Benchmark of quantum-inspired heuristic solvers for quadratic unconstrained binary optimization

Hiroki Oshiyama¹ and Masayuki Ohzeki¹

¹Graduate School of Information Sciences, Tohoku University, Sendai 980-8579, Japan

ABSTRACT

Recently, inspired by quantum annealing, many solvers specialized for unconstrained binary quadratic programming problems have been developed. For further improvement and application of these solvers, it is important to clarify the differences in their performance for various types of problems. In this study, the performance of four quadratic unconstrained binary optimization problem solvers, namely D-Wave Hybrid Solver Service (HSS), Toshiba Simulated Bifurcation Machine (SBM), Fujitsu Digital Annealer (DA), and simulated annealing on a personal computer, was benchmarked. The problems used for benchmarking were instances of real problems in MQLib, instances of the SAT-UNSAT phase transition point of random not-all-equal 3-SAT (NAE 3-SAT), and the Ising spin glass Sherrington-Kirkpatrick (SK) model. Concerning MQLib instances, the HSS performance ranked first; for NAE 3-SAT, DA performance ranked first; and regarding the SK model, SBM performance ranked first. These results may help understand the strengths and weaknesses of these solvers.

1 Introduction

Quantum annealing $(QA)^{1,2}$, which is a quantum algorithm for solving combinatorial optimization problems, has attracted a great deal of attention because it is implemented using real quantum systems by D-Wave Systems Inc.^{3,4}, aiming at becoming more powerful than classical algorithms such as simulated annealing $(SA)^{5,6}$. To use the current D-Wave's QA device, a combinatorial optimization problem must be mapped to a quadratic unconstrained binary optimization (QUBO) problem. QUBO is an optimization problem of binary variables $x_i \in \{0, 1\}$, where $i \in \{1, 2, ..., N\}$, and its cost function to be minimized is defined as

$$E(\mathbf{x}) = \sum_{i,j} Q_{i,j} x_i x_j,\tag{1}$$

where $Q_{i,j}$ is a real number called QUBO matrix element. In general, QUBO is NP-hard⁷, and many NP-complete problems and combinatorial optimization problems are mapped to QUBO⁸.

Although current QA devices have limited capability owing to hardware implementation limitations, in anticipation of future developments of QA devices, methods using QUBO models for solving real-world problems in a variety of fields have been actively studied^{9–15}. Inspired by this trend, several sophisticated heuristic QUBO solvers have been developed and commercialized^{16–19}. It is highly non-trivial to determine whether a particular algorithm is more powerful than another because the performance of heuristic algorithms varies depending on the target problem. For successful application to real-world problems and further development of these QUBO solvers, it is necessary to clarify the strengths and weaknesses of each solver for various types of QUBO problems. In this study, we benchmarked the performance of three commercialized QUBO solvers including one using a real QA device: D-Wave Hybrid Solver Service (HSS), Toshiba Simulated Bifurcation Machine (SBM), and Fujitsu Digital Annealer (DA); three types of problem sets were used.

The remainder of this paper is organized as follows. In Sec. 2, we briefly explain the solvers benchmarked. In Sec. 3, the definition of the problem instances used for benchmarking are provided. In Sec. 4, we present the results of the benchmarking experiment. Finally, in Sec. 5, we summarize our results and conclusions.

2 QUBO solvers

In this section, we briefly explain the four solvers used in this study. Three commercial solvers were benchmarked. For comparison, we also experimented with SA on a personal computer.

The first solver is HSS, commercialized by D-Wave Systems Inc.¹⁶. This solver is a so-called quantum-classical hybrid algorithm that employs QA as an accelerator. Note that the actual implementation of the algorithm is not open to the public. Thus, it is unclear how QA is used internally. We used HSS hybrid BQM solver, version 2.0, which can manage up to one million variables and two hundred million couplings²⁰.

