A New Attempt to Identify Long-term Precursors for Endogenous Financial Crises in the Market Correlation Structures

Anton J. Heckens[∗](#page-0-0) and Thomas Guhr[†](#page-0-1)

Fakultät für Physik, Universität Duisburg-Essen, Duisburg, Germany

Prediction of events in financial markets is every investor's dream and, usually, wishful thinking. From a more general, economic and societal viewpoint, the identification of indicators for large events is highly desirable to assess systemic risks. Unfortunately, the very nature of financial markets, particularly the predominantly non-Markovian character as well as non-stationarity, make this challenge a formidable one, leaving little hope for fully fledged answers. Nevertheless, it is called for to collect pieces of evidence in a variety of observables to be assembled like the pieces of a puzzle that eventually might help to catch a glimpse of long-term indicators or precursors for large events – if at all in a statistical sense. Here, we present a new piece for this puzzle. We use the quasistationary market states which exist in the time evolution of the correlation structure in financial markets. Recently, we identified such market states relative to the collective motion of the market as a whole. We study their precursor properties in the US stock markets over 16 years, including two endogenous crises, the dot-com bubble burst and the pre-phase of the Lehman Brothers crash. We identify certain interesting features and critically discuss their suitability as indicators.

I. INTRODUCTION

Critical events in the financial markets bear, in the age of globalization, ever higher risks for the world's economic system, which then, in a feedback loop, can cause negative impacts on the financial markets. An early warning system is as desirable as in the case of geologic, seismic and volcanic hazards, but at least as difficult to design. The natural laws under which the latter emerge do not alter, while the fast economic and societal development implies, for the structure and the functionality of the financial system, a new and considerable unpredictability which adds to the risks due to the kind of non-stationarity which has always been present in the markets [\[1](#page-14-0)[–6\]](#page-14-1).

Musmeci et al. [\[7\]](#page-14-2) showed that the correlation structure can be used, to some extent, to forecast the volatilities within "persistent" periods, i.e. periods of quasistationary correlation structures. This ends when transitions between persistent periods take place which is often followed by larger volatility changes. These persistent periods are strongly connected to "market states" or "regimes" in the economics terminology [\[8–](#page-14-3)[14\]](#page-14-4). There are different ways to define market states [\[15\]](#page-14-5). Here, we follow Refs. [\[9,](#page-14-6) [16](#page-14-7)[–21\]](#page-14-8) and identify quasi-stationary markets states in the time evolution of the non-stationary correlation structure. The industrial sectors, which are clearly visible in the correlations [\[22–](#page-14-9)[29\]](#page-14-10) and covariances [\[30\]](#page-14-11), and their mutual connections are thereby analyzed in a time resolved fashion. This is accomplished by applying k-means clustering [\[31](#page-14-12)[–35\]](#page-14-13), a machine learning algorithm, to a set of correlation matrices measured over time in a moving window. The resulting clusters which we identify as market states can be regarded as

quasi-stationary structures in time, such that the individual correlation matrices fluctuate about the cluster centers [\[16,](#page-14-7) [18\]](#page-14-14). The market states emerge, exist for some time and eventually disappear [\[9,](#page-14-6) [16](#page-14-7)[–21,](#page-14-8) [36–](#page-14-15)[40\]](#page-15-0). Recently, similar methods have been applied in other fields, such as studies of epileptic seizures [\[41\]](#page-15-1) of freeway traffic [\[21\]](#page-14-8).

The market states are known to be dominated by the collective motion of the market as a whole [\[16\]](#page-14-7) which is related to the fact that the corresponding eigenvalue is largest and a measure for the average correlation coefficient [\[42\]](#page-15-2). To uncover the dynamics of the correlation structure, particularly due to the industrial sectors, relative to the dominating collective motion, i.e. to measure the correlations in the moving frame of the collective motion, we recently put forward a systematic and mathematically well-defined method [\[20\]](#page-14-16). We subtract the dyadic matrix belonging to the largest eigenvalue and thereby define two types of reduced-rank correlation matrices whose dynamics are then analyzed with the above k-means clustering algorithm. Reduced-rank correlation matrices of another kind appear in the context of filtering where the smaller eigenvalues are removed as a noise reduction technique [\[22,](#page-14-9) [29,](#page-14-10) [43–](#page-15-3)[45\]](#page-15-4). Subsequently, from the filtered standard correlation matrices, reduced-rank correlation matrices are calculated in order to obtain welldefined correlation matrices [\[46–](#page-15-5)[48\]](#page-15-6). As exogenous effects often affect the market as a whole, our reduced-rank correlation matrices are likely to be dominated by endogenous effects [\[20\]](#page-14-16).

The quasi-stationary market states in the time evolution of these reduced-rank correlation matrices are not directly related to the ones of the standard, i.e. not reduced-rank, ones. Surprisingly, they appear to be more stable, sometimes over several years, than the ones for the standard correlation matrices. This observation prompted the present study. Pharasi et al. [\[49\]](#page-15-7) proposed to identify precursors for critical events in the quasistationary market states of the standard correlation ma-

[∗] anton.heckens@uni-due.de

[†] thomas.guhr@uni-due.de

trices, while we here use the reduced-rank ones in view of their higher stability. More precisely, we exploit the separation of two different time scales. The quickly changing collective contribution is separated from the more stable one due to the industrial sectors.

