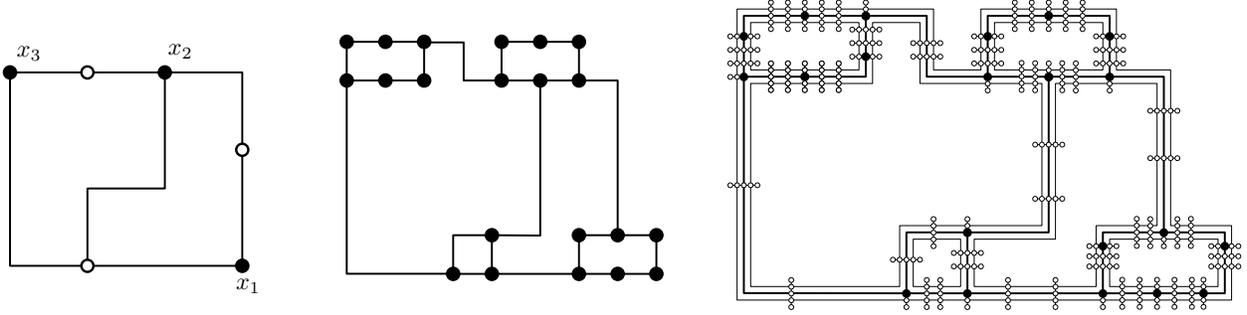

Figure 6: Left: incidence graph of $\phi = (x_1 \vee \neg x_2 \vee x_3) \wedge (x_1 \vee x_2) \wedge (x_2 \vee \neg x_3)$ drawn in a grid. Middle: an instance of VERTEX COVER where variables are replaced with length-6 variable cycles, and size-3 clauses are replaced with triangles. Right: adding a skeleton (see [28]) to get an instance of CONNECTED VERTEX COVER.

in a crossing gadget or are inside ϕ itself, having t unsatisfied clauses in ϕ_2 means that there can be at most $6t$ clauses that are unsatisfied by the assignment. \square

Initially, we mostly follow the first few steps of the connected vertex cover construction in [21]. Namely, refine this grid drawing by a factor of 4, that is, we scale the drawing from the origin by a factor of 4 while keeping the underlying grid unchanged. This allows us to replace the vertices corresponding to variables with cycles of length 6, where the selection of odd or even vertices on the cycle corresponds to setting the variable to true or false. We connect graph edges corresponding to true literals to distinct even vertices and graph edges corresponding to false literals to distinct odd vertices. Each vertex corresponding to the size 3 clause is replaced by a cycle of length 3, with one incoming edge for each of the literals. For vertices corresponding to the size 2 we subdivide one of the incident edges into a path of length 3. Finally, vertices corresponding to the clauses of size one can be removed in a preprocessing step. Let G_2^* be the resulting graph, which is drawn in an $\mathcal{O}(n) \times \mathcal{O}(n)$ grid. In particular, if G_2^* has n_2^* vertices, then $n_2^* = \mathcal{O}(n^2)$.

Note that each variable cycle needs at least 3 of its vertices in the vertex cover, each size-3 clause needs at least two vertices of its triangle in the vertex cover, and each size-2 clause needs at least two internal vertices of its path in the vertex cover. A size 3-clause should be satisfied by some literal, which would mean that the edge corresponding to this literal would be covered from the variable cycle, and therefore it is sufficient to select the other two vertices of the triangle. In a size-2 clause at least one of the contained literals should be true, which exactly corresponds to the fact that one of the endpoints of the corresponding edge has to be selected. Since there is a path of length 5 connecting these two vertices, we need to select the two odd or even index internal vertices from it. With these at hand, the following is a simple observation.

Lemma 6.6. *The formula ϕ_2 has a satisfying assignment if and only if G_2^* has a vertex cover of size $k_2^* = 3n' + 2m' = \mathcal{O}(n^2)$, where n' and m' are the number of variables and size-3 clauses in ϕ_2 . If G_2^* has a vertex cover of size $k_2^* + t$, then ϕ_2 has an assignment that satisfies all but at most $9t$ clauses.*

Proof. If ϕ_2 is satisfiable, then we select the true or false vertices on the variable cycles according to the assignment. In each clause, there is at least one literal that is true; we select the vertices on the clause cycle that correspond to the other two literals. The resulting set is clearly a vertex cover. On the other hand, every vertex cover must have at least $3n' + 2m'$ vertices, as in order to cover the variable cycles and the clause triangles individually, one needs at least 3 vertices per variable cycle and at least 2 vertices per clause triangle. Such a vertex cover in addition will select only even or odd vertices from variable cycles, which yields a variable assignment that satisfies ϕ_2 .

If G_2^* has a vertex cover of size $k_2^* + t$, then there can be at most t variable cycles or clause triangles where the number of vertices selected is more than 3 (respectively, 2). Therefore we can mark "bad" any variable whose cycle has more than 3 vertices or that appears in size-3 clause whose triangle has all vertices selected. Consequently, we have at most $3t$ bad variables. Since $3t$ variables can appear in at most $9t$ clauses, all but at most $9t$ clause triangles will have exactly two vertices selected. One can check that the assignment on the non-bad variables will then satisfy all but $9t$ clauses. \square

As a final step for the planar construction, we introduce the *skeleton* described by Garey and Johnson [28]; this again requires that we refine the drawing by a constant factor. The procedure subdivides each edge of the graph twice, using n_{sub} new vertices, and also adds n_{skel} *skeleton vertices*. An important property of the skeleton is that the number of newly added vertices is $n_{skel} + n_{sub} = \Theta(|V(G_2^*)| + |E(G_2^*)|) = \mathcal{O}(n^2)$. The resulting graph is drawn in an $\mathcal{O}(n) \times \mathcal{O}(n)$ grid. We use a final 4-refinement to ensure that inside the ℓ_1 -disk of radius 4 around each vertex v the only grid edges being used are on the horizontal or vertical line going through v . Let G_2 denote the resulting plane graph (i.e., the graph together with its embedding in the plane).

Lemma 6.7. *The graph G_2^* has a vertex cover of size k^* if and only if G_2 has a connected vertex cover of size $k_2 := k^* + (n_{skel} + n_{sub})/2$. If G_2 has a connected vertex cover of size $k_2 + t$, then G^* has a vertex cover of size $k^* + t$.*

Proof. The construction of Garey and Johnson [28] has the properties that (i) any connected vertex cover of G_2 , when restricted to the vertices of G_2^* , is a vertex cover of G_2^* , and (ii) one can add $(n_{skel} + n_{sub})/2$ vertices among the subdivision and skeleton vertices to any vertex cover of G_2^* to get a connected vertex cover of G_2 . The first claim follows directly from the above properties. For the second claim, we note that the n_{skel} skeleton vertices come in pairs, where one vertex in the pair has degree one and is connected only to the other vertex. Therefore, at least one vertex in each pair must be selected in every vertex cover. Similarly, the vertices in n_{sub} also come in pairs, each pair being connected to each other, therefore one must select at least one vertex from each pair into any vertex cover. Now consider a connected vertex cover of size $k_2 + t$ in G_2 . Since there must be at least $(n_{skel} + n_{sub})/2$ vertices selected among the vertices newly introduced in G_2 , there can be at most $k_2 + t - (n_{skel} + n_{sub})/2 = k^* + t$ vertices selected among the original vertices in G_2^* . It follows that G_2^* has a vertex cover of size $k^* + t$. \square

