Ten Points on a Cubic

Will Traves and David Wehlau

May 26, 2021

Abstract

In 1639 the 16-year old Blaise Pascal found a way to determine if 6 points lie on a conic using a straightedge. We develop a method that uses a straightedge to check whether 10 points lie on a plane cubic curve.

Books I through VI of Euclid's *Elements* treat ruler and compass constructions, which remain a mainstay of high school geometry in America today. Two classical problems that cannot be solved by ruler and compass are to double the cube – to construct a line segment of length $\sqrt[3]{2}$ given a segment of length 1 – and to trisect a general angle. Today these impossibility results are usually proven using Galois theory, but the first proof dates to 1837, just five years after Evariste Galois was killed in a duel. That proof [24], given by the 23-year old mathematician Laurent Wantzel, was ignored and forgotten for over 80 years. There are many variants of the constructibility problems. In some we use a rusty compass which only has one setting. In another we replace the compass by the ring left from a coffee cup: we have no compass but are given a single circle. Our favorite is to toss the compass away completely and just consider straightedge-only constructions! Using a straightedge, we are only allowed to draw lines between known points and construct points by intersecting lines. This requires us to produce incidence relations – three collinear points or three concurrent lines – to characterize geometric properties. It may be surprising that even with this reduced material there are many beautiful results.

The 16-year old Blaise Pascal found a nice incidence result characterizing points on a conic in 1639. If six points lie on a conic then connecting the points with line segments forming a path gives a (degenerate) hexagon whose three pairs of opposite sides extend to meet in three *collinear* points. The Pascal line through these three auxiliary points is depicted in Figure 1 as a dotted line. There are 6! = 720 ways to reorder the points but since rotations and reflections of the hexagon do not produce a new picture, we can draw just 60 hexagons, each giving rise to a Pascal line. The reader is invited to choose a different hexagon and draw the Pascal line. This arrangement of 60 lines is known as Pascal's Hexagrammum Mysticum and has been studied by many important geometers, including the Reverend T.P. Kirkman, Arthur Cayley, Jakob Steiner, Julius Plücker and George Salmon. See Conway and Ryba's papers [7, 8] for details, including a reference to the hand-drawn diagram of all 60 lines due to Anne and Elizabeth Linton [16], twin sisters who completed doctoral studies together at the University of Pennsylvania in 1921.

The English mathematicians William Braikenridge and Colin Maclaurin established the converse to Pascal's Theorem almost a hundred years after Pascal's discovery: if three lines meet another set of three lines in 9 points with three of the points lying on yet another line then the remaining six points lie on a conic. Today we know these theorems are part of a family of such results described by the Cayley-Bacharach Theorem.

While a straightedge construction cannot use angles or distances directly, many incidence conditions are equivalent to angle or distance constraints. The best known of these are Menelaus's and Ceva's

Figure 1: An incidence result relating six points on a conic to 3 points on a line.

Theorems. The first theorem, due to Menelaus of Alexandria (70-140 A.D.) says that three points on the three (extended) edges of a triangle are collinear precisely when the product of three oriented length ratios is -1, as illustrated in Figure 2 (left). Ceva's Theorem was first proven by Yusuf Al-Mu'taman ibn Hüd, an eleventh-century king of Saragossa in present-day Spain, and later proven and popularized by Giovanni Ceva in 1678. Ceva's Theorem dualizes Menelaus's Theorem, interchanging lines and points: the sides of a triangle are cut by three concurrent lines that pass through the corresponding opposite vertex precisely when the product of the three oriented length ratios is 1, as illustrated in Figure 2 (right).

Figure 2: Menelaus's Theorem (left) and Ceva's Theorem (right).

Lazare Carnot is best known as the "Organizer of Victory" for the French Revolutionary Army at the end of the 18th century but after being exiled for his revolutionary activities he retired to write about mathematics and military tactics. Like Pascal's Theorem, Carnot's Theorem characterizes when six points lie on a conic, but the result involves products of distance ratios like Menelaus's and Ceva's theorems. Carnot drew three lines through pairs of the six points, producing the triangle *ABC*. Labeling the points a_1 , a_2 , b_1 , b_2 , c_1 and c_2 as in Figure 3, Carnot observed that the six points lie on a conic precisely when a product of six distance ratios equals 1.

A natural next step is to look for incidence theorems involving cubic curves. One consequence of the Cayley-Bacharach Theorem is the *Eight Implies Nine Theorem*: Given any eight points, there is a ninth special point so that every cubic through the eight given points must pass through the ninth point. Using a straightedge to construct the ninth point from the eight given points was a problem considered by several people in the 19th century, including A. S. Hart [14], Thomas Wheedle [25], Michel Chasles [6], and Arthur Cayley [5]. Recently, Qingchun Ren, Jürgen Richter-Gebert, and Bernd Sturmfels [21] took a modern approach to the problem. Though the Cayley-Bacharach Theorem plays a vital role in our work, we do not even state it here. The curious reader is referred to the excellent survey paper by Eisenbud, Green and Harris [10], who trace the history of the theorem and prove several versions of the theorem.

Our main result gives a straightedge construction that checks whether 10 general points lie on a cubic. We give an incidence result reminiscent of the results of Pascal, Braikenridge, and Maclaurin: ten points lie on a cubic precisely when three constructed points are collinear. The key step is to realize the 10 points

Figure 3: Carnot's Theorem: labeling the six points (left) and the product condition (right).

as a subset of 16 points that are the intersection of two degree-4 curves, each the union of two conics. The Cayley-Bacharach Theorem implies that the 10 points lie on a cubic precisely when the 6 remaining points lie on a conic, which we test using Carnot's Theorem. A serious complication is that when using a straightedge we can only find two of the 6 extra points together with two lines that contain the remaining four points. Remarkably, we are able to overcome this difficulty using important methods from geometry, such as the power of a point and cross ratios. These tools allow us to use Carnot's Theorem to check whether the six residual points lie on a conic, reducing the computation to an instance of Menelaus's Theorem.

The next section describes the geometric context and introduces some mathematical tools. Section 2 deals with constructive problems in synthetic geometry involving conics and lines, results that will be needed in our construction. Section 3 gives the construction to check whether 10 points lie on a cubic. We give a second, computer-aided proof, that the construction works in Section 4. The last section contains some pointers to the literature and several exercises for the interested reader.

1 Context

The plane. We will be working with lines and points in the plane, but even this simple statement needs some clarification. It will be convenient to allow complex coordinates in many of our proofs so we'll work with \mathbb{C}^2 rather than \mathbb{R}^2 . This means that our straightedge is a *complex* straightedge: it allows us to draw the complex line $\{(x_0 + x_1t, y_0 + y_1t) : t \in \mathbb{C}\}$ joining two complex points (x_0, y_0) and (x_1, y_1) in \mathbb{C}^2 and to intersect two complex lines. Fortunately, if all of the geometric objects used as inputs to our constructions are defined over a subfield (like \mathbb{R} , \mathbb{Q} , or $\mathbb{Q}(\sqrt{2})$) of \mathbb{C} then our output will also be defined over the same field.

