Abstract

Cyberattacks are a major issues and it causes organizations great financial, and reputation harm. However, due to various factors, the current network intrusion detection systems (NIDS) seem to be insufficient. Predominant NIDS identifies Cyberattacks through a handcrafted dataset of rules. Although the recent applications of machine learning and deep learning have alleviated the enormous effort in NIDS, the security of network data has always been a prime concern. However, to encounter the security problem and enable sharing among organizations, Federated Learning (FL) scheme is employed. Although the current FL systems have been successful, a network's data distribution does not always fit into a single global model as in FL. Thus, in such cases, having a single global model in FL is no feasible. In this paper, we propose a Segmented-Federated Learning (Segmented-FL) learning scheme for a more efficient NIDS. The Segmented-FL approach employs periodic local model evaluation based on which the segmentation occurs. We aim to bring similar network environments to the same group. Further, the Segmented-FL system is coupled with a weighted aggregation of local model parameters based on the number of data samples a worker possesses to further augment the performance. The improved performance by our system as compared to the FL and centralized systems on standard dataset further validates our system and makes a strong case for extending our technique across various tasks. The solution finds its application in organizations that want to collaboratively learn on diverse network environments and protect the privacy of individual datasets.

1 Introduction

Cybersecurity plays a very crucial role in our lives, including social, economic, and political systems. Moreover, with the rise and emergence of the internet, Cybersecurity will become more important than ever as there are various instances of network attacks occurring regularly. Cyberattacks cause

organizations great financial, and reputation harm. To name one example: Maersk, one of the world's largest shipping companies, suffered massively from 2017's NotPetya malware outbreak. Lack of an efficient Network Intrusion Detection System (NIDS) has been a major factor contributing to the Cyberattacks happening.

There has been ample amount of research recently in the field of NIDS using various supervised machine learning and deep learning algorithms [Vigneswaran *et al.*, 2018; Obeidat *et al.*, 2019]. With the advancement of AI, many of the data privacy challenges have also been cited, especially when working on real-world tasks with the existing data [Jagannathan and Wright, 2005; Mohassel and Zhang, 2017]. Being able to re-identify information using large datasets, lack of transparency in the use of data, regulations by countries, and unions have been some major factors in intensifying this problem. Thus, there is an inherent risk and higher probability of sensitive information getting exposed and shared.

Federated Learning (FL) was first proposed by Google to solve problems of data security and privacy in the field of Machine Learning [McMahan *et al.*, 2016]. Recent years have seen a widespread application of FL methods in various areas [Shingi, 2020; Smith *et al.*, 2017]. It showed that by using FL, workers could share intelligence on a machine learning task without disclosing their private data. However, FL has mostly stressed on combining parameters/updates from individual models trained on different samples of data, but FL builds a single global model group to which the individual workers share their updates. However, there might be workers' who wish to build a global model group based on the similarity. Consider the task of intrusion detection, where different networks do not necessarily possess uniform environments. The best system should be able to adapt itself and create global model groups based on the performance and network environment similarity. However, if these segmented global models are not created, quality collaborative learning from such decentralized diverse network environments is a challenging task.

In this paper, we propose the use of an adaptive learning approach of Segmented-Federated Learning (Segmented-FL) for better learning from decentralized diverse network environments. We employ periodic local model evaluation and segmentation for adaptive model training. Unlike FL, Segmented-FL has a feature that each segmented group of

workers is arranged with a particular global model for adaptive learning. Segmented-FL is used for parameter sharing among the workers as well as automatic segmentation of workers for adapting to diverse network environments. For each round, selected workers perform model training on their private data and upload their model parameters to their particular global model group where the parameters from various local models are aggregated to update the global model. The parameter aggregation is based on the weighted aggregation of local model parameters according to number of samples each local worker possesses as well as averaging (mean) of the other global model parameters. Periodic evaluation of local workers' model is carried out to validate and divide the workers into different groups for adaptive learning based on recent performance. We prove the effectiveness of our architecture when working with artificial neural networks as our local workers' model. The proposed architecture is found to be superior in handling the diverse network environments while protecting the data privacy and also provides optimum results on publicly available datasets [Ring *et al.*, 2017a; Ring *et al.*, 2017b]. Our main contributions in this paper could be listed as:

1. We have made effective use of segmentation to make our system more adaptive and robust to diverse environments.
2. We made apt use of the number of samples based weighted aggregation of local model parameters to augment the performance of our system.
3. We have been able to achieve better performance through the Segmented-FL system, as compared to the conventional FL and centralized approaches.