Grid embedding in \mathbb{R}^d for $d \geq 3$. We again start with the incidence graph G of ϕ , and let $L = |E(G)|$ denote the number of literal occurrences in ϕ . Let G^* be the graph where variable vertices are replaced with variable cycles and clause vertices by triangles (or for size 2 clauses, paths) in the same manner as seen in G_2^* . We will now define a different type of skeleton for these graphs. First, we subdivide each edge of G^* twice, that is, we remove the edge vw , add the vertices u', v' , and add the edges $uu', u'v'$, and $v'v$. Let G^{**} be the resulting graph, and let n^{**} denote the number of its vertices. Consider the disjoint union of G^{**} and the cycle graph C^* with n^{**} vertices. For each vertex v of G^{**} , we can associate a distinct vertex v' in the cycle, and we also create a new vertex v'' . Finally, we add the edges vv' and $v'v''$. It is routine to check that the resulting graph has $\mathcal{O}(n)$ vertices and $\mathcal{O}(n)$ edges, and it has maximum degree 4. Therefore, we can apply the following theorem, which is paraphrased from [21].

Theorem 6.8 (Cube Wiring Theorem [21]). *There is a constant c such that for any $d \geq 3$ it holds that any graph G of maximum degree $2d$ on n vertices can be drawn in a d -dimensional grid cube of side length $cn^{1/d-1}$. Moreover, given G and d the embedding can be constructed in polynomial time.*

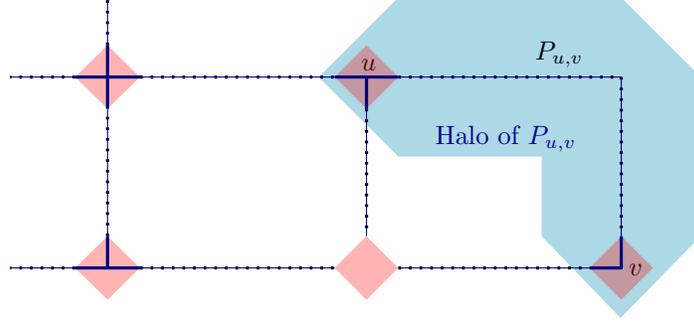

Figure 7: Construction of components from [28] in \mathbb{R}^2 . Dotted edges are edge components, and the red rotated squares are the cutouts. The blue object represents the halo of the edge component $P_{u,v}$ in the top-right corner. Blue (thin and thick) edges correspond to the edges of a canonical Steiner tree.

Since the graph has maximum degree $4 < 2d$ and $\mathcal{O}(n)$ vertices and edges, the resulting drawing is in a grid cube of side length $\mathcal{O}(n^{1/(d-1)})$. For a vertex v , let $\ell_1(v)$ and $\ell_2(v)$ be the lines that are parallel to the first and second coordinate axis respectively and pass through v . We use a constant-refinement and reorganize the neighborhood of each vertex v in the grid drawing so that the grid edges used by the drawing in the ℓ_1 -ball of radius 4 around v all fall on ℓ_1 and ℓ_2 . Let G_d denote the resulting graph together with the obtained grid drawing.

One can prove the analogue of Lemma 6.6 for G^* (with ϕ instead of ϕ_2), and also the analogue of Lemma 6.7 for G_d .

Putting Lemmas 6.5, 6.6 and 6.7 together, and putting the higher dimensional analogues of Lemmas 6.6, 6.7 together, we get the following corollary, which is all that we will need from this subsection for the proof.

Corollary 6.9. *For each $d \geq 2$ the following holds. Given a $(3, 3)$ -CNF formula ϕ on n variables, we can generate a graph G_d of degree at most 4 drawn in a d -dimensional grid of side length $\mathcal{O}(n^{1/(d-1)})$ in polynomial time such that (a) if ϕ is satisfiable then G_d has a connected vertex cover of size $k_d = \mathcal{O}(n^{d/(d-1)})$ and (b) if G_d has a connected vertex cover of size $k_d + t$, then ϕ has an assignment satisfying all but $\mathcal{O}(t)$ clauses.*

6.2.2 Construction and canonization

Given any graph G_d that is drawn in a d -dimensional grid, we construct a point set P_d the following way.

1. Refine the drawing of G_d by a factor of 137. (The constant 137 will be justified in Lemma 6.13.)
2. Add all grid points that are internal to edges of G_d to P_d .
3. Remove any point from P_d that is at distance strictly less than 2 from a vertex of G_d .

We call the set of points in P_d that fall on an edge of G_d *edge components*, and the ℓ_1 balls of radius 2 around vertices of G_d are the *cutouts*. (The cutouts are cubes of diameter 4 whose diagonals are axis-parallel; i.e., they are regular “diamonds” in \mathbb{R}^2 .)

The resulting set P_d is our construction for RECTILINEAR STEINER TREE. The following lemma can be found in [28], but we provide a proof for completeness.

Lemma 6.10 (Garey and Johnson [28]). *If G_d has a connected vertex cover of size k_d , then P_d has a rectilinear Steiner tree of total length $\ell_d := L + 2|E(G_d)| + 2(k_d - 1)$, where L is the total length of the edge components.*

Proof. Given a connected vertex cover S of size k_d , we construct a Steiner tree T the following way. First, we add all length 1 edges connecting neighboring vertices in edge components to T ; these have total length L . Since S induces a connected graph, it has a spanning tree that has $k_d - 1$ edges. The total length of these edges is $4(k_d - 1)$. On each such edge component, we add the length 2 edges that connect to the incident cutouts on both ends. Furthermore, on each edge e of G_d that is not an edge of this spanning tree, there is at least one endpoint s of e that is in S as S is a vertex cover. We add a length 2 cutout edge connecting the edge component of e to the center of the cutout of s . These edges have a total length of $2(|E(G_d)| - k_d + 1)$. The result is a tree T on P_d that has total length

$$L + 4(k_d - 1) + 2(|E(G_d)| - k_d + 1) = L + 2|E(G_d)| + 2(k_d - 1). \quad \square$$

In the remainder of this subsection, we will canonize an approximate Steiner tree of P_d in order to prove the following lemma.

Lemma 6.11. *If P_d has a rectilinear Steiner tree of length $\ell_d + \ell'$, then G_d has a connected vertex cover of size $k_d + \ell'/2$.*

Canonization We say that a Steiner tree of P_d is *canonical* if (i) every length 1 edge in edge components is included in T and (ii) all other segments in T have length 2 and connect the center of some cutout to the nearest point in one of the incident edge components.

A Steiner point of T is a point that has degree at least 3. The vertices of T are its Steiner points and P_d . An edge of T is a curve connecting two vertices. It follows that T has at most $|P_d| - 2$ Steiner points.

For a fixed constant $d \geq 2$ we can change each edge of T so that it is a minimum length path in the ℓ_1 norm between these two vertices, by moving parallel to the x_1 axis, then to the x_2 axis, etc. until we arrive at the destination. The resulting tree consists of $\mathcal{O}(|P_d|)$ axis-parallel segments.