Moreover we work in the projective plane \mathbb{P}^2 , a copy of the usual plane together with points at infinity. More generally, the points in the projective space \mathbb{P}^n are modeled as one-dimensional subspaces of \mathbb{C}^{n+1} , lines through the origin $\mathbf{0} \in \mathbb{C}^{n+1}$. Each point in \mathbb{P}^n is defined by its homogeneous coordinates: the subspace with basis given by the vector $\langle x_1, x_2, \ldots, x_{n+1} \rangle \neq \mathbf{0}$ is denoted $[x_1 : x_2 : \ldots : x_{n+1}]$ (or just [x : y : z] for points in the projective plane), where the square brackets remind us that a point is really an equivalence class of all possible basis vectors for the subspace. Since the basis vectors for a fixed one-dimensional subspace are nonzero scalar multiples of one another, this forces the equality $[\lambda x_0 : \lambda x_1 : \ldots, \lambda x_n] = [x_1 : x_2 : \ldots : x_{n+1}]$ for all non-zero scalars $\lambda \in \mathbb{C}$. The colon in the notation indicates that it is the ratios of these coordinates that determine the point in the projective space; the actual values of the coordinates are not so important since they can always be multiplied by a common scalar. It is customary to identify points $[x_0: x_1: \ldots: x_{n+1}]$ satisfying $x_{n+1} \neq 0$ with points in the usual \mathbb{C}^n : the point $[x_1: x_2: \ldots: x_{n+1}] = [x_1/x_{n+1}: x_2/x_{n+1}: \cdots: 1]$ is identified with $(x_0/x_{n+1}, x_1/x_{n+1}, \ldots, x_n/x_{n+1})$. The remaining points, all of the form $[x_1: x_2: \ldots: x_n: 0]$, are thought of as points at infinity. To get a sense of how the regular points connect with the points at infinity, we can traverse a line starting at $\mathbf{b} = (b_1, \ldots, b_n) \in \mathbb{C}^n$, moving in the direction $\mathbf{m} = \langle m_1, \ldots, m_n \rangle \in \mathbb{C}^n$, and take a limit:

$$\lim_{t \to \pm \infty} (m_1 t + b_1, \dots, m_n t + b_n) = \lim_{t \to \pm \infty} [m_1 t + b_1 : \dots : m_n t + b_n : 1]$$

=
$$\lim_{t \to \pm \infty} \left[m_1 + \frac{b_1}{t} : \dots : m_n + \frac{b_n}{t} : \frac{1}{t} \right]$$

=
$$[m_1 : \dots : m_n : 0].$$

The limiting point at infinity $[m_1 : \ldots : m_n : 0]$ corresponds to the direction vector of the line, irrespective of the starting point, the speed, or even which way we move along the line.

Just as points in \mathbb{P}^2 are modeled by one-dimensional subspaces of \mathbb{C}^3 , lines in the projective plane are modeled by two-dimensional subspaces of \mathbb{C}^3 . Such a subspace is a plane through the origin and is completely determined by its normal vector $\langle a, b, c \rangle \neq \langle 0, 0, 0 \rangle$: $L = \{[x : y : z] \in \mathbb{P}^2 : ax + by + cz = 0\}$. Note that all the points at infinity lie on the line z = 0, the *line at infinity*. The line through distinct points P and Q has normal vector given by the cross product $P \times Q$. The cross product $v \times w$ also gives the homogeneous coordinates of the point of intersection of two distinct lines with normal vectors v and w. In particular, two different lines in \mathbb{P}^2 always meet in a point: the point lies at infinity if the lines are parallel. We will use an *infinitely long* straightedge. That is, we can construct the common point at infinity of two parallel lines. If the line at infinity can be constructed from our given input data then we can also construct the intersection point of any given line with the line at infinity. The collection of lines in \mathbb{P}^2 is itself a 2 dimensional projective space, called the dual projective plane. The line with equation ax + by + cz = 0 is identified with the point [a : b : c]. Note that this identification is well-defined since any other equation of the line is a nonzero scalar multiple $\lambda ax + \lambda by + \lambda cz = 0$ of the original equation and its associated point $[\lambda a : \lambda b : \lambda c]$ equals [a : b : c].

Circles as special conics. Given a curve defined by a polynomial equation g(x, y) = 0 in the usual plane, there is a standard way to extend the curve to all of \mathbb{P}^2 . If the polynomial g has degree d, we homogenize g by multiplying each term in the polynomial by a power of z to ensure that it too has total degree d. The homogenization G(x, y, z) vanishes at all points in the regular plane where g vanished since G(x, y, 1) = g(x, y). While we cannot talk about the value of G at a point [x : y : z] because the value of G changes when we scale the point, $G(\lambda x, \lambda y, \lambda z) = \lambda^d G(x, y, z)$, the vanishing of G(x, y, z) is well-defined. For instance, homogenizing the line cut out by y - (mx + b) = 0 gives the projective line y - (mx + bz) = 0, which meets the line at infinity z = 0 at [1 : m : 0]. As a second example, a general conic is defined by the vanishing of a degree-2 polynomial

$$g(x,y) = ax^2 + bxy + cy^2 + dx + ey + f$$

and its extension to the full projective plane is cut out by setting the homogenization

$$G(x, y, z) = ax2 + bxy + cy2 + dxz + eyz + fz2$$

equal to 0. Note that imposing the requirement that a given point $P[x_0 : y_0 : z_0]$ lies on the conic G(x, y, z) = 0 imposes a linear condition on the coefficients a, b, \ldots, f of the polynomial G. Imposing five such conditions gives a 5×6 system of linear equations, which always has a nonzero solution by the

Rank-Nullity Theorem, so there is a conic through any five points. However, the 6×6 system of linear equations imposed by six general points has a nonzero solution precisely when the six points lie on a conic. The extension of these ideas to degree-*d* polynomials show there is a degree-*d* curve through any $\binom{d+2}{2} - 1$ points but $\binom{d+2}{2}$ points need to be in special position to lie on such a curve. In particular, 10 points need to be in special position in order to lie on a cubic curve. Our goal in this paper is to give a criterion describing these special positions in terms of incidence relations.

One feature of working with curves in the projective plane is that intersections are easy to describe. Isaac Newton first observed in the Principia that two projective plane curves of degrees d and e meeting in finitely many points actually meet in precisely de points, counted appropriately. Over a hundred years later, Étienne Bézout [3] generalized this observation to geometric objects in higher dimensional projective spaces and the result is generally known as Bézout's Theorem. For instance, as we've already seen, any two lines (degree-1 curves) meet in one point, though that point might lie at infinity. Lines meet conics in two points, but we need to count the intersection properly: a tangent point is counted twice (as in Figure 4 (middle)) and the intersection points may be complex (and so not visible in the real drawing, as in Figure 4 (right)). See Fulton [11] for details.

Figure 4: Three instances of a conic meeting a line.

Let's see where the circle with center (x_0, y_0) and radius r meets the line at infinity. The homogenization of the defining polynomial of the circle is $(x - x_0z)^2 + (y - y_0z)^2 - r^2z^2$ and setting z = 0 we see that the circle meets the line at infinity at points [x : y : 0] where $x^2 + y^2 = 0$. There are two such points, I = [1 : i : 0] and J = [1 : -i : 0], and they are independent of the radius and center of the circle. Everyone knows that circles are special kinds of conics, but now we know that they can be characterized as the irreducible conics that meet the line at infinity at the special points I and J!