The rest of the paper is structured as follows: Section 2 talks about related work in this area while the proposed methodology is explained in section 3. Dataset description and the results obtained are discussed in section 4. Our analysis of the work conducted is presented in section 5 while the paper is concluded in section 6.

2 BACKGROUND AND RELATED WORK

Network intrusion detection has been a much-discussed topic in the industry but the number of publicly available and efficient works are rather limited. Large number of approaches have been tried in the past to solve issues faced in the area of NIDS chiefly due to the rise in the use of machine learning algorithms. One of the earlier and commonly used methods was based on expert knowledge of known malicious patterns and network behavior in a network [Premaratne *et al.*, 2010; Carcano *et al.*, 2011]. In [Shin *et al.*, 2010; Tsang and Kwong, 2006], network-based activity study is used to determine if a node is compromised, such as traffic or frequency analysis, and deep packet inspection. However, these approaches seem to be insufficient due to issues of privacy and adaptivity. Lately, various machine learning and neural networks have been implemented for better performance of NIDS systems, such as artificial neural networks (ANN) and support vector machine (SVM) [Omran *et al.*, 2017]. [A. Salama *et al.*, 2011] proposed a hybrid

deep belief network and SVM for intrusion detection on the NSL-KDD dataset. [Yang *et al.*, 2017] proposed a combined approach of employing Boltzmann machine to extract high-level feature representation of network traffic and classifying these features with SVM. [Saxe and Berlin, 2015] used two-dimensional binary program features based on deep neural network for malware detection. [Yousefi-Azar *et al.*, 2017] used unsupervised learning model, named as auto encoder to extract latent features of network traffic for malware detection.

The majority of the work is done in limited environments. Recently, [Abeshu and Chilamkurti, 2018] proposed a federated learning (FL) based cyberattack detection model approach to enhance the performance, protect the privacy of workers, and reduce the traffic load. [Zhao *et al.*, 2019] also implemented FL to overcome the problem of data insufficiency and data security, where multiple participants collaboratively train a global model. [Daga *et al.*, 2019] proposed Cartel, a system to learn collaboratively in edge clouds. A notable observation is that all of these approaches have not taken into consideration the network diversity issue and have proposed single global model based approaches. [Yu *et al.*, 2020] presented a Mobility-aware Proactive edge Caching scheme based on Federated learning (MPCF) for predicting content popularity with the private training data distributed on local vehicles. This scheme could adapt to various mobility patterns and references of vehicles and protect users' privacy. However, unlike former research, we propose a Segmented-FL approach for adaptive intrusion detection in distributed networks.

3 METHODOLOGY

3.1 Data preprocessing and Local model training

Data preprocessing

The data is stripped of superfluous features which may create biases and will not be useful to detect the attacks accurately and reliably. Further, a label encoder is applied to convert the categorical features into numerical form. The retained features dataset is normalized by using MinMax Scaler, which computes the minimum and maximum values of the feature and scales the data to 0-1 range. We perform normalization on our data as input variables affect algorithms that fit a model, which uses a weighted sum of input variables.

On analysis, it was found that the data is imbalanced, and to reduce the variance in the training data we undersample the data using Near Miss 3 [Zhang and Mani, 2003]. It operates by only selecting the closest samples from the majority class for each minority class. In 2011, [Chawla *et al.*, 2002] presented an oversampling approach known as Synthetic Minority Oversampling Technique (SMOTE). However, oversampling too many samples may lead to the creation of inaccurate data samples. Therefore, to overcome the problem of class imbalance we used undersampling, to obtain an accurate and balanced data distribution. Initially, the data had a ratio close to 17:1.2:1 for normal to the attacker to victim class. By selecting only the nearest samples from the normal class, we were able to form a data distribution with a ratio of 2:1.2:1.