Lemma 6.12. *For any approximate Steiner tree T on P_d there is a Steiner tree T' so that it contains all length-1 edges in edge components and all of its edges have length at most 4, and T' is no longer than T .*

Proof. Recall that the Hanan-grid [33] of P_d is the set of points $H_d \subset \mathbb{R}^d$ that can be defined as the intersection of d distinct axis-parallel hyperplanes incident to d (not necessarily distinct) points of P_d . Snyder [54] shows that there exists a minimum rectilinear Steiner Tree whose Steiner points are on the Hanan-grid. In fact, he proposes modifications that are local, and can be applied also to a non-optimal Steiner tree, i.e., affect only a vertex of a Steiner tree and its neighbors, and result in a tree whose Steiner points lie on the Hanan-grid. None of the local modifications lengthen the tree. Moreover, each type of local modification either shortens T by removing at least one segment, or it does not shorten the tree but it can be repeated no more than $\mathcal{O}(|P_d|)$ times. Consequently, given a tree T , we can use the local modifications of Snyder exhaustively to get a tree that is not longer than T , and whose Steiner points lie in the Hanan-grid of P_d .

Suppose now that T is a rectilinear Steiner tree of P_d whose Steiner points are in H_d . Notice that the minimum distance between points of H_d is 1, and the minimum distance between points from two distinct edge components is at least 4. Suppose that there is an edge uv of length 1 in an edge component that is not in T . Then adding uv to T creates a cycle, and that cycle has at least one edge e that has either length more than 1, or e has length exactly one but its endpoints are not covered by any edge component. Replacing e with uv therefore results in a tree that is no longer than T and has one more length-1 edge that is inside an edge component. Repeating the above

check $\mathcal{O}(|P_d|)$ times results in a tree T that contains all length-1 edges in edge components. Suppose now that T has an edge uv of length more than 4. Removing the edge uv from T creates a forest of two trees. Suppose that one tree spans $P \subset P_d$ and the other spans $Q \subset P_d$. Note that P and Q are non-empty, disjoint, and their union is P_d . Observe that there exists $p \in P$ and $q \in Q$ such that $\|p - q\|_1 \leq 4$. Now the shortest edge connecting p and q is shorter than e was, therefore by adding this edge the created tree is not longer than the original. As each such modification decreases the number of edges of length more than 4 and there are only $\mathcal{O}(|P_d|)$ edges in T , we can remove all edges longer than 4 in $\mathcal{O}(|P_d|^2)$ time. The resulting tree T' satisfies the required properties. \square

Lemma 6.13. *For any approximate Steiner tree T' on P_d that contains all length-1 edges in edge components and no edges longer than 4, there is a canonical tree T'' that is no longer than T' .*

Proof. A full Steiner subtree of T is a subtree of T whose internal vertices are Steiner points of T , and whose leaves are points of P_d . Let F be a full Steiner subtree of T' with k leaves. The halo of an edge component P_{uv} is the set of points in \mathbb{R}^d whose ℓ_1 -distance from P_{uv} is at most 68. The refinement step of the construction of P_d (see step (i)) ensures that two halos intersect if and only if the corresponding edges are incident to the same vertex.

Since T' contains all length-1 edges in edge components, the role of F is to connect a certain set of edge components; each edge component contains at most one leaf of F (as otherwise there would be a cycle). Let γ be the number of edge components adjacent to F in the tree, that is, F has γ leaves. Let β be the number of Steiner points in F . Notice that $\beta < \gamma$.

First, we show that the leaves of F are in edge components that are incident to the same cutout. Let μ be the number of pairs (p, H) where p is a Steiner point of F , and H is a halo for one of the edge components connected to F , and moreover $p \in H$. On one hand, every Steiner point can be contained in at most 4 halos, since that is the maximum overlap achieved by the halos. This is a consequence of the fact that halos corresponding to non-incident edge components are disjoint so any set of intersecting halos must correspond to the neighborhood of a single vertex, and the maximum degree of a vertex in G_d is 4. Therefore, we have that $\mu \leq 4\beta$.

On the other hand, since the maximum degree of G_d is 4, there is a set E of at least $\gamma/4$ pairwise non-incident edge components; in particular, there is a point r in F that is outside all the closed halos corresponding to edge components in E . Let r be the root of F , and for an edge component $P_{uv} \in E$, consider the unique path in F from the leaf in $P_{u,v}$ to r . This path must intersect the halo of P_{uv} at some point, and the portion of this path within the halo of P_{uv} has length at least 68. Notice that these paths are disjoint for each edge component of F . Since edges of F have length at most 4, there must be at least $68/4 - 1 = 16$ Steiner points on each such path, so altogether we have $\mu \geq (\gamma/4) \cdot 16 = 4\gamma$. Putting the upper and lower bound on μ together, we have that $4\gamma \leq 4\beta$. But this contradicts the fact that $\beta < \gamma$.

Consider now a full Steiner subtree F that is connecting $\gamma \in \{2, 3, 4\}$ adjacent edge components. Then F could have length 2γ , as we can connect the point associated with the common vertex v from the point set P_1 with length two segments to the nearest vertex of all the edge components connected by F . We show that this is the shortest possible tree for γ edge components. Notice that any pair of edge components have ℓ_1 -distance exactly four, so the shortest path in the rectilinear Steiner tree between any pair of components is at least four. Now consider the geometric graph that we get by doubling every segment in the tree, so that we get parallel edges everywhere. This graph has an Euler tour (since every degree is even); on such an Euler tour, the length required between any pair of tree leaf vertices is at least the length of a shortest path between them, which is at least 4. Since the length of the tour is exactly twice the length of the tree, we get that the tree has total length at least $4\gamma/2 = 2\gamma$, as claimed. Therefore, we can exchange each full Steiner subtree with a canonical connection. The resulting tree T'' is canonical and no longer than T' . \square

We can now prove the correspondence between an approximate rectilinear Steiner tree and a connected vertex cover.

Proof of Lemma 6.11. Let T be a Steiner tree of P_d of length $\ell_d + \ell'$. Using Lemma 6.12 and Lemma 6.13, we can create a canonical tree T'' in $n^{\mathcal{O}(1)}$ time of length at most $\ell_d + \ell'$. Let k be the number of non-empty cutouts. Observe that the vertices of G_d corresponding to the non-empty cutouts form a connected vertex cover.

Consider the subtree U of T'' that is spanned by the centers of the non-empty cutouts. Every edge component in U must be connected to the centers of both neighboring cutouts, and U contains $k - 1$ edge components. Furthermore, every edge component outside U must be connected to the center of at least one of the neighboring cutouts. Consequently, the length of T'' is at least $L + 4(k - 1) + 2(|E(G_d)| - k + 1) = L + 2|E(G_d)| + 2(k - 1)$. Therefore, we have

$$L + 2|E(G_d)| + 2(k - 1) \leq \ell_d + \ell' = L + 2|E(G_d)| + 2(k_d - 1) + \ell',$$

and thus $k \leq k_d + \ell'/2$, as required. \square

6.2.3 Concluding the proof of Theorem 6.4

Proof of Theorem 6.4. Putting Corollary 6.9 and Lemmas 6.10 and 6.11 together, we have that if a $(3, 3)$ -CNF formula ϕ on n variables has a satisfying assignment then P_d has a rectilinear Steiner tree of length $\ell_d = \mathcal{O}(n^{d/(d-1)})$. Let c_1 be such that $\ell_d = c_1 n^{d/(d-1)}$. Additionally, if P_d has a rectilinear Steiner tree of length $\ell_d + \ell'$, then ϕ has an assignment that satisfies all but $c_2 \ell'$ clauses, where c_2 is a constant.