Projective transformations. In 1872 Felix Klein announced his Erlangen program for geometry, classifying geometries by the type of transformations that act on the underlying space and properties invariant under those maps. Projective space \mathbb{P}^2 admits *projective transformations*, multiplication of points by an invertible 3×3 matrix $M \in GL_3(\mathbb{C})$. Such maps are well-defined since $M(\lambda \mathbf{v}) = \lambda(M\mathbf{v})$ and they send any collection of collinear points to new collinear points since multiplication by an invertible matrix preserves linear dependence. In fact, any four points in general position in \mathbb{P}^2 – no three collinear – can be sent to any other four points in general position by a projective transformation. To see this, we first note that if the vectors $\mathbf{v_1}$, $\mathbf{v_2}$, $\mathbf{v_3}$, and $\mathbf{v_4} = a\mathbf{v_1} + b\mathbf{v_2} + c\mathbf{v_3}$ are representatives for the homogeneous coordinates of four points in general position, then multiplying by the matrix M whose columns are $a\mathbf{v_1}$, $b\mathbf{v_2}$, and $c\mathbf{v_3}$ sends the three standard basis vectors $\mathbf{e_1}$, $\mathbf{e_2}$, $\mathbf{e_3}$ and $\mathbf{e_1} + \mathbf{e_2} + \mathbf{e_3}$ to the four given points. If multiplying by the matrix N sends the four points $\mathbf{e_1}$, $\mathbf{e_2}$, $\mathbf{e_3}$ and $\mathbf{e_1} + \mathbf{e_2} + \mathbf{e_3}$ to four new points, then multiplying by NM^{-1} sends $\mathbf{v_1}$, $\mathbf{v_2}$, $\mathbf{v_3}$, and $\mathbf{v_4}$ to these four new points too.

Projection from a point gives a geometric example of a projective transformation from one line to another. Given a point O and two lines ℓ and ℓ' not passing through O then the projection map $\pi : \ell \to \ell'$ given by $\pi(P) = OP \cap \ell'$, and illustrated in Figure 5, is obtained by crossing the normal vector to ℓ' with the vector obtained from the cross product of the homogeneous coordinates of O and P. The reader can check that this map can also be represented as multiplication by a matrix depending on O and ℓ' .

Returning to the Erlangen program, multiplying by a matrix can be interpreted as changing the

Figure 5: The projection π from ℓ to ℓ' through the point O.

basis of the underlying space \mathbb{C}^3 , so projective geometry is mainly concerned with properties that are independent of the choice of coordinates on our space. Incidence relations are geometric properties that do not depend on our coordinate system. The property of six points lying on a conic is also independent of the coordinates since Pascal's Theorem reduces the question of whether six points lie on a conic to an incidence statement. However, projective transformations do not preserve distances or angles, so the Erlangen program suggests that properties depending on distances and angles are not proper objects of study in projective geometry. Our point of view in this paper carefully blends projective and Euclidean geometry, using distances to prove results in Euclidean geometry and interpreting those results in terms of projective objects. For instance, to check whether six points lie on a conic we will apply a change of coordinates to move two of those points to I and J, which reduces the problem to checking whether the remaining transformed points lie on a *circle*, which we can check by measuring distances. This viewpoint seems in conflict with Klein's original Erlangen program but is consistent with his response to later developments [15]. Jacques-Salomon Hadamard [13] wrote "It has been written¹ that the shortest and best way between two truths of the real domain often passes through the imaginary one." Similarly, the

Cross Ratios. The cross ratio (A, B; C, D) of four collinear points A, B, C and D is the quantity

$$(A, B; C, D) = \frac{|AC||BD|}{|AD||BC|}.$$

Alexander Jones [18] claims that Pappus of Alexandria already knew about cross ratios in 340 A.D but it was Carnot who introduced the use of oriented distances in the cross ratio. We fix a direction on the line to be positive and let |AB| be the signed displacement from A to B. If O is any point off the line, the cross ratio (A, B; C, D) equals [OAC][OBD]/[OAD][OBC], where [ABC] is the determinant of the 3×3 matrix whose columns are the homogeneous coordinates of the points A, B, and C. Going forward, we will implicitly assume this interpretation of the distance ratios, allowing us to consistently orient all of our lines. With this interpretation, if B is the point at infinity on the line then [OBD] = [OBC]and (A, B; C, D) = |AC|/|AD| is a quotient of directed distances measured from the common point A. The cross ratio is invariant under projective transformation since if we multiply by a matrix M then the determinant of the matrix [(MA)(MB)(MC)] of transformed points equals det(M)[ABC] and then the determinant det(M) cancels from all terms in the fraction defining (MA, MB; MC, MD), yielding (A, B; C, D).

¹Apparently, Hadamard was paraphrasing Paul Painlevé [19], the French mathematician and statesman who served twice as Minister of War and twice as Prime Minister of France.

2 Geometric Constructions

In this section we deal with some problems in constructive synthetic geometry: given enough information to uniquely define two geometric objects, we show how to construct their intersection with a straightedge.

Construction 1: Find the second point of intersection of a line with a conic. Given five points P_1, \ldots, P_5 lying on a unique conic \mathcal{C} (that is, no four are collinear) and another point Q, we show how to use a straightedge to locate the second point of intersection R of the line $\ell = P_1Q$ with the conic \mathcal{C} . This follows immediately from Pascal's Theorem if we arrange for one of the six lines in Pascal's Theorem to be the line P_1Q . Construct the three collinear points $Q_1 = P_1P_2 \cap P_4P_5$, $Q_2 = P_3P_4 \cap \ell$ and $Q_3 = P_2P_3 \cap Q_1Q_2$. Then the point $R = P_5Q_3 \cap \ell$ lies on \mathcal{C} and ℓ . This is illustrated in Figure 6 below.

Figure 6: Using Pascal's Theorem to find the fourth point of intersection of C with ℓ .

Construction 2: Find the fourth point of intersection of two conics. Suppose that two conics C_1 and C_2 share the points E_1 , E_2 , and E_3 and that C_1 also passes through points $P_1 = [x_1 : y_1 : z_1]$ and $P_2 = [x_2 : y_2 : z_2]$ and C_2 passes through points $P_3 = [x_3 : y_3 : z_3]$ and $P_4 = [x_4 : y_4 : z_4]$. Further, suppose that all points are in general position so that no three are collinear. We show how to locate the fourth point of intersection R of C_1 with C_2 using a straightedge.

After a projective change of coordinates, we may assume that $E_1 = [1:0:0]$, $E_2 = [0:1:0]$ and $E_3 = [0:0:1]$. We choose to write the equation of the conic C_1 as $a_1yz + a_2xz - a_3xy + \alpha_1x^2 + \alpha_2y^2 + \alpha_3z^2 = 0$ and the equation of C_2 as $b_1yz + b_2xz - b_3xy + \beta_1x^2 + \beta_2y^2 + \beta_3z^2 = 0$. Since both conics pass through E_1 , E_2 and E_3 , we find that all the α -coefficients and all the β -coefficients are zero.