Local Model Training

We propose the use of a light-weight 3 layer neural network, a common architecture, which will be the primary component of all the local workers. The common model architecture is as shown in fig 1. At local workers, the private data present is preprocessed using the method explained above seamlessly. Further, the workers will train their model on the preprocessed data they possess, whose weights will contribute to the development of a shared global model. As the task in hand is multi-class classification, local models use categorical cross-entropy loss function.

Figure 1: Block diagram of common architecture model

3.2 Federated Learning (FL)

Federated learning [McMahan *et al.*, 2016] enables us to learn collaboratively by sharing intelligence on model training with others without sharing their private data. In traditional machine learning algorithms, intrusion detection in networks can expose private information to the outside world while analyzing the data at the central server. The implementation of FL in network intrusion allows us to learn collaboratively by sharing local model training results without accessing any users' private data. The structure and architecture of FL is illustrated in fig 2.

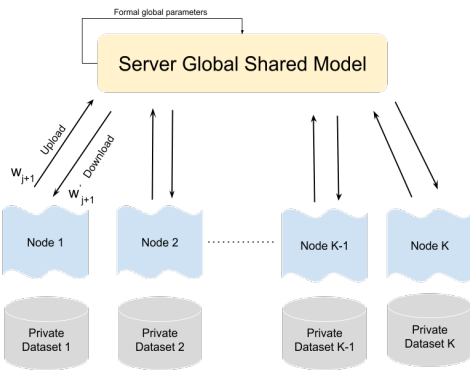

Figure 2: Block diagram of the FL framework. w_{j+1} represents the current round network parameters that upload to the server, w'_{j+1} represents the parameters that are aggregated by server.

In this figure, initially, the worker participants download the latest global shared model and update their local models. Then, every worker trains their model by using the local

private training data. After training, these trained models' parameters will be uploaded to the central global model for aggregation. Further, based on the aggregated local parameters and former shared global model weights, the global model is updated for the next iteration of collaborative learning.

3.3 Segmented-FL Model Architecture

We propose the use of a novel architecture, Segmented-FL as the principal learning mechanism. By implementing the Segmented-FL system, the worker/network diversity problem is resolved. Unlike FL, Segmented-FL enables us to adapt to various network environments, as well as safeguard the data privacy of the worker nodes by implementing multiple global models. The structure of Segmented-FL is illustrated in fig 3. The working of components is as follows:

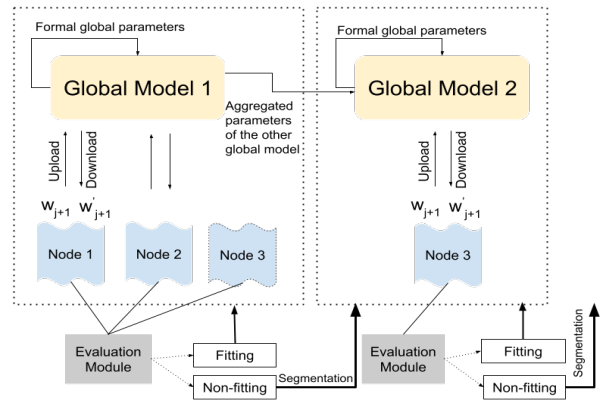

Figure 3: Block diagram of the Segmented-FL framework.

Evaluation Module

According to fig 3, periodic evaluation is carried out. We have used the F1 score as the metric for periodic evaluation. The periodic evaluation is vital for quality verification of local model training, based on the evaluation module defined in (1). Average validation result is used to evaluate the performance of each worker's local model for training and sharing with the current global model. If the worker's model perfectly fits in the current global model group based on the evaluation module, it remains in the global model group, but if the worker's model does not fit into the current global model group, it is moved to another group. If there is no group created or the worker's model does not fit into any group, a new group is initialized based on the average aggregation result of the workers' who do not fit into any global model group. A flexible threshold is applied, and an evaluation result below the threshold indicates that the worker does not fit into the group. A high threshold brings more workers to segmentation, whereas a lower threshold brings fewer workers for segmentation. The workers moved into the new global model group, conduct the next round's collaborative learning with the initialized global model. We can also set the maximum global model number to a specific low number for simplicity.