Suppose that there is a $2^{\gamma/\varepsilon^{d-1}}$ poly(n) algorithm for RECTILINEAR STEINER TREE for all $\gamma > 0$. Given a formula ϕ , we create the set P_d in polynomial time, and we run the above algorithm with $\varepsilon = \frac{\delta m}{c_1 c_2 n^{d/(d-1)}}$, where m is the number of clauses in ϕ . Since $m = \Theta(n)$, we have that $\varepsilon = \Theta(1/n^{1/(d-1)})$. We can now distinguish between a satisfiable formula (when a rectilinear Steiner tree on P_d is of length ℓ_d) and a formula in which all assignments violate at least δm clauses (when any rectilinear Steiner tree on P_d has length greater than $(1 + \varepsilon)\ell_d$). Since the construction time of P_d is polynomial in n , the total running time of this algorithm is $2^{\gamma/\varepsilon^{d-1}} \text{poly}(n) = 2^{\gamma c n}$ for some constant c . The existence of such algorithms for all $\gamma > 0$ would therefore violate Gap-ETH by Corollary 6.1. \square

7 Conclusion and Open Problems

In this article we gave randomized $(1 + \varepsilon)$ -approximation algorithms for EUCLIDEAN TSP, EUCLIDEAN STEINER TREE and RECTILINEAR STEINER TREE that run in $2^{\mathcal{O}(1/\varepsilon)^{d-1}} n + \text{poly}(1/\varepsilon)n \log n$ time. In case of EUCLIDEAN TSP and RECTILINEAR STEINER TREE, we have shown that there are no $2^{o(1/\varepsilon)^{d-1}} \text{poly}(n)$ algorithms under Gap-ETH. We achieved the improved algorithms by extending Arora's method [1] with a new technique: *Sparsity-Sensitive Patching*.

As mentioned in the beginning of this paper, the methods from [1, 48] have been greatly generalized and extended to various other problems by several authors. A natural direction for further research would be to see whether Sparsity-Sensitive Patching can also be employed to obtain improved (and possibly, Gap-ETH-tight) approximation schemes for these problems. Examples of problems where such a question can be studied include

- Euclidean versions of MATCHING, k -TSP and k -STEINER TREE [1], STEINER FOREST [11], k -CONNECTIVITY [17], k -MEDIAN [39, 5] and SURVIVABLE NETWORK DESIGN [18],

- versions of some of the above problems in other metric spaces (e.g., doubling, hyperbolic), and in planar, surface-embedded and minor free graphs (see Section 1.4 for such studies for TSP).

Since the publication of the conference version of this paper, our sparsity-sensitive patching was already used in the follow up papers [25, 56] on a certain separation problem and k -TSP. For both these problems, spanners do not seem to be useable and therefore the sparsity-sensitive technique was especially instrumental to obtain the results.

There are several open questions worth exploring further. The ideal algorithm for EUCLIDEAN TSP would have a running time of $2^{\mathcal{O}(1/\varepsilon)^{d-1}}n$, and it would be *deterministic*. However, achieving this running time with a randomized algorithm is already a challenging question. The most natural way to pursue this would be to try and unify Bartal and Gottlieb’s techniques [7] with ours. Is it possible to get this running time without spanners by using some new ideas to handle singletons (e.g., crossings that appear on their own on a facet of a quadtree cell)?

One could also pursue a $(1 + \varepsilon)$ -approximation algorithm that uses $f(1/\varepsilon)n^{\mathcal{O}(1)}$ time and only $\text{poly}(1/\varepsilon, n)$ space, but this would likely require an algorithm that is not based on dynamic programming. Is such an algorithm possible (say, for $d = 2$)?

Acknowledgement

We thank Hans L. Bodlaender for his double counting argument in Lemma 6.13, Artur Czumaj for sharing the full version of [18] with us, and Hung Le for answering multiple questions regarding spanners.

A Filtering Algorithm

The goal of this section is to prove Lemma 5.1. **Most of this section is taken almost verbatim from the unpublished full version of [18].** We include it for four reasons:

- to make this paper self-contained,
- we need to analyze the running time dependence in a slightly different setting,
- we need to extend the result to the ℓ_1 metric in addition to the ℓ_2 metric,
- we are able to simplify some of the arguments due to our special setting.

For a given set of points $P \subseteq \mathbb{R}^d$ let $\text{ST}(P)$ be the minimum Steiner tree⁹ with terminals P and $\text{MST}(P)$ be the minimum spanning tree of P . For any $X \subseteq \mathbb{R}^d$ let $\text{ST}(P; X)$ be the⁹ minimum length Steiner tree that connects the terminal set P and is only allowed to use a subset of X as Steiner vertices (therefore $\text{ST}(P; \mathbb{R}^d) = \text{ST}(P)$). We use $\mathcal{B}(x, r)$ to denote the ball centered at x of radius r .

We will use some named constants in the following definitions, which all depend only on the dimension d . The constant k will be defined later in Claim A.6; it will be set so that $k = \Theta(d^2)$. Let Δ be the maximum degree of any minimum spanning tree of points in \mathbb{R}^d . It is well-known that $\Delta \leq 3^d$ [53]. We furthermore define:

$$\begin{aligned}\gamma &:= 4k\Delta^k/\varepsilon = 2^{\mathcal{O}(d^3)}/\varepsilon, \\ \phi &:= \frac{\varepsilon}{80d\Delta\gamma} = \varepsilon^2/2^{\mathcal{O}(d^3)}.\end{aligned}$$

Finally, let c^* be a universal constant to be defined later (completely independent of d and ε).

Definition A.1 (Steiner filter). *For point sets $P_0, P_1 \subseteq \mathbb{R}^d$ and $\varepsilon > 0$ we say that $X \subseteq P_1$ is a Steiner filter of P_1 with respect to P_0 if:*

- (i) $|X| \leq \frac{2^{c^*d^4}}{\varepsilon^{c^*d}} |P_0|$, and
- (ii) $\text{wt}(\text{ST}(P_0; X)) \leq (1 + c^*\varepsilon) \cdot \text{wt}(\text{ST}(P_0; P_1))$, and
- (iii) $\text{wt}(\text{MST}(P_0 \cup X)) \leq \frac{2^{c^*d^4}}{\varepsilon^{c^*d}} \cdot \text{wt}(\text{MST}(P_0))$.

In this section we prove the following filtering Lemma.