Now we define two maps. Let $E = \{ [x : y : z] \in \mathbb{P}^2 : xyz = 0 \}$ and define $\phi : \mathbb{P}^2 \setminus E \to \mathbb{P}^2 \setminus E$ that sends the point [x : y : z] to [yz : xz : -xy]. It will be convenient to think of the target \mathbb{P}^2 as the dual \mathbb{P}^2 so that the image $\phi([x_0 : y_0 : z_0])$ is the line $y_0z_0x + x_0z_0y - x_0z_0z = 0$. The second map Φ identifies the set of conics through E_1 , E_2 , and E_3 as a copy of \mathbb{P}^2 . The map Φ sends the conic with equation axz + bxz - cxy = 0 to the point $[a : b : c] \in \mathbb{P}^2$. The map Φ is well-defined: any other equation of the conic is a nonzero scalar multiple of the original equation and its associated point $[\lambda a : \lambda b : \lambda c]$ equals [a : b : c]. The two maps are closely related:

$$\Phi(\mathcal{C}) \in \phi(P) \Leftrightarrow P \in \mathcal{C},$$

that is, the point $\Phi(\mathcal{C}) \in \mathbb{P}^2$ lies on the line $\phi(P)$ precisely when the point $P \in \mathbb{P}^2$ lies on the conic \mathcal{C} . This follows immediately from the definitions of the two maps, but the reader is encouraged to pause and check this fact.

Now the point $\Phi(\mathcal{C}_1)$ lies on both lines $\phi(P_1)$ and $\phi(P_2)$ so $\Phi(\mathcal{C}_1) = \phi(P_1) \cap \phi(P_2)$. Similarly, $\Phi(\mathcal{C}_2)$ is

the intersection of the two lines $\phi(P_3)$ and $\phi(P_4)$. In fact, we can *construct* the lines $L_i = \phi(P_i)$ with a straightedge using the process illustrated in Figure 7 (left). We join the points $[0: y_i: z_i] = E_1P_i \cap E_2E_3$ and $[x_i: 0: z_i] = E_2P_i \cap E_1E_3$, producing the line L_i with equation $y_iz_ix + x_iz_iy - x_iy_iz = 0$. You can check that this is the correct equation using the fact that the cross product of two points gives the coefficients of the line through the points and the cross product of the vectors of coefficients for the lines gives the homogeneous coordinates of their intersection.

Figure 7: Constructing L_i from P_i (left) and R from Q_1Q_2 (right).

So we can construct the two points $\Phi(\mathcal{C}_1)$ and $\Phi(\mathcal{C}_2)$ coming from the two conics. The line $L = \Phi(\mathcal{C}_1)\Phi(\mathcal{C}_2)$ joining these two points is the image $\phi(R)$ of a point R that lies on both conics and is not E_1, E_2 or E_3 . So R is the fourth point of intersection we are looking for! We can reverse the process for constructing the image of ϕ to find the point R with $\phi(R) = L$. The line L meets the line E_1E_3 at F and meets the line E_2E_3 at G. Then the lines FE_1 and GE_2 meet at R, constructing the fourth point of intersection works even when E_1, E_2 and E_3 do not lie in the special positions above since the projective transformation moving these points to the three given points of intersection of \mathcal{C}_1 and \mathcal{C}_2 preserves collinearities.

Let's pause our projective considerations to examine special results that hold for circles. In particular, we will make use of oriented distances. But don't worry, we will interpret these results in a projective way too.

The Power of a Point Theorem. Given a point X and a circle, draw a line through X that intersects the circle at A and B. The power of the point X with respect to this circle POP(X, C) is defined to be the product $|XA| \cdot |XB|$. The Power of a Point Theorem says that this quantity does not depend on the line drawn through X; if another line through X meets the circle at C and D then

$$|XA| \cdot |XB| = |XC| \cdot |XD|.$$

The result follows easily from considerations about angles and similar triangles. Indeed, referencing Figure 8, the two inscribed angles $\angle ADC$ and $\angle ABC$ are equal since both are half the central angle $\angle AOB$ supported at the center O of the circle. Then the triangles XAD and XCB are similar so

$$\frac{|XA|}{|XD|} = \frac{|XC|}{|XB|}$$

and hence $|XA| \cdot |XB| = |XC| \cdot |XD|$.

We will make use of the next result in our third construction.

Figure 8: The Power of a Point Theorem: $|XA| \cdot |XB| = |XC| \cdot |XD|$.

Lemma 1. Let C_1 and C_2 be irreducible conics meeting in four points A, B, I' and J'. If a line through A meets C_1 and C_2 at points C and D, respectively, and a line through B meets C_1 and C_2 at points E and F, respectively, then the three lines CE, DF, and I'J' are concurrent. In the special case where I' = I and J' = J, the two conics are both circles and the two lines CE and DF meet on the line at infinity and hence are parallel.

Figure 9: The point O_1 lies on lines CE, DF and I'J'.

Proof. Let \mathcal{L}_A denote the line through A and \mathcal{L}_B denote the line through B. Then Pascal's Theorem applied to the 6 points C, E, B, J', I', A of \mathcal{C}_1 tells us that the 3 points $O_1 = CE \cap I'J', O_2 = BE \cap AI' = \mathcal{L}_B \cap AI'$, and $O_3 = AC \cap BJ' = \mathcal{L}_A \cap BJ'$ are collinear. Similarly applying Pascal's Theorem to the 6 points D, F, B, J', I', A of \mathcal{C}_2 tells us that the 3 points $O'_1 = DF \cap I'J', O'_2 = BF \cap AI' = \mathcal{L}_B \cap AI'$, and $O'_3 = AD \cap BJ' = \mathcal{L}_A \cap BJ'$ are collinear.

Since $O_2 = O'_2$ and $O_3 = O'_3$ we see that $O_1 = O_2O_3 \cap I'J' = O'_2O'_3 \cap I'J' = O'_1$. Hence $O_1 \in CE \cap DF \cap I'J'$.

Construction 3: Given two conics sharing two known points, find the line through the remaining two points of intersection. Consider the following situation. We are given 5 points P_1 , Q_1 , R_1 , U and V, with no three collinear. These determine a unique irreducible conic C_1 passing through the points. Further suppose we have 3 more points P_2 , Q_2 and R_2 which together with U and V also determine a unique irreducible conic C_2 . Then U and V are two of the four points of intersection of C_1 with C_2 . We now explain how to find the line through the other two points of the intersection of C_1 with C_2 , which we call the radical axis of C_1 and C_2 .

Pick a point P and define $C = PU \cap C_1$ and $D = PU \cap C_2$. Similarly we take $E = PV \cap C_1$ and $F = PV \cap C_2$. We can construct these 4 points C, D, E, F using Construction 1. By Lemma 1 the point $O = CE \cap DF$ lies on the line through the other two points of intersection of C_1 with C_2 .

Now we repeat the above with a new point P' and construct C', D', E', F' and O' from P' in exactly the same manner. Then the line OO' is the desired line through the other two points of intersection of C_1 with C_2 .