$$d_i = C_i - \frac{\sum_{i=1}^n C_i}{n}$$

$$c_i = \frac{1}{1 + e^{-d_i}} \quad (1)$$

$$threshold = 0.5 - h_f \times 0.01$$

where

n is the number of participants, and C_i represent the average validation result of worker i in the recent rounds, d_i is the difference between the worker i 's performance and the average performance of all group workers, c_i is the output of the evaluation module using the Sigmoid function to convert d_i into the interval of (0, 1), and h_f is the segmentation fineness to adaptively adjust the threshold

After experimental results, we found out threshold (h_f) = 7 with evaluation frequency = 3 to be ideal values in our case.

Global model aggregation and parameters updation

At each communication round $j = 1, 2, \dots$, workers in the current global model group update their models parallelly and send the updated model to the central server for aggregation. Federated Averaging (FedAvg) algorithm is the generic algorithm, which aggregates the workers parameters by averaging (mean). However, averaging the parameters of local workers based on mean affects the performance of the global model where the data is distributed heterogeneously and local workers with very little training examples (n_k) contribute equally as other local workers. To overcome the inefficiencies caused by the FedAvg algorithm in heterogeneous data distribution, we proposed an aggregating method based on the number of data samples. For the parameter aggregation and updating of the global model, we apply the former global parameters, the weight-aggregated local model parameters, and the average-aggregated parameters of the other global models with different component ratios, defined in (2)

$$w_j = \alpha \cdot w_{j-1} + \beta \cdot \frac{\sum_{i=1}^k n_i w_i}{n}$$

$$+ \gamma \cdot \frac{\sum_{i=1}^m v_i}{m} \quad (\alpha + \beta + \gamma = 1) \quad (2)$$

where

w_j represents the updated global parameters, w_{j-1} represents the former global parameters, w_i represents the local worker i 's parameters, n_i represents the number of data samples worker i posses, n represents total data samples present across all workers, v_i represents the global model i 's parameters, k is the number of participant workers who conducted local model training in this round, and m is the number of the other global models, α , β , and γ represent the ratios of each component respectively, with a sum of 1.

We perform a weighted aggregation of the local models as increasing the weight of strong classifiers enables the formation of a better global shared model.

Algorithm 1: Segmented-FL algorithm: $w_g = 1$ is the initialized global model. N_g is the number of workers related to global model g . N_t is the number of workers conducting local model training in a group. D_t is the local dataset of worker t . G represents all global models. h_j is the number of rounds for periodic local model evaluation. L_g is a list including segmentation information of workers. B is the batch size. E is the local training epoch. η is the learning rate. α , β and γ are the component ratios for aggregation. w_{new} is the newly initialized global model from the segmentation.

```

1 initialize  $w_{g=1}$ 
  for each round  $j = 1, 2, \dots$  do
2   for each global model  $g = 1, 2, \dots$  do
3      $B_t \leftarrow$  (split  $N_g$  into batches with a size  $N_t$ )
4      $s_t \leftarrow$  (workers conducting model training
      from  $B_t$ )
5      $s_r \leftarrow$  (the other workers not conducting model
      training)
6     for each worker  $t \in s_t$  in parallel do
7       Execute( $w_t, D_t$ )
8     end
9     for each worker  $r \in s_r$  in parallel do
10       $w_r \leftarrow w_g$ 
11       $w_g \leftarrow$  Aggregate( $w_t, t \in s_t; w_g, g \in G$ )
12    end
13    if  $j \% h_j == 0$  then
14      for each worker  $k \in s_g$  do
15         $E_k \leftarrow$  avg(validation results of  $k$  in
          recent  $R_e$  rounds)
16         $L_g \leftarrow$  Segment( $E_k, k \in s_g; L_g$ )
17      end
18    end
19  end
20 end

```

4 DATASET DESCRIPTION AND RESULTS

The proposed architecture is evaluated on the combination of publicly available standard datasets for network intrusion detection, Coburg intrusion detection dataset (CIDDS-001 and CIDDS-002) [Ring *et al.*, 2017a; Ring *et al.*, 2017b].