Lemma A.2. *For any point set $P \subset \mathbb{R}^d$ and any $\varepsilon > 0$, there is an algorithm that:*

- (a) finds a $X \subseteq \mathbb{R}^d$ that is a Steiner filter of P with respect to \mathbb{R}^d , and
- (b) runs in $\frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} \cdot |P| \log(|P|)$ time.

The proof of our Lemma is based on the following theorem proved by Czumaj et al. [18].

Theorem A.3 (Lemma 4.1 from full version of [18]). *For any point sets P_0 and P_1 in \mathbb{R}^d and any $\varepsilon > 0$, there is an algorithm that finds a subset X of P_0 that is a Steiner filter of P_1 with respect to P_0 and runs in $(d/\varepsilon)^{\mathcal{O}(d)} n \log n$ time, where $n = |P_0 \cup P_1|$.*

Algorithm: Steinerfiltering(P), points $P \subseteq \mathbb{R}^d$ snapped to L^d grid, where $L = \mathcal{O}(n/\varepsilon)$

- 1 Build a light $(1 + \varepsilon)$ -spanner G on P // Theorem 15.3.20 in [49]
- 2 **foreach** edge e of G **do**
- 3 $r_e := 20\gamma|e|$
- 4 Set $\text{grid}(e) := d$ -dimensional grid of side length $\phi \cdot |e|$ and $z_e :=$ midpoint of e
- 5 $X_e := \text{grid}(e) \cap \mathcal{B}(z_e, r_e)$
- 6 **return** $X := \bigcup_{e \in E[G]} X_e$

Algorithm 3: Pseudocode for the Steiner filtering algorithm of Czumaj et al. [18] when $P_0 = \mathbb{R}^d$.

Observe that if we were to plug naively the set $P_1 = \mathbb{R}^d$ into Theorem A.3 we would already prove Lemma A.2. Unfortunately, the running time of Theorem A.3 depends on $|P_0 \cup P_1|$. For our purposes we only need to analyze their algorithm in the special case of $P_1 = \mathbb{R}^d$. In Algorithm 3 we present (a simplified version of) the Steiner filtering procedure of [18] in the special case of $P_1 = \mathbb{R}^d$. First a light $(1 + \varepsilon)$ -spanner G of P is computed (this step already takes $\varepsilon^{-\mathcal{O}(d)}|P| \log(|P|)$ time). Next, for every edge e of G we consider the d -dimensional axis-parallel grid of cell side length $\phi|e| = \varepsilon^2|e|/2^{\mathcal{O}(d^3)}$. We add to X all the grid points within distance $20\gamma|e| = 2^{\mathcal{O}(d^3)}|e|/\varepsilon$ from the midpoint of e . After processing all edges of G in this manner we return the resulting point set X .

Now, we show that Algorithm 3 runs in $\frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}}|P|$ time.

Proof of Lemma A.2 (b). To construct a light spanner G we need $\varepsilon^{-\mathcal{O}(d)}|P| \log |P|$ time (note that Algorithm 3 computes the spanner on P). Known constructions guarantee that the number of edges of such a spanner is bounded by $|P|/\varepsilon^{\mathcal{O}(d)}$ [18, 32, 49]. For any edge $e \in E[G]$, the number of grid points that we add to X is bounded by $2^{\mathcal{O}(d^4)}/\varepsilon^{\mathcal{O}(d)}$. The time needed to construct the grid around edge e is bounded by $2^{\mathcal{O}(d^4)}/\varepsilon^{\mathcal{O}(d)}$. Therefore the total runtime of Algorithm 3 is bounded by $T_{\text{spanner}}(|P|, \varepsilon) + \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}}|P|$. \square

Lemma A.2 (a) follows from Theorem A.3. For completeness we provide the detailed arguments in Section A.2, making some simplifications that come from our specific setting.

A.1 Properties of Spanners and Steiner Trees

Claim A.4 (Lemma 4.6 in [18]). *Let $P \subseteq \mathbb{R}^d$ and let x, y be any pair of distinct points in P . Let uv be any edge in $\text{ST}(P)$ that separates x and y in T .*

Suppose that G is a connected graph on P and $p_{x \rightsquigarrow y}$ is the shortest path in G from x to y . Then at least one edge of $p_{x \rightsquigarrow y}$ is not shorter than $\text{dist}(u, v)$.

Proof. Suppose for the sake of contradiction that all edges on $p_{x \rightsquigarrow y}$ are shorter than $\text{dist}(u, v)$, and let T_1, T_2 be the two connected components of $\text{ST}(P) - uv$. Since x and y are in two different components there must exist an edge $e \in p_{x \rightsquigarrow y}$ such that its endpoints are in different components T_i and $|e| < \text{dist}(u, v)$. This means that $T_1 \cup T_2 \cup \{e\}$ is a Steiner tree of P and has smaller length than $\text{ST}(P)$, which contradicts the minimality of $\text{ST}(P)$. \square

Claim A.5 (Lemma 4.7 in [18]). *For any $P, X \subseteq \mathbb{R}^d$ let T be any subtree of $\text{ST}(P; X)$ and let L_T be the set of leaves of T . Then $T = \text{ST}((P \cap T) \cup L_T; X)$.¹⁰*

⁹For the simplicity of notation we act as if the minimum Steiner trees and minimum spanning trees are unique; one can check that all our arguments hold if there are multiple minima.

¹⁰More precisely, T is a minimum Steiner tree of $(P \cap T) \cup L_T$ that uses Steiner points only from X .

Proof. For the sake of contradiction assume that $T^* = \text{ST}((P \cap T) \cup L_T, X)$ and $\text{wt}(T^*)$ is smaller than $\text{wt}(T)$. We replace the tree T by the tree T^* in $\text{ST}(P, X)$. We get a connected graph of weight smaller than $\text{ST}(P; X)$ that contains a Steiner Tree of P and uses only X as Steiner points. However, this graph has smaller weight than $\text{ST}(P; X)$ which implies a contradiction. \square

Claim A.6 (Lemma 4.8 in [18]). *For any $P, X \subseteq \mathbb{R}^d$ and $\rho_0 \in \mathbb{R}^d$ if $\mathcal{B}(\rho_0, 1)$ has at most 1 terminal from P , then for any $\alpha \in (0, 1/2]$ the tree $\text{ST}(P; X)$ contains less than 2^k Steiner points from $X \cap \mathcal{B}(\rho_0, \alpha)$ where $k = \mathcal{O}(d^2)$ is an integer multiple of d^2 . The statement is true for both ℓ_1 and ℓ_2 norms.*

The proof of this claim follows [18]. An analogous statement to Claim A.6 also appears in [52, Lemma 36].

Proof. For brevity of notation let \mathcal{B}_r be $\mathcal{B}(\rho_0, r)$. Let T_r be the subforest of $\text{ST}(P; X)$ consisting of edges with 1 or 2 endpoints in \mathcal{B}_r . Let s_r be the number of internal vertices in T_r . Note that when $r \leq 1$, then all but one internal vertex of T_r has to be a Steiner vertex. Finally, let n_r be the number of edges of $\text{ST}(P; X)$ with exactly one endpoint inside \mathcal{B}_r . Observe that for any $r \in (0, 1]$, the value s_r counts the internal points of T_r plus perhaps the single terminal from P , while n_r counts the number of leaf edges of T_r . Our goal is therefore to show $s_r \leq 2^{\mathcal{O}(d^2)}$.