3 Ten Points on a Cubic

We are ready to determine if ten general points lie on a cubic curve. We first partition the ten points into two sets of five, S_1 and S_2 . There is a conic C_i through the points in each S_i . Now swap two points of S_1 for two points of S_2 to make a second partition of the ten points into two sets of five, T_1 and T_2 , so that S_i and T_i share three points in common. Again there is a conic \mathcal{D}_i through the points in each T_i . The two unions of the pairs of conics form reducible degree-4 curves, $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2$ and $\mathcal{D} = \mathcal{D}_1 \cup \mathcal{D}_2$. From Bézout's Theorem we know that \mathcal{C} and \mathcal{D} meet in 16 points, 10 of which were our original 10 points. The remaining six points will be referred to as the *residual points*. The Cayley-Bacharach Theorem implies that the 10 original points lie on a cubic precisely when the six residual points lie on a conic. We will show how to locate the residual points and check that they lie on a conic using a straightedge.

To locate the residual points, note that the conics C_i and D_i share 3 known points, $S_i \cap T_i$, in common so we can construct their fourth point of intersection P_i using Construction 2. As well, C_1 and D_2 share two known points in common, $S_1 \cap T_2$, so we know that their two remaining points of intersection, Q_1 and Q_2 , lie on a line \mathcal{L}_Q that we can draw using Construction 3, even though we cannot construct the points Q_1 and Q_2 themselves. Similarly, C_2 and D_1 have two known points in common, $S_2 \cap T_1$, so the other two points of intersection, R_1 and R_2 , lie on a line \mathcal{L}_R that we can draw using Construction 3. The three lines $\mathcal{L}_P = P_1 P_2$, \mathcal{L}_Q , and \mathcal{L}_R form a triangle with vertices $P = \mathcal{L}_Q \cap \mathcal{L}_R$, $Q = \mathcal{L}_P \cap \mathcal{L}_R$, and $R = \mathcal{L}_P \cap \mathcal{L}_Q$. We would like to apply Carnot's Theorem to the six residual points P_1 , P_2 , Q_1 , Q_2 , R_1 and R_2 , on this triangle to determine whether they lie on a conic. However, to use Carnot's Theorem we would need to compute terms like $|PQ_1|$ and $|PQ_2|$ and we do not know Q_1 and Q_2 ! Fortunately, we can use the Power of a Point Theorem to compute this quantity and achieve Galileo's dictum, "make measurable what cannot be measured."

The two conics C_1 and \mathcal{D}_1 intersect in four points, one of which is the residual point P_1 . We choose one of the three other intersection points not on the line PP_1 and call it G. We label the other two intersection points A and B. We draw the line PG, as illustrated in Figure 10 (left). Construct W as the second point of intersection of the line PG with the conic C_1 and construct Z as the second point of intersection of the line PG with the conic \mathcal{D}_1 using Construction 1. Noting that $P_1 \in \mathcal{L}_P$ lies on both C_1 and \mathcal{D}_1 , we can use Construction 1 to construct X the second point of intersection of \mathcal{L}_P with \mathcal{C}_1 and Ythe second point of intersection of \mathcal{L}_P with \mathcal{D}_1 . Now set $U = WX \cap \mathcal{L}_Q$ and $V = YZ \cap \mathcal{L}_R$.

Theorem 1. The 10 general points lie on a cubic precisely when the six residual points lie on a conic and this happens if and only if the points P_2 , U, and V are collinear.

Theorem 1 shows that we can check whether 10 points lie on a cubic curve using just an infinitely long complex straightedge on the projective plane.

Proof. As pictured in Figure 10 (right), let $O = WX \cap YZ$, $M = OP \cap RQ$, $S = AB \cap RQ$ and $T = AB \cap PG$.

After applying a projective transformation we can assume Q is [0:0:1], Y is [1:0:1], A is I = [1:i:0] and B is J = [1:-i:0]. The transformed conics C_1 and D_1 are circles since they pass

Figure 10: Two illustrations of the incidence relations.

through I and J. The points S and T lie on the line at infinity AB = IJ. Moreover, the point O now lies on the line at infinity since, by Lemma 1, the two lines WX and YZ are parallel. Now consider the projection through O mapping points on the line PG to points on the line QR via $p \mapsto Op \cap QR$. This map sends P, W, and Z to the points M, X, and Y, respectively. Moreover, the point T where the line PG meets the line at infinity AB = IJ is sent to the point S where the line QR meets the line at infinity since all three points S, T and O are collinear.

By Carnot's Theorem, the six residual points P_1 , P_2 , Q_1 , Q_2 , R_1 , and R_2 , lie on a conic if and only if

$$\frac{|QP_1||QP_2||RQ_1||RQ_2||PR_1||PR_2|}{|RP_1||RP_2||PQ_1||PQ_2||QR_1||QR_2|} = 1.$$
(1)

Now we reduce this condition using the Power of a Point several times. We have

$$\begin{array}{ll} |RQ_1||RQ_2| &= POP(R, \mathcal{C}_1) &= |RP_1||RX| \\ |PR_1||PR_2| &= POP(P, \mathcal{D}_1) &= |PG||PZ| \\ |PQ_1||PQ_2| &= POP(P, \mathcal{C}_1) &= |PG||PW| \\ |QR_1||QR_2| &= POP(Q, \mathcal{D}_1) &= |QP_1||QY| \end{array}$$

Replacing terms in (1), canceling three terms, and reordering the remaining products gives the equivalent condition

$$\frac{|QP_2|}{|QY|} \frac{|RX|}{|RP_2|} \frac{|PZ|}{|PW|} = 1.$$
(2)

Each of the three ratios in the product in (2) is the value of a cross ratio of four points. Recalling that S is the point at infinity on QR and T is the point at infinity on ZW, we see that the six residual points lie on a conic precisely when

$$(Q, S; P_2, Y)(R, S; X, P_2)(P, T; Z, W) = 1.$$
(3)

Using the above projection from O to the line $\mathcal{L}_P = QR$ that sends P to M, T to S, W to X, and Z to Y, we can rewrite the term (P, T; Z, W) as (M, S; Y, X). Converting back to products of distance ratios and reordering we get an equivalent condition for the six residual points to lie on a conic

$$\frac{|P_2Q|}{|P_2R|} \frac{|XR|}{|XM|} \frac{|YM|}{|YQ|} = 1,$$
(4)

which can be expressed as a product of cross ratios $(P_2, S; Q, R)(X, S; R, M)(Y, S; M, Q) = 1$.

Now apply the projection onto the line PR via O to the four points in the middle cross ratio. This maps X to U, where $U = OX \cap PR$, and sends S to the point at infinity $E = AB \cap PR = IJ \cap PR$ on the line PR. Also apply the projection from O onto the line PQ to the four points in the third cross ratio. This maps Y to V, where $V = OY \cap PQ$, and sends S to the point at infinity $F = AB \cap PQ = IJ \cap PQ$, on the line PQ. This produces the equivalent condition

$$\begin{array}{rcl} (P_2,S;Q,R)(U,E;R,P)(V,F;P,Q) &=& 1\\ \Leftrightarrow & \frac{|P_2Q|}{|P_2R|} \frac{|UR|}{|UP|} \frac{|VP|}{|VQ|} &=& 1\\ \Leftrightarrow & \frac{|QP_2|}{|P_2R|} \frac{|RU|}{|UP|} \frac{|PV|}{|VQ|} &=& -1. \end{array}$$

Using Menelaus's Theorem, this last condition can be interpreted as saying that the six points P_1 , P_2 , Q_1 , Q_2 , R_1 , and R_2 lie on a conic precisely when the three points P_2 , U and V are the intersections of the extended edges of the triangle PQR with a straight line.