4.1 Dataset Description

The datasets are generated by emulating a small business environment using OpenStack. The datasets are labeled as flow-based datasets and contain unidirectional NetFlow data. The dataset consists of 10 features and manually labeled classes and attack types, out of which features such as source IP address, destination IP address, and date were not used. Throughout the study, we focused only on the seven remaining features, and classes as we can see in table 1. We also dropped samples from our dataset, which had classes other than the normal, attacker, and the victim, as the number of data samples having such labels were insignificant in comparison to the other classes samples. Also, we tried using

the techniques of undersampling and oversampling on other classes, but the result was not satisfactory. The combined dataset consists of approximately 31 million samples, out of which around 28 million of them are labeled as normal. After dropping other class samples and employing undersampling the majority class, we get 6,472,054 (6.4 million) data samples with a ratio of 2:1.2:1 for normal to attacker to victim classes.

Table 1: Attributes description of Coburg intrusion detection dataset (CIDDS)-001 and CIDDS-002) dataset.

Attributes	Description
Duration	Duration of the flow
Protocol	Transport Protocol (e.g. ICMP, TCP, or UDP)
Source Port	Source Port
Destination Port	Destination Port
Packets	Number of transmitted packets
Bytes	Number of transmitted bytes
Flags	OR concatenation of all TCP Flags
Class	Class label (normal, attacker, or victim)

We distributed the combined data of CIDDS-001 and CIDDS-002 dataset heterogeneously among workers and applied a train-test split of 90% and 10% on each worker, and the technique discussed above to overcome class imbalance is applied. We train our system with 4, and 5 workers, and the data is distributed as shown in table 2. In the case of 4 workers, we distribute the CIDDS-001 among node 1, and node 2 whereas node 3, and 4 contained data majorly from the CIDDS-002. Similarly, for 5 workers, we distribute the CIDDS-001 among node 1, node 2, and node 3, while node 4 and node 5 contain maximum data from the CIDDS-002.

Table 2: Data distribution among workers

No. of workers	Worker	Training	Testing
n = 4	Node 1	873,727	97,081
	Node 2	2,038,697	226,522
	Node 3	1,747,454	194,162
	Node 4	1,164,970	129,441
n = 5	Node 1	698,982	77,664
	Node 2	1,980,448	220,050
	Node 3	815,479	90,609
	Node 4	1,456,212	161,802
	Node 5	873,727	97,081

4.2 Results obtained

Firstly, different machine learning approaches were applied to the combined CIDDS-001 and CIDDS-002 datasets. The results of each approach are evaluated on the test set on each of the metrics discussed previously.

The results obtained by 4 participants/workers through centralized, federated, and Segmented-FL approaches are shown in table 3. In table 4, we compare results obtained by the respective approaches per label across precision, recall

and F1 score. For simplicity, we compare the average of the scores obtained by the workers across the metric.

Table 3: Comparison across multiple metrics(n = 4)

Approach	Worker	Accuracy	AUROC
Centralized	Node 1	96.89	97.68
	Node 2	97.6	98.4
	Node 3	95.36	96.59
	Node 4	96.04	96.97
Federated Learning	Node 1	96.63	0.95
	Node 2	96.92	0.96
	Node 3	95.49	0.94
	Node 4	96.16	0.95
Segmented Federated Learning	Node 1	97.72	0.97
	Node 2	98.58	0.98
	Node 3	96.64	0.95
	Node 4	97.12	0.96

Table 4: Comparison of approaches per label score for n = 4 (FL refers to Federated Learning and Seg-FL refers to Segmented-Federated Learning)

Metric	Approach	Normal	Attacker	Victim
Average Precision	Centralized	0.95	0.96	0.95
	FL	0.95	0.96	0.94
	Seg-FL	0.96	0.97	0.97
Average Recall	Centralized	0.85	0.86	0.85
	FL	0.85	0.86	0.84
	Seg-FL	0.87	0.88	0.87
Average F1 Score	Centralized	0.89	0.91	0.89
	FL	0.88	0.90	0.88
	Seg-FL	0.91	0.92	0.91

Figure 4: Segmentation Points for n = 4 with threshold ($h_f = 7$)

It can be seen that the Segmented-FL algorithm outweighs the centralized approach models and FL algorithm in all the metrics. The drop in the performance of the FL algorithm could be due to the distribution of the combined dataset, but our Segmented-FL approach has given better results in comparison to other approaches. Further, fig 4 shows that after six rounds of learning, a new global model group is being formed

by nodes 3 and 4 as their F1 score was below the threshold of the first global model group in the Segmented-FL approach. In the next tables and figure, we compare our results for five workers and observe the segmentation point.