Observe that we can assume that the degree of Steiner vertices is at least 3 and at most Δ . Therefore $s_r + 1 \leq n_r \leq \Delta \cdot (s_r + 1) \leq 2\Delta s_r$ (we use $s_r \geq 1$, as otherwise the claim is obviously true). Therefore, T_r has at most $(s_r + 1) + n_r \leq 2n_r$ vertices.

Consider arbitrary r and r^* , such that $\alpha \leq r < r^* \leq 1$. If $n_\alpha < 2^d$, then $s_\alpha < n_\alpha < 2^d$ and the claim is correct. Hence, we assume from now that $n_{r^*} \geq n_r \geq n_\alpha \geq 2^d$.

Next, we show that the length of T_{r^*} is at least $(r^* - r) \cdot s_r$. Observe that each edge counted by n_r is on at least one path to a leaf of the tree T_r . Moreover, there is at most one non-Steiner point inside \mathcal{B}_1 . Hence every edge (except perhaps one) counted by n_r is on at least one path from \mathcal{B}_r to the outside of \mathcal{B}_1 . Hence the length of T_{r^*} is at least $(r^* - r)(n_r - 1) \geq (r^* - r)s_r$.

Next, we upper bound the length of T_{r^*} . Observe that T_{r^*} contains at most $2n_{r^*}$ points. It is well known that for any $P \subseteq \mathcal{B}_1$ of at least 2^d points we have $\text{MST}(P) \leq 8r|P|^{1-1/d}$ [49, Exercise 6.3], [18, Lemma 4.4]. Therefore,

$$(r^* - r) \cdot s_r \leq \text{wt}(T_{r^*}) \leq 16 \cdot (n_{r^*})^{1-1/d}.$$

We combine this with $n_{r^*} \leq 2\Delta s_{r^*}$ and set $r^* = r + \varepsilon$. We get that for every $\varepsilon \in (0, 1)$ and $r \in (0, 1 - \varepsilon)$ it holds that:

$$s_r \leq \frac{16}{\varepsilon} (n_{r+\varepsilon})^{1-1/d} < \frac{32\Delta}{\varepsilon} \cdot (s_{r+\varepsilon})^{1-1/d}. \quad (7)$$

It remains to show that s_α must be bounded by $2^{\mathcal{O}(d^2)}$ for $\alpha \leq 1/2$. Let $\tau := \frac{1}{\ln \ln(s_1)}$ (we can assume that $\tau < 1/2$, as otherwise s_1 is constant-bounded). Fix some $r \in (0, 1 - \tau]$ and set $\varepsilon = \frac{1}{d(\ln \ln s_{r+\tau})^2}$. Observe that $s_{r+\tau} < s_1$ and thus $\tau/\varepsilon < d \ln \ln s_{r+\tau}$. We iterate Inequality (7) $\lfloor \tau/\varepsilon \rfloor$ times:

$$\begin{aligned} s_r &< 32\Delta d (\ln \ln s_{r+\tau})^2 (s_{r+\varepsilon}^{1-1/d}) < \dots \\ &< (32\Delta d (\ln \ln s_{r+\tau})^2)^{\sum_{j>0} (1-1/d)^j} \cdot s_{r+\tau}^{(1-1/d)^{\tau/\varepsilon}} \\ &< (100d \cdot \Delta \cdot \ln \ln s_{r+\tau})^{2d}, \end{aligned} \quad (8)$$

where we used that $\sum_{j>0} (1-1/d)^j = d$ and the following bound:

$$s_{r+\tau}^{(1-1/d)^{\tau/\varepsilon}} < s_{r+\tau}^{(1-1/d)^{d \ln \ln s_{r+\tau}}} < s_{r+\tau}^{(1/e)^{\ln \ln s_{r+\tau}}} = s_{r+\tau}^{1/\ln s_{r+\tau}} = e.$$

Next, we iterate Inequality (8) $\ell = \ln^*(s_1)$ times for $r \in \{\alpha, \alpha + \tau, \dots\}$. Assuming $\alpha \in [0, 1 - \ell\tau)$, we have that $\ln^{(\ell)} s_{\alpha+\ell\tau} < \ln^{(\ell)} s_1 \leq 1$, where $\ln^{(j)}(\cdot)$ denotes the j -times iterated natural logarithm. Therefore we can bound s_α as follows.

$$\begin{aligned}
s_\alpha &< (100d\Delta \cdot \ln \ln s_{\alpha+\tau})^{2d} \\
&< \left(100d\Delta \cdot \ln \ln (100d \cdot \Delta \cdot \ln \ln s_{\alpha+2\tau})^{2d}\right)^{2d} \\
&= \left(100d\Delta \cdot (\ln(2d) + \ln(\ln(100d) + \ln \Delta + \ln^{(3)} s_{\alpha+2\tau}))\right)^{2d} \\
&< \left(100d\Delta \cdot (4 \ln d + \max\{\ln \ln(100d), \ln \ln \Delta, \ln^{(4)} s_{\alpha+2\tau}\})\right)^{2d} \\
&< \left(100d\Delta \cdot (4 \ln d + \max_{j \geq 1} \{\ln^{(2j+1)}(2d), \ln^{(2j)}(100d), \ln^{(2j)} \Delta, \ln^{(2\ell)} s_{\alpha+\ell\tau}\})\right)^{2d} \\
&< (100d\Delta \cdot 20 \ln d)^{2d} \\
&< (2000\Delta d \ln d)^{2d} \\
&= 2^{\mathcal{O}(d^2)}
\end{aligned}$$

Note that when $\ell\tau \geq 1/2$, then s_1 is constant-bounded. Hence, for every $\alpha \in (0, 1/2]$, it holds that $s_\alpha \leq 2^{\mathcal{O}(d^2)}$. \square

A.2 Proving that X is a Steiner filter of P

A.2.1 Property (i) of X :

The set X returned by Algorithm 3 satisfies property (i) of Definition A.1 because there are at most $|P|/\varepsilon^{\mathcal{O}(d)}$ edges in G and for each edge we add at most

$$|X_e| = \mathcal{O}\left(\frac{20\gamma}{\phi}\right)^d = 2^{\mathcal{O}(d^4)}/\varepsilon^{\mathcal{O}(d)} \quad (9)$$

points to X .

A.2.2 Property (ii) of X :

We prove that $\text{wt}(\text{ST}(P; X)) \leq (1 + 2\varepsilon) \cdot \text{wt}(\text{ST}(P; \mathbb{R}^d))$. Let \mathcal{T}^* be the minimum Steiner tree of P that can use any point in \mathbb{R}^d as a Steiner point. We build a graph H in three steps, consisting of edge sets H_1, H_2 and H_3 . The set H_1 consists of all the edges $(u, v) \in \mathcal{T}^*$ with $u, v \in P$. The set H_2 will be defined later; these edges are created from edges $(u, v) \in \mathcal{T}^*$ by moving the endpoints (u, v) to X . Finally, the set H_3 makes H connected by adding additional edges incident to the endpoints of $H_1 \cup H_2$ that have total minimum weight.