Applying the inverse transformation preserves the incidence relations: the original six residual points lie on a conic precisely when the three points P_2 , $U = WX \cap PR$ and $V = YZ \cap PQ$ are collinear. This same condition checks whether the original 10 points lie on a cubic.

We summarize our construction to check whether 10 points lie on a cubic.

Construction 4: Checking whether 10 general points lie on a cubic.

- 1. Partition the 10 points into two sets S_1 and S_2 , each with 5 points.
- 2. Swap two points of S_1 with two points of S_2 to produce a second partition $T_1 \cup T_2$ of the 10 points with $|S_i \cap T_i| = 3$.
- 3. Use Construction 2 to find the fourth points P_i of intersection of the conic through S_i with the conic through T_i (i = 1 or 2).
- 4. Use Construction 3 to find the line \mathcal{L}_Q through the two unknown points of intersection of the conic through S_1 and the conic through T_2 . Use the same construction to find the line \mathcal{L}_R through the two unknown points of intersection of the conic through T_1 and the conic through S_2 . Use $\mathcal{L}_P = P_1 P_2$, \mathcal{L}_Q and \mathcal{L}_R to construct $P = \mathcal{L}_Q \cap \mathcal{L}_R$, $Q = \mathcal{L}_P \cap \mathcal{L}_R$, and $R = \mathcal{L}_P \cap \mathcal{L}_Q$.
- 5. Take $G \in S_1 \cap T_1$ with $G \notin PP_1$. Draw PG and use Construction 1 to locate the intersection W (resp. Z) of PG with the conic through S_1 (resp. T_1).
- 6. Use Construction 1 to find the second point of intersection X (resp. Y) of the line $\mathcal{L}_P = P_1 P_2$ with the conic through S_1 (resp. T_1).
- 7. Take $U = XW \cap \mathcal{L}_Q$ and $V = YZ \cap \mathcal{L}_R$.
- 8. The 10 points lie on a cubic precisely when P_2 , U and V are collinear.

Our construction works for all sets of ten points off a set of measure zero. We can extend this construction to give an algorithm that will determine whether any set of 10 distinct points lies on a cubic curve. The extra work required is quite involved so we omit the details. The construction given here may fail when the 10 original points lie in special position. In particular, if our construction intersects two lines to create a point and the two lines are equal then the point is not well-defined. Similarly if we

try to form the line through two points but the points are equal then the line is not well-defined. The degenerate configurations for which such problems occur possess additional geometric structure. We may exploit this extra structure using our straightedge to settle the question of whether the ten points lie on a cubic by ad-hoc means. As one example, if the 7 points of $|S_1 \cup T_1|$ lie on a single conic then $C_1 = D_1$ and so Step 3 does not produce a well-defined point P_1 . Besides just making a less fateful choice of S_1 and T_1 , there is a simpler way to proceed. By Bézout's Theorem, the cubic would have to be a union of the conic C_1 and a line, so the ten points lie on a cubic precisely when the points off the conic C_1 are collinear, which we can check using our straightedge. The other special cases are similar.

Example. We start with ten points: $K_1 = [0, 0, 1], K_2 = [6, -15, 1], K_3 = [1, 0, 1], K_4 = [2, 2, 1], K_5 = [-\frac{5}{9}, \frac{8}{27}, 1], K_6 = [2, -3, 1], K_7 = [\frac{1}{4}, -\frac{3}{8}, 1], K_8 = [-1, 0, 1], K_9 = [-1, -1, 1], K_{10} = [6, 14, 1].$ Let C_1 be the conic through K_1, K_2, K_3, K_4 , and K_5 ; C_2 the conic through K_6, K_7, K_8, K_9 , and K_{10} ; \mathcal{D}_1 the conic through K_3, K_4, K_5, K_6 , and K_7 ; and \mathcal{D}_2 the conic through K_1, K_2, K_8, K_9 , and K_{10} . Conics C_1 and \mathcal{D}_1 share three known points and meet in a fourth point $P_1 = [-10:11:1]$ and conics C_2 and \mathcal{D}_2 also share three known points and meet in a fourth point $P_2 = [2:5:1]$. Conics C_1 and \mathcal{D}_2 share two known points and their radical axis is 10X - 7Y + 18Z = 0. Similarly, the radical axis of conics C_2 and \mathcal{D}_1 is 2X - Y + 10Z = 0. The two radical axes meet in P = [-13:-16:1], the first radical axis meets P_1P_2 in $R = [\frac{16}{9}:\frac{46}{9}:1]$, and the second radical axis meets P_1P_2 in $Q = [-\frac{8}{5}:\frac{34}{5}:1]$. Conic C_1 meets \mathcal{L}_P in P_1 and $X = [\frac{12}{5}:\frac{24}{5}:1]$ and conic \mathcal{D}_1 meets \mathcal{L}_P in P_1 and $Y = [\frac{34}{11}:\frac{49}{11}:1]$. The conics \mathcal{C}_1 and \mathcal{D}_1 meet at $G = K_3, A = K_4, B = K_5$, and P_1 . The line PG meets \mathcal{C}_1 at $W = [\frac{20}{13}:\frac{8}{13}:1]$ and meets \mathcal{D}_1 at $Z = [\frac{15}{2}:-\frac{4}{11}:1]$. The line WX meets the line \mathcal{L}_Q at $U = [\frac{11}{4}:\frac{13}{2}:1]$ and \mathcal{L}_R are parallel lines meeting at $V = [\frac{1}{2}:1:0]$ on the line at infinity. Now we can check that P_2, U and V all lie on the line 2X - Y + Z = 0, which tells us that the 10 points we started with lie on a cubic curve. In fact, they all lie on the curve $X^3 - XZ^2 - Y^2Z - YZ^2 = 0$.

The reader is warned that this example was meticulously constructed, involving very careful choices combined with a computer search among over a billion sets of points, to find an example involving rational coefficients expressible using small integers. More typical examples generate coefficient explosion leading to coefficients for the constructed points requiring integers several tens or hundreds of digits long as numerators and denominators.