The second solver is SBM, commercialized by Toshiba¹⁸. This solver, inspired by QA, uses the adiabatic time evolution of Kerr-nonlinear parametric oscillators (KPOs)²¹. The dynamics in the classical limit of KPOs can be quickly computed in classical computers by solving the independent equations of motion in parallel¹⁸. We use SBM PoC version 1.2, which can manage all-to-all coupling of up to 10000 variables²². In this study, we used the autoising solver; the calculation parameters of SBM were not specified.

The third solver is DA, commercialized by Fujitsu¹⁹. DA uses an SA-specific hardware architecture to accelerate SA calculation^{23,24}. Although DA does not use quantum algorithms, it is inspired by D-Wave devices in the sense that the hardware is specialized for QUBO solving. We used fujitsuDA2PT solver, which can manage all-to-all coupling of up to 8192 variables.

For comparison with these commercial solvers, we ran SA using the open-source software D-Wave neal, version 0.5.7²⁵, on a personal computer. The CPU used in the experiment was Intel(R) Core(TM) i9-9900K, and single-threaded runs were performed.

3 Problem instances for benchmarking

In this section, we explain the three problem sets used in the conducted benchmarking.

3.1 MQLib repository instances

We used the same set of 45 problems used in the benchmarks presented in HHS's white paper^{16,26}. This problem set is extracted from the MQLib repository, and some of the problems have their origin in real-world problems, such as image segmentation²⁷. This problem set was reported to be time-consuming to solve because of all the heuristics contained in the MQLib library. Concerning benchmarking, a 20-minute run is recommended for each problem.¹⁶. The 45 problems are uniformly classified into nine classes: three classes according to size (small: $1000 \le N \le 2500$, medium: $2500 < N \le 5000$, and large: $5000 < N \le 10000$) and three classes according to edge density (sparse: $d \le 0.1$, medium: $0.1 < d \le 0.5$, and dense: 0.5 < d), where *d* is the number of edges divided by the number of edges in a complete graph of the same size¹⁶.

3.2 Not-All-Equal 3-SAT

Not-all-equal 3-SAT (NAE 3-SAT) is a variant of the Boolean satisfiability problem and is an NP-complete problem²⁸. NAE 3-SAT requires at least one literal to be true and at least one literal to be false in each clause with three literals. The cost function of a random NAE 3-SAT with *N* variables and *M* clauses is expressed in a straightforward manner in the Ising model with $\sigma_i \in \{-1, 1\}$, where $1 \le i \le N$:

$$E(\boldsymbol{\sigma}) = \frac{1}{4} \sum_{m=1}^{M} (\zeta_{m,1} \zeta_{m,2} \sigma_{i_{m,1}} \sigma_{i_{m,2}} + \zeta_{m,2} \zeta_{m,3} \sigma_{i_{m,3}} - \zeta_{m,3} \zeta_{m,1} \sigma_{i_{m,3}} \sigma_{i_{m,1}} + 1),$$
(2)

where $i_{m,l} \in \{1, 2, ..., N\}$ and $\zeta_{m,l} \in \{-1, 1\}$ for $1 \le m \le M$ and $1 \le l \le 3$ are random variables that follow a discrete uniform distribution; $\zeta_{m,l} = -1$ corresponds to the negation of the *l*-th Boolean variable in clause *m*. Each clause has three different variables, i.e., $i_{m,l} \ne i_{m,l'}$ if $l \ne l'$. If the minimum of $E(\boldsymbol{\sigma})$ in Eq. (2) is 0 for a given formula, it is satisfiable (SAT); otherwise, it is unsatisfiable (UNSAT). The QUBO formulation as in Eq. (1) can be easily obtained from this Ising formulation by the variable transformation $x_i = (\sigma_i + 1)/2$.

When the clause-to-variable ratio is M/N = 2.11, the SAT-UNSAT phase transition occurs, and problem instances are most difficult to solve^{29,30}. In this study, we used randomly generated instances with this critical clause-to-variable ratio for benchmarking.