Table 5: Comparison across multiple metrics($n = 5$)

Approach	Worker	Accuracy	AUROC
Centralized	Node 1	96.47	97.24
	Node 2	97.36	98.19
	Node 3	96.83	97.71
	Node 4	94.69	95.98
	Node 5	93.93	95.07
Federated Learning	Node 1	96.21	97.35
	Node 2	96.96	97.97
	Node 3	96.53	97.61
	Node 4	94.79	95.88
	Node 5	94.03	95.13
Segmented Federated Learning	Node 1	97.39	98.41
	Node 2	98.42	99.25
	Node 3	97.91	98.94
	Node 4	96.85	97.73
	Node 5	96.13	97.31

Table 6: Comparison of approaches per label score for $n = 5$ (FL refers to Federated Learning and Seg-FL refers to Segmented-Federated Learning)

Metric	Approach	Normal	Attacker	Victim
Average Precision	Centralized	0.94	0.96	0.95
	FL	0.94	0.95	0.95
	Seg-FL	0.96	0.97	0.97
Average Recall	Centralized	0.84	0.85	0.85
	FL	0.84	0.85	0.84
	Seg-FL	0.87	0.88	0.87
Average F1 Score	Centralized	0.88	0.9	0.88
	FL	0.88	0.89	0.87
	Seg-FL	0.90	0.92	0.90

Figure 5: Segmentation Points for $n = 5$ with threshold ($h_f = 7$)

In table 5 and table 6, it can be observed that even in the case of $n = 5$, the Segmented-FL approach outperforms

the FL and Centralized approaches. Also, fig 5 shows that due to variance in F1 score, nodes 4 and 5 (having CIDDS-002 dataset) formed a new global model group after the periodic evaluation at 6th round. Thus, Segmented-FL tends to be more robust to data variance and number of participants/workers, and the result analysis clearly shows the benefit of using Segmented-FL over conventional methods.

5 ANALYSIS

Our main observations after performing out the study have been:

- Segmented-FL automatically adapts the architecture based on the periodic evaluation. This feature helps adapt to diverse networks from massively distributed environments.
- As compared to the FL approach, Segmented-FL showed more robustness to collaborative learning and had better performance with diverse network traffic.
- Due to diverse network environments, there was a drop in the performance of the FL approach for some nodes as compared to the centralized approach. The drop was majorly due to the worker diversity and lower performance from other remaining nodes. This suggests that when workers are diverse, FL can fail to efficiently learn in a collaborative manner.
- If all data is to be present at one location, the single centralized model will tend to give better performance than the Segmented-FL and FL approach, but having all data at one location is not possible in every case. Thus, based on the network diversity, Segmented-FL and FL approaches can be implemented to develop a better model.

6 CONCLUSION

We proposed the use of the Segmented-FL approach in the area of network intrusion detection. Through this approach, we were able to solve the problem of a network's traffic data not always fitting into the single global model of FL situation. Besides, the Segmented-FL approach provided considerably better performance across all the employed metrics as compared to the FL and centralized approaches while preserving the privacy of data. Hence, the improved results across various metrics are a testament to the power which the Segmented-FL approach holds in sensitive and diverse worker training. Future improvements in our work include the use of techniques like differential privacy and a neutral third-party aggregation server to overcome the minor privacy problems federated learning possesses. The mechanism can also be extended further for different dataset structures where a more advanced aggregation mechanism would be required. With the rise in the computing capability of edge devices (like a mobile phone) and strong legislative rules been enforced on data security and privacy, techniques that allow these devices to train their model remotely and collaborate to the global models without needing to share their actual data would be desired. This will lay the foundation for a more secure, ethical, private, and robust data analysis environment.