4 A Binomial Proof

Having formulated Theorem 1, we give a second, independent, proof of Theorem 1 found using an automated geometric theorem prover that we built. To explain how this works, we return to the bracket expressions [ABC], representing the determinant of the 3×3 matrix whose columns are the homogeneous coordinates of three points in \mathbb{P}^2 . Consider the point P that lies on the intersection of two lines AB and CD. Then P can be written as a linear combination of the points A and B: $P = \alpha A + \beta B$. Since P, C and D are collinear, we have [CDP] = 0 and substituting $\alpha A + \beta B$ for P we find that $\alpha [CDA] + \beta [CDB] = 0$. It follows that α and β can be chosen to be [CDB] and -[CDA], respectively; so P = [CDB]A - [CDA]B. Similarly, P = [ABD]C - [ABC]D. Equating the two expressions we have [CDB]A - [CDA]B - [ABD]C = -[ABC]D. Let E be a fifth point and apply the operator taking the point Q to [QDE], giving (after some column interchanges)

$$[BCD][ADE] - [ACD][BDE] - [ABD][CDE] = 0.$$

This expression is one of several quadratic relations among the brackets, called Grassmann-Plücker relations (see Richter-Gebert [22] for details). Now note that if A, B, and D are collinear then [ABD] = 0 and so we get a *binomial relation*, an equality of two bracket *monomials*:

$$[BCD][ADE] = [ACD][BDE]$$

which we denote as h(D, A, B, C, E). As well, this expression is equivalent to the collinearity of A, B and D if $[CDE] \neq 0$.

The locus $\{X \in \mathbb{P}^2 : [ABX] = 0\}$ is the line through A and B. Similarly, [ABX][CDX] = 0 represents a reducible conic, two lines whose union contains A, B, C and D. Another reducible conic with the same property is [ACX][BDX] = 0. In fact, any conic through the four points has an equation of the form $\gamma[ABX][CDX] + \delta[ACX][BDX] = 0$ for constants γ and δ . If we insist that the conic also pass through the point E then γ and δ can be taken to be [ACE][BDE] and -[ABE][CDE], respectively. That conic, [ACE][BDE][ABX][CDX] - [ABE][CDE][ACX][BDX] = 0, passes through a sixth point F precisely when we have an equality of bracket monomials which we denote c(A, B, C, D, E, F):

$$[ACE][ABF][CDF][BDE] = [ACF][ABE][CDE][BDF].$$

In the notation and setting of Theorem 1, we have the following equalities from our collinearities:

$h(R_1, V, R_2, P_2, Y):$	$[V, R_1, P_2][Y, R_2, R_1]$	=	$-[V, Y, R_1][R_2, R_1, P_2]$
$h(R_2, R_1, P, Q_1, Z):$	$[R_2, R_1, Q_1][Z, R_2, P]$	=	$-[Z, R_2, R_1][R_2, Q_1, P]$
$h(R_1, R_2, P, Q_2, G):$	$[R_2, R_1, Q_2][G, R_1, P]$	=	$-[G, R_2, R_1][R_1, Q_2, P]$
$h(P_1, Y, P_2, Q_2, R_2):$	$[Y, Q_2, P_1][R_2, P_2, P_1]$	=	$[Y, R_2, P_1][Q_2, P_2, P_1]$
$h(Y, P_2, P_1, U, V):$	$[U, Y, P_2][V, Y, P_1]$	=	$[V, Y, P_2][U, Y, P_1]$
$h(P_1, X, P_2, Q_1, R_1):$	$[X, Q_1, P_1][R_1, P_2, P_1]$	=	$[X, R_1, P_1][Q_1, P_2, P_1]$
$h(U, Q_2, P, P_2, X):$	$[U, Q_2, P_2][U, X, P]$	=	$-[U, X, Q_2][U, P_2, P]$
$h(Z,G,P,R_2,Y):$	$[G, Z, R_2][Z, Y, P]$	=	$[G, Z, Y][Z, R_2, P]$
$h(G, W, P, P_1, Q_1):$	$[G, W, P_1][G, Q_1, P]$	=	$[G, W, Q_1][G, P_1, P]$
$h(Y, V, Z, P, P_1)$:	$[V, Y, P][Z, Y, P_1]$	=	$[V, Y, P_1][Z, Y, P]$
$h(V, R_1, P, P_2, Y):$	$[V, Y, R_1][V, P_2, P]$	=	$-[V, R_1, P_2][V, Y, P]$
$h(P_1, Y, X, Q_2, U):$	$[U, Y, P_1][X, Q_2, P_1]$	=	$[Y, Q_2, P_1][U, X, P_1]$
$h(P_1, Y, X, R_1, G):$	$[G, Y, P_1][X, R_1, P_1]$	=	$[Y, R_1, P_1][G, X, P_1]$
$h(Q_2, U, Q_1, P_2, X):$	$[U, X, Q_2][Q_2, Q_1, P_2]$	=	$-[U, Q_2, P_2][X, Q_2, Q_1]$
$h(Q_2, Q_1, P, R_1, W):$	$[W, Q_2, Q_1][R_1, Q_2, P]$	=	$[R_1, Q_2, Q_1][W, Q_2, P]$
$h(Q_1, Q_2, P, R_2, G):$	$[G, Q_2, Q_1][R_2, Q_1, P]$	=	$[R_2, Q_2, Q_1][G, Q_1, P]$
$h(G, Z, P, P_1, R_1)$:	$[G, Z, R_1][G, P_1, P]$	=	$[G, Z, P_1][G, R_1, P]$
$h(W, G, P, Q_2, X)$:	$[G, X, W][W, Q_2, P]$	=	$[G, W, Q_2][X, W, P]$
$h(X, U, W, P, P_1)$:	$[U, X, P_1][X, W, P]$	=	$[U, X, P][X, W, P_1]$

We also have equalities coming from six points lying on a conic:

Multiplying all the left-hand sides of these equalities together and multiplying all the right-hand sides together and canceling like terms leaves just a pair of brackets on each side:

$$[V, P_2, P][U, Y, P_2] = [V, Y, P_2][U, P_2, P]$$

This is precisely the equality $h(P_2, V, U, P, Y)$, so we find that P_2 , U and V are collinear as long as P, P_2 and Y are not collinear (and all the brackets that we canceled are not zero, which requires a large collection of triples of points to be noncollinear). This is precisely the conclusion of Theorem 1! This binomial proof was found using MATLAB [17] to set up an integer programming problem, which we then passed to the optimization solver Gurobi [12] to solve. Our optimization problem involved 552 variables and 22,022 constraints, which Gurobi solved in just under 33 seconds on a five-year old laptop. We used the conclusion of Theorem 1 to set up the optimization problem, so this second proof only verifies the result in Theorem 1; this method is not immediately applicable in the search for geometric results.

We find this computational proof of Theorem 1 very amusing but it is hard to get any intuition for why the result is true. This tendency of computer-assisted proofs to lead to results that cannot be easily explained to a human is one of the central problems with deep neural networks and other advanced tools in artificial intelligence today.

5 Extensions and Exercises

We close with some fun problems, pointers to further reading, and comments about how this work connects to related topics. Two excellent books in geometry are Coxeter and Greitzer [9] and Richter-Gebert [22]. The geometry chapter in Zeitz [26] contains many challenging and enjoyable problems. The Cayley-Bacharach Theorem played a key role in our construction, but we never formally stated it. We refer the interested reader to the wonderful paper by Eisenbud, Green and Harris [10]. The reader may also enjoy the enumerative study of conics in Bashelor et al. [2] and Traves [23], which contains another application of the Cayley-Bacharach Theorem to cubics.

Problem 1. Use the Power of a Point Theorem to prove Carnot's Theorem. A solution can be found at the wonderful Cut the Knot website.