3.3 Sherrington-Kirkpatrick model

The Sherrington-Kirkpatrick (SK) model is an Ising spin glass model with infinite spatial dimensions^{31,32}. The cost function of N variables with no external field is expressed as

$$E(\boldsymbol{\sigma}) = \frac{1}{\sqrt{N}} \sum_{1 \le i < j \le N} J_{i,j} \sigma_i \sigma_j, \tag{3}$$

where $J_{i,j}$ is a random Gaussian variable. As previously explained, the QUBO formulation can be easily obtained. The mean field analysis shows that the energy landscape of the SK model has a many-valley structure separated by asymptotically infinitely large energy barriers, which implies that it is extremely difficult to find the exact solution³³. In this study, we used randomly generated instances with $J_{i,j}$ presenting zero mean and unity standard deviation for benchmarking.

		Sma	.11			Medium			Large			Total

Table 1. Number of wins for a 5-min experiment of MQLib instances. The row direction is classified in terms of size (Small, Medium, and Large), whereas the column direction is classified in terms of edge density (Sparse, Medium, and Dense).

4 Results

In this section, we present benchmarking results for each of the three problem sets introduced in the previous section. In the results shown below, the network time required to send the instance and receive the result was ignored in the measurement of execution time. Regarding HSS, the number of seconds specified in time_limit was used as the execution time. For SBM, the time specified in timeout was used as the execution time. Concerning DA, there was no parameter to specify the execution time directly, so total_elapsed_time recorded in the response file was used as the execution time. Finally, for SA with D-Wave neal, we measured the time taken for the sample function to finish.

4.1 MQLib instances

First, we present the results for a 5-min experiment of the instances from the MQLib repository. For HSS and SBM, the execution time was set to 5 min. For DA, number_replicas was set to 128 and number_iterations was adjusted for each instance so that the deviation of execution time in 5 min was within 20 s. Concerning SA, num_sweeps was adjusted for each instance such that the execution time was 5 min. Table 1 shows the number of wins for each solver; this number was counted when the solver obtained the best solution. If there was more than one solver with the best solution, the number of wins was counted for all of them. The total result for all classes was that HHS won most of the problems (22), followed by DA (20), SBM (16), and SA (7). The results for each class classified by size show that HSS won the most for the small class, while DA won the most for the medium and large classes. The results for each class classified by edge density show that, for Sparse class, HSS won the most, for Medium class, DA won the most, and HSS and DA won the most. The number of wins of SA was only 2 at most, and most of the time, it was 0 or 1 for each of the nine classes. Tables 2-10 show the value of the cost function obtained by each solver for each instance; this value is the ratio of the best value found in this experiment. For almost all instances, the solutions by HSS and SBM were in agreement by more than three orders of magnitude with the best solution found in this experiment. The solutions by DA tended to have larger differences from the best solution compared to other solvers. The lowest values of the cost function found in this benchmarking are listed in Table 11.

4.2 NAE 3-SAT instances

Next, we present the results for the random NAE 3-SAT instances with a number of variables N = 8192 and a number of clauses M = 17285, i.e., instances with a clause-to-variable ratio $N/M \approx 2.11$. Figure 1 (a) shows the average of ten randomly generated instances of the cost function as a function of the execution time. As a reference, Fig. 1 (b) shows the results for ten different instances. Given that each data point was obtained from an independent run, a longer run may lead to a worse solution than a shorter run. In the range 100-600 s, DA presented the lowest value of the cost function, closely followed by SBM and SA; HSS presented the highest value. In the region below 100 s, SBM and SA showed lower energy than DA. Focusing on the slope in the region beyond 200 s, HSS was the steepest, while SBM and SA were almost flat. Therefore, it is likely that HSS can obtain a much better solution than SBM and SA in a longer calculation. DA presented a steeper slope than SBM and SA in the region that we could calculate. In summary, SBM and SA are better for short-time calculations, while DA and HSS are better for long-time calculations. The lowest values of the cost function in this experiment were obtained using DA.