Let \mathcal{E}_1 denote the edges of \mathcal{T}^* with both endpoints in P . Moreover, \mathcal{E}_2 are the edges of \mathcal{T}^* that are transformed in the second phase into H_2 and $\mathcal{E}_3 = \mathcal{T}^* \setminus (\mathcal{E}_1 \cup \mathcal{E}_2)$.

Clearly the graph H is spanning P and uses only points from $X \cup P$ as endpoints; consequently, it contains a Steiner tree spanning P that uses only X as Steiner vertices. We need to bound the total weight of H . Czumaj et al. [18] show that $\text{wt}(H_2) \leq \text{wt}(\mathcal{E}_2) + \varepsilon \cdot \text{wt}(\mathcal{T}^*)$ and $\text{wt}(H_3) \leq \text{wt}(\mathcal{E}_3) + \varepsilon \cdot \text{wt}(\mathcal{T}^*)$. Since $\text{wt}(H_1) = \text{wt}(\mathcal{E}_1)$, this leads to:

$$\begin{aligned}
\text{wt}(H) &\leq \text{wt}(H_1) + \text{wt}(H_2) + \text{wt}(H_3) \\
&\leq \text{wt}(\mathcal{E}_1) + (\text{wt}(\mathcal{E}_2) + \varepsilon \text{wt}(\mathcal{T}^*)) + (\text{wt}(\mathcal{E}_3) + \varepsilon \text{wt}(\mathcal{T}^*)) \\
&\leq (1 + 2\varepsilon) \text{wt}(\mathcal{T}^*).
\end{aligned}$$

We now expand on the construction of H_2 and H_3 .

Construction of H_2 : We begin by constructing the graph H_2 . First, we define its set of edges \mathcal{E}_2 . Recall that we defined k to be the constant from Claim A.6 and $k = \Theta(d^2)$ and $\gamma = 4k\Delta^k/\varepsilon$.

Since the edge $(u, v) \in \mathcal{T}^*$ is not in \mathcal{E}_1 either u or v are not in P . Let t be the midpoint of (u, v) . For a tree \mathcal{T}^* , let ST_u and ST_v be the two subtrees of \mathcal{T}^* that arise after removing an edge (u, v) from \mathcal{T}^* and $u \in \text{ST}_u$ and $v \in \text{ST}_v$. Let T_u^k be the subtree of ST_u induced by the vertices within hop-distance k from u (analogously T_v^k is a subtree of ST_v induced by the vertices within hop-distance k from v). Let $\ell = \text{dist}(u, v)$. Then, Czumaj et al [18] add an edge (u, v) to \mathcal{E}_2 if all the following conditions hold:

(C1) every edge in T_u^k and T_v^k is shorter than $2\gamma\ell/k$.

(C2) ST_u has at least one point (call it x) from P that is contained in the ball $\mathcal{B}(t, 4\gamma\ell)$.

(C3) ST_v has at least one point (call it y) from P that is contained in the ball $\mathcal{B}(t, 4\gamma\ell)$.

This concludes the construction of \mathcal{E}_2 . Let \mathcal{E}_3 be $\mathcal{T}^* \setminus (\mathcal{E}_1 \cup \mathcal{E}_2)$. It remains to analyse the total length of these edges.

Bound on $\text{wt}(H_2)$: Since T_u^k contains vertices within hop-distance k from u , Condition (C1) implies that $T_u^k \subset \mathcal{B}(t, 4\gamma\ell)$, and the same holds for T_v^k . Conditions (C2) and (C3) ensure that x and y are disconnected in T^* after the removal of the edge uv . Claim A.4 shows that the spanner G has at least one edge e on $p_{x \rightsquigarrow y}$ whose length is at least $|e| \geq \ell$.

Next, we prove that $p_{x \rightsquigarrow y}$ is contained in $\mathcal{B}(t, (20\gamma\ell))$. First note that $x, y \in \mathcal{B}(t, 4\gamma\ell)$, and thus $\text{dist}(x, y) \leq 8\gamma\ell$. On the other hand, we have $|p_{x \rightsquigarrow y}| \leq (1 + \varepsilon)\text{dist}(x, y)$ by the spanner property of G . Thus for any point z of $p_{x \rightsquigarrow y}$ we have $\text{dist}(x, z) \leq (1 + \varepsilon)\text{dist}(x, y) < 2\text{dist}(x, y) \leq 16\gamma\ell$, and by the triangle inequality $\text{dist}(t, z) \leq \text{dist}(t, x) + \text{dist}(x, z) < 20\gamma\ell$.

Now since $p_{x \rightsquigarrow y}$ is contained in $\mathcal{B}(t, 20\gamma\ell)$ and e is in $p_{x \rightsquigarrow y}$, we have that both endpoints of e are contained in $\mathcal{B}(t, 20\gamma\ell)$. By Claim A.4 and the construction of X , there exist two points u^* and v^* in $P \cup X$, such that $\text{dist}(u, u^*)$ and $\text{dist}(v, v^*)$ are at most $d\phi|e|$; this is because the axis-parallel square grid of side-length $\phi|e|$ has cells of ℓ_2 -diameter $\sqrt{d}\phi|e|$ and ℓ_1 -diameter $d\phi|e|$. We modify \mathcal{T}^* by moving all edges incident to u and v to have their endpoints at u^* and v^* . Since the degree of both u and v is bounded by Δ , the operations at u and v will increase the cost of T^* by at most an additive term $2\Delta \cdot d\phi|e|$. Because e is completely contained in $\mathcal{B}(t, 20\gamma\ell)$, we have $|e| \leq 2 \cdot 20\gamma\ell \leq 40\gamma\ell$. Thus, the cost of T^* will increase by at most an additive term

$$2\Delta d\phi|e| \leq 2\Delta d\phi \cdot 40\gamma\ell = \varepsilon\ell = \varepsilon\text{dist}(u, v).$$

To summarize the total cost of the edges in H_2 is bounded by $\text{wt}(\mathcal{E}_2) + \sum_{(u,v) \in \mathcal{T}^*} \varepsilon \cdot \text{dist}(u, v) \leq \text{wt}(\mathcal{E}_2) + \varepsilon\text{wt}(\mathcal{T}^*)$.

Construction of H_3 : Observe that \mathcal{E}_3 induces a forest. For each tree T' in this forest let V' be the set of vertices in T' belonging to P . Take any minimum spanning tree on V' and add it to H_3 . This concludes the construction of H_3 .

Bound on $\text{wt}(H_3)$: Consider removing edge $(u, v) \in \text{ST}(P)$ from $\text{ST}(P)$. Let $\text{ST}_u(P)$ and $\text{ST}_v(P)$ denote the resulting trees containing u and v respectively. Recall that T_u^k is the subtree of $\text{ST}_u(P)$ induced by the vertices that is at a hop distance at most k from u for some parameter $k = \Theta(d^2)$.

Consider an edge $(u, v) \in \mathcal{E}_3$. Because $(u, v) \notin \mathcal{E}_1 \cup \mathcal{E}_2$ at least one of the following conditions hold: (i) either T_u^k or T_v^k contains an edge of length greater than $2\gamma\ell/k$, or (ii) $\text{ST}_u(P)$ or $\text{ST}_v(P)$ has no endpoint in the ball $\mathcal{B}(t, 4\gamma\ell)$ (where t is the midpoint of edge (u, v)) (see conditions (C1), (C2) and (C3)).