Problem 2. Use Pascal's Theorem to construct the tangent line to a conic at a given point, given four additional points on the conic. As well, show that the tangent lines to a circle at I and J both pass through the center of the circle.

Problem 3. Define a transformation on homogeneous polynomials: if M is a 3×3 matrix and $H(\mathbf{v}) = H(x, y, z)$ is a homogeneous polynomial of degree d, then define the transformed polynomial $M \cdot H$ to be $(M \cdot H)(\mathbf{v}) = H(M^{-1}\mathbf{v})$. Check that $M \cdot H$ is a homogeneous degree-d polynomial and that $H(\mathbf{v}) = 0$ precisely when $(M \cdot H)(M\mathbf{v}) = 0$, so changing the basis of \mathbb{P}^2 does not affect whether a collection of points lies on a degree-d curve.

Problem 4. Four points A, B, C, and D whose cross ratio (A, B; C, D) is -1 are said to be in *harmonic position*. Let x and y be real numbers. Show that

$$(-x, x; 0, \infty) = (x, y; \frac{x+y}{2}, \infty) = (-1, 1; x, -x) = -1.$$

As well, show that permuting the four points in the cross ratio (A, B; C, D) only produces six distinct values, rather than 4! = 24 values. How are the six values related to one another? Which permutations fix the cross ratio?

Problem 5. In 1857, Karl Georg Christian von Staudt introduced a way to view addition and multiplication in terms of cross ratios and incidence constructions. Fixing three points 0 = [0:0:1], 1 = [1:0:1]and $\infty = [1:0:0]$ and a fourth point X = [x:0:1] on the x-axis in \mathbb{P}^2 show that the cross ratio $(0,\infty; X, 1)$ equals x. If we follow the convention that $1/0 = \infty$ then $(0,\infty;\infty,1) = \infty$ too, and we can identify the x-axis with the extended real numbers $\mathbb{R} \cup \{\infty\}$ via the cross ratio: the point X corresponds to the value $(0,\infty; X, 1)$. The arithmetic operations of addition, subtraction, multiplication and division are defined on the extended real numbers and they induce corresponding operations on the projective line. Von Staudt's two key incidence structures are illustrated in Figure 11, with some artistic license. For instance, given a second point Y = [y:0:1] we construct a point X + Y corresponding to the sum x + y as follows. Pick a point Q off the line containing 0, 1, ∞ , X and Y and pick a second point Q_1 on the line joining Q to ∞ (this line appears parallel to the x-axis in the finite part of the plane). Draw lines 0Q and XQ_1 , meeting in point P. Draw lines $P\infty$ and YQ, meeting in point R. Then intersect the line RQ_1 with the original line 0X to obtain the point X + Y. Show that the resulting point X + Y has the desired coordinates [x + y: 0: 1], corresponding to the value x + y, irrespective of our choices for Q and Q_1 . As well, show that the incidence in Figure 11 (right) constructs the point $X \cdot Y = [xy: 0: 1]$.

Figure 11: Von Staudt's incidence structures that implement addition (left) and multiplication (right).

Problem 6. As in Construction 2, let $E_1 = [1:0:0], E_2 = [0:1:0]$ and $E_3 = [0:0:1]$ and let $E = \{[x:y:z] \in \mathbb{P}^2 : xyz = 0\}$. Show that the map $f : \mathbb{P}^2 \setminus E \to \mathbb{P}^2 \setminus E$ given by $f([x:y:z]) = [\frac{1}{x} : \frac{1}{y} : \frac{1}{z}]$ agrees with the map $\phi : \mathbb{P}^2 \setminus E \to \mathbb{P}^2 \setminus E$ given by $\phi([x:y:z]) = [yz:xz:-xy]$ and both are bijections. The map ϕ is actually defined on a slightly larger domain, $\mathbb{P}^2 \setminus \{E_1, E_2, E_3\}$. What are the images of the lines $E_i E_j$ under the map ϕ ? The map ϕ is an example of a Cremona transformation in algebraic geometry, a bijective map whose components are defined by polynomials from one dense open set of \mathbb{P}^n to another.

Problem 7. The $8 \Rightarrow 9$ theorem says that every plane cubic curve passing through 8 points of intersection of two cubic curves must pass through their ninth point of intersection as well. It follows that if these nine points of intersection are nine of our 10 points, then there is always a cubic through our ten points – the result does not depend on the location of the tenth point! In this situation our construction to check

whether ten points lie on a cubic is *degenerate*. For instance, we need to draw a line through two points but these are the same point, or we need to intersect two lines, but these lines are the same line. Set up an example of this phenomenon and determine which kind of degeneracy occurs. We recommend working on this problem with a computer algebra system.

Here is a matrix algebra approach to checking whether six points lie on a conic. For each point $P_i = [x_i : y_i : z_i] \ (i \in \{1, \dots, 6\})$ we plug into the conic equation $ax^2 + bxy + cxz + dy^2 + eyz + fz^2 = 0$, producing a linear condition on the coefficients of the conic, a, \ldots, f . Together these six linear equations form a matrix equation $A\mathbf{v} = \mathbf{0}$, where $\mathbf{v} = [a, b, c, d, e, f]^T$. There is a conic through the six points precisely when this matrix A has a nonzero nullspace. This occurs precisely when det(A) = 0. This determinant condition can be written as a polynomial in the brackets $[P_iP_iP_k]$, each a determinant of a 3×3 matrix. The determinant of A is a degree-4 polynomial in the brackets with 720 summands. But the Grassmann-Plücker relations among the brackets allow us to reduce the number of summands. One can check that the polynomial evaluates to a scalar multiple of the expression $c(P_1, P_2, P_3, P_4, P_5, P_6)$ from the last section. The same approach can be used to check whether ten points lie on a cubic. In this case the matrix A is a 10×10 matrix and in 1870 Reiss [20] wrote down an expression for det(A) as a degree-10 polynomial in the brackets with just 20 terms. Suzanne Apel [1] developed an algorithm to express a multiple of this polynomial by a monomial in the brackets as an expression in the Grassmann-Cayley algebra, which can be interpreted as a massive incidence structure. Unfortunately, it is hard to get any intuition about why that structure implies the presence of a cubic through the ten points. The reader might want to search for a short bracket polynomial expression for the determinant of the 15×15 matrix that determines whether 15 points lie on a degree-4 curve. This is an open research problem!

We have focused on incidence structures in this paper and it is fun to consider *extremal problems* with incidence structures. For instance, imagine a finite set of points for which every line through a pair of the points also contains a third point. One such collection consists of the nine points of inflection of a cubic curve. In fact, there are 12 lines passing through pairs (necessarily, triples) of the nine points, forming the beautiful incidence pattern depicted in Figure 12. However, at least one of the points here has to have complex coordinates. The Sylvester-Gallai Theorem says that the only such point configuration with all real coordinates has all the points lying on a common line!

Figure 12: The Hesse configuration: 12 complex lines through 9 points.

Acknowledgments: The authors thank Bernd Sturmfels for suggesting the problem to us and Mike Roth for helpful discussions. The computer algebra system MAGMA [4] was also extremely helpful.