4.3 SK model

Finally, we present the results for the SK model with 8192 variables. As with the NAE 3-SAT instances, the experiments were performed by varying the execution time. Figure 2 (a) shows the average of six randomly generated instances of the cost function as a function of the execution time. As a reference, Fig. 2 (b) shows the results for six different instances. SBM achieved the best solutions at the 100-s mark, with little energy change for longer runs. HSS and DA showed almost the same time dependence, although HSS provided a slightly better solution. In runs longer than 600 s, SA obtained as good solutions as HSS and DA, but due to the all-to-all coupling, its pre-processing calculation was expensive, requiring at least approximately 500 s for the total calculation time. In summary, SBM performs the best in terms of both computation time and solution quality. HSS and DA show similar performance.

5 Summary

In this study, we benchmarked the QUBO solvers, HSS, SBM, DA, and SA, using the instances from the MQLib repository, random NAE 3-SAT, and the SK model. HSS exhibited the steepest time dependence concerning the cost function on both NAE 3-SAT and SK models in the long-execution-time region, which implies that HSS can obtain good solutions in long runs. SBM showed the best performance on the SK model, while other solvers provided worse solutions than those given by SBM in a 100-s run, and even in runs longer than 600 s, while for the NAE-3AT problem, SBM showed almost the same time dependence regarding the cost function as SA. DA performed the best for the large-size MQLib instances and the NAE 3-SAT instances in the long-execution-time region. Interestingly, SBM and DA behaved almost identically for the NAE 3-SAT problem, whereas HSS and DA behaved almost identically for the SK model. It is an important challenge to understand the characteristics of each solver found in this study from the viewpoint of their algorithms.

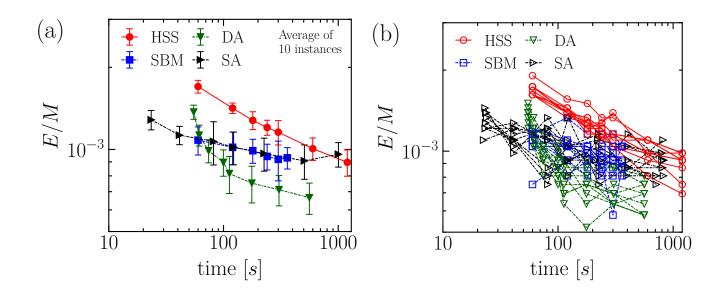

Figure 1. Value of the cost function per clause as a function of the execution time, obtained for NAE 3-SAT with a number of variables N = 8192 and a number of clauses M = 17285, i.e., $M/N \approx 2.11$. Each data point was obtained from an independent run. See the main text for the time metric of each solver. (a) Average of ten instances. The error bars denote standard deviation. For DA and SA, the execution time was also averaged. (b) Results for ten different instances.

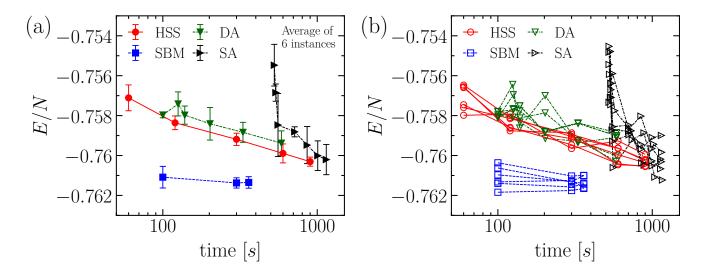

Figure 2. Value of cost function per variable as a function of the execution time, obtained for the SK model with a number of variables N = 8192 and J = 1. Each data point was obtained from an independent run. See the main text for the time metric of each solver. (a) Average of ten instances. The error bars denote standard deviation. For DA and SA, the execution time was also averaged. (b) Results for six different instances.