Next, we will show that when $(u, v) \in \mathcal{E}_3$ then (ii) cannot hold.

Claim A.7. *If $(u, v) \in \mathcal{E}_3$ then there is an edge $(u^*, v^*) \in T_u^k \cup T_v^k$ of length at least $2\gamma\ell/k$.*

Proof. Fix $R := 4\gamma\ell$. Suppose for the sake of contradiction that all edges in T_u^k are smaller than $R/2k$. Since $(u, v) \notin \mathcal{E}_1 \cup \mathcal{E}_2$, we have that $\text{ST}_u(P) \cap \mathcal{B}(t, R)$ or $\text{ST}_v(P) \cap \mathcal{B}(t, R)$ is empty of terminals (other than u, v). Without loss of generality, assume that $P \cap \text{ST}_u(P) \cap \mathcal{B}(t, R) = \{u\}$. Then, T_u^k must be fully contained in $\mathcal{B}(t, R/2)$. Since there are no terminals in $\mathcal{B}(t, R)$ other than u , the tree T_u^k must contain at least 2^k Steiner points. Note that $\text{ST}_u(P)$ is a Steiner tree of its leaves by Claim A.5. Now applying Claim A.6 to $\text{ST}_u(P)$ and the balls $\mathcal{B}(t, R)$ and $\mathcal{B}(t, R/2)$ leads to a contradiction, as $\mathcal{B}(t, R/2)$ has at least 2^k Steiner points. \square

Czumaj et al. [18] charge the cost of the edge $(u, v) \in \mathcal{E}_3$ to the edge $(u^*, v^*) \in T_u \cup T_v$ guaranteed by Claim A.7 in order to bound the cost of edges in H_3 . We will show that the total cost of all edges charged to e is upper bounded by $\varepsilon|e|$.

To analyze the charging scheme observe that an edge can be charged to $e \in \mathcal{T}^*$ only if it is at most $(k-1)$ hops from one of the endpoints of e . The number of such edges is at most $4\Delta^k$ (where $\Delta \leq 3^d$ is the maximum degree of any minimum spanning tree in \mathbb{R}^d). Moreover, the lengths of such edges are upper bounded by $\varepsilon|e|/(4\Delta^k)$: by Claim A.7 an edge (u, v) is charged to (u^*, v^*) only if $\text{dist}(u, v) \geq 2\gamma\ell/k$. This shows that $\text{wt}(\mathcal{E}_3) \leq \varepsilon \text{wt}(\mathcal{T}^*)$.

Recall that for each tree T' of the forest in \mathcal{E}_3 with vertex set $V' = V(T')$ there is a spanning tree of V' in H_3 . Because the cost of the minimum spanning tree on V' is at most twice the cost of $\text{wt}(\text{ST}(V')) \leq \text{wt}(T')$ it shows that $\text{wt}(H_3) \leq 2\text{wt}(\mathcal{E}_3)$ and therefore $\text{wt}(H_3) \leq \text{wt}(\mathcal{E}_3) + \varepsilon \text{wt}(\mathcal{T}^*)$. This concludes the proof of Property (ii).

A.2.3 Property (iii) of X :

Now, we prove property (iii) of X , namely that $\text{wt}(\text{MST}(P \cup X)) \leq 2^{\mathcal{O}(d^5)}/\varepsilon^{\mathcal{O}(d)} \cdot \text{wt}(\text{MST}(P))$ (see Lemma 4.10 in the full version of [18]). We construct a spanning graph \mathcal{T} of $P \cup X$. First we take \mathcal{T} to be the minimum spanning tree of P . Next for every edge $e \in G$ we find a minimum spanning tree \mathcal{T}_e of X_e and connect it to any of the endpoints of e . Such a graph is a spanning graph of $P \cup X$. Now we focus on estimating the cost of \mathcal{T} .

Fix an arbitrarily edge e in G . By (9) we have $|X_e| = \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}}$, and each edge has length at most $d\phi|e| = \varepsilon^2/2^{\mathcal{O}(d^3)}$. Therefore the total length of the minimum spanning tree \mathcal{T}_e is:

$$\mathcal{O}(|X_e| \cdot \mu) = \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} |e|.$$

Hence, the total cost of \mathcal{T} is bounded by

$$\text{wt}(\text{MST}(P)) + \sum_{e \in E[G]} \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} \cdot |e| \leq \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} \cdot \text{wt}(G) \leq \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} \cdot \text{wt}(\text{MST}(P))$$

This concludes the proof of Property (iii) of the set X and the proof of Lemma A.2. Note that the constant c^* used in Definition A.1 can be properly defined to be global constant greater than any constant hidden behind the $\mathcal{O}(\cdot)$ notation in this section.

A.3 Proof of Lemma 5.1

Now we proceed with the proof of Lemma 5.1. Recall that we are given a point set P and a random offset \mathbf{a} . The task is to find a set \tilde{S} of segments with the property that (i) there is a Steiner tree that uses \tilde{S} which is a $(1 + \varepsilon)$ -approximation of the optimum solution and (ii) it has at most $(1/\varepsilon)^{\mathcal{O}(d)}$ crossings with each facet of the quadtree.

We use the Lemma A.2 and get a set $X \subseteq \mathbb{R}^d$, with the property that $\text{ST}(P; X)$ is a $(1 + \varepsilon)$ -approximation of $\text{ST}(P)$ and $\text{MST}(P \cup X) \leq \frac{2^{\mathcal{O}(d^4)}}{\varepsilon^{\mathcal{O}(d)}} \cdot \text{MST}(P)$. Next, we compute a graph G that is a light $(1 + \varepsilon)$ -spanner of $P \cup X$. Here, we use a spanner construction due to [27] that guarantees a light spanner in doubling metrics (to make it work both in Euclidean and Rectilinear Space) and works in $\mathcal{O}(n \log n)$ time.

The graph G has weight $\text{poly}(1/\varepsilon)\text{MST}(P)$ and there is a $(1 + \mathcal{O}(\varepsilon))$ -approximate Steiner tree on P that uses only the edges of G . Now, we need to guarantee that edges of G are crossing each facet of a quadtree at most $1/\varepsilon^{\mathcal{O}(d)}$ times. To achieve that we use the lightening procedure of Rao and Smith [52] (see Lemma 4.1). Their lightening procedure works for any connected graph (see also the lightening procedures in [18, 17] and [49, Lemma 19.3.2]).

This gives us a graph \tilde{G} with $\text{wt}(\tilde{G}) - \text{wt}(G) \leq \varepsilon \text{wt}(\text{ST}(P))$, it contains a Steiner tree on P that is only $(1 + \mathcal{O}(\varepsilon))$ times heavier than $\text{ST}(P)$, and each shared facet of sibling cells in the quadtree is crossed by \tilde{G} at most $1/\varepsilon^{\mathcal{O}(d)}$ times. The set \tilde{S} consists of the edges of \tilde{G} . This concludes the proof of Lemma 5.1.