Furthermore, we investigate the average dynamics of standard and reduced-rank matrices taking the mean value of all matrix elements. This adds to preceding studies on volatilities such as the absolute value of returns [\[50\]](#page-15-8) or cross-sectional volatilities and correlations [\[51–](#page-15-9)[53\]](#page-15-10).

It is worth mentioning that the collective market motion is at least more likely to be influenced by exogenous effects than the motion relative to it. Exogenous information can trigger collective volatility outbursts as the traders' reaction to unexpected events [\[54](#page-15-11)[–57\]](#page-15-12). By removing these risk contributions, we analyze the dynamics of the endogenous risk in the mutual interaction of the industrial sectors and the corresponding contagious effect for the whole market. For instance, we search for drastic changes in the financial sector in the pre-phase of the Lehman crash as an endogenous crisis which emerged from a major crisis in the US housing market. Such changes to which we refer as precursors (cf. Ref. [\[49\]](#page-15-7)) indicate systemic instabilities not necessarily but potentially leading to a crash. Our analysis adds to previous studies of systemic risk [\[58\]](#page-15-13). Noteworthy are investigations related to principal components analysis [\[59](#page-15-14)[–61\]](#page-15-15) and causality measures [\[60,](#page-15-16) [62\]](#page-15-17).

Here, we take data into account exclusively from epochs before crises events or within crises periods in order to investigate market state transitions as precursors. We address these two questions: How many epochs before a crisis event or within a crisis period does a "crisis market state" in the correlation structure show up? – Can we identify characteristic precursor signals in the dynamics of the reduced-ranked correlation matrices without using cluster methods?

The paper is organized as follows. In Sec. [II,](#page-1-0) we introduce our set of daily data for the analysis. The construction of reduced-rank correlation matrices is briefly sketched in Sec. [III.](#page-1-1) In Sec. [IV,](#page-3-0) we analyze the data and present our results. The conclusions are given in Sec. [V.](#page-12-0)

II. DATA SET

Using data collected by QuoteMedia [\[63\]](#page-15-18) and provided by Quandl [\[64\]](#page-15-19) we construct a data set of $K = 250$ US stocks (see Tab. [IV](#page-17-0) in App. [A\)](#page-17-1), i.e. the selected stocks do not change for the entire investigation period. The investigation period ranges from 02 January, 1997 to 31 December, 2012 in order to concentrate on the two periods, the dot-com bubble burst and the Lehman Brothers precrash phase. Our data set represents the S&P 500 index since it comprises the 11 Global Industry Classification Standard (GICS) sectors in Tab. [I](#page-1-2) (cf. [\[65\]](#page-15-20)). Furthermore, we also sorted the stocks within the sectors according to the sub-industry sectors (see Tab. [IV](#page-17-0) in App. [A\)](#page-17-1). In Ref. [\[20\]](#page-14-16), we demonstrated that the market states de-

TABLE I. Global Industry Classification Standard (GICS).

Abbreviation	Sector	Number of stocks
E	Energy	16
M	Materials	14
	Industrials	43
CD	Consumer Discretionary	24
CST	Consumer Staples	24
HС	Health Care	28
F	Financials	36
RE	Real Estate	8
	Information Technology	27
CSE	Communication Services	9
	Utilities	21

pend on the choice of the stocks. Nevertheless, our data set allows us to make general statements about the correlation structure of the US stock markets because all GICS industry sectors [\[65\]](#page-15-20) are covered by our data set and no industry sector is underrepresented, even not the real estate sector which mainly causes a market state transition in Ref. [\[20\]](#page-14-16).

From adjusted closing prices $S_i(t)$, we calculate the daily logarithmic returns ($\Delta t = 1$ day)

$$
G_i(t) = \ln \frac{S_i(t + \Delta t)}{S_i(t)}, \quad i = 1, \dots, K. \tag{1}
$$

We set up a $K \times T_{\text{tot}}$ data matrix for the total investigation period

$$
G_{\text{tot}} = \begin{bmatrix} G_1(1) & \dots & G_1(T_{\text{tot}}) \\ \vdots & & \vdots \\ G_i(1) & \dots & G_i(T_{\text{tot}}) \\ \vdots & & \vdots \\ G_K(1) & \dots & G_K(T_{\text{tot}}) \end{bmatrix}
$$
 (2)

with $K = 250$, being the number of stocks and $T_{\text{tot}} =$ 4026, being the total number of points in the return time series of a stock. We do not use the full data matrix G_{tot} for the market state analysis. In order to analyze the nonstationarity of correlation matrices we select subblocks of the data matrix G_{tot} with all $K = 250$ stocks and intervals of $T_{ep} = 42$ trading days which correspond to 2 trading months. Only in the case of disjoint intervals we refer to these intervals as epochs.

III. REDUCED-RANK MATRICES

In Ref. [\[20\]](#page-14-16), we introduced the covariance approach and the correlation approach. The covariance approach uses the standard covariance matrix, the correlation approach employs the standard correlation matrix, where the term "standard" refers to the original covariance and

FIG. 1. Reduced-rank correlation matrices of $K = 250$ stocks for [\(a\)](#page-2-0) the covariance approach and [\(b\)](#page-2-1) the correlation approach. Both matrices are calculated for the 16 year period from 02 January, 1997 to 31 December, 2012. Capital Letters indicate industrial sectors (see Tab. [I\)](#page-1-2) [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

correlation matrix as obtained from the measured time series. In Sec. [III A,](#page-2-2) we give a short introduction to the covariance approach, as well as in Sec. [III B](#page-2-3) to the correlation approach.

A. Covariance approach

The starting point is the evaluation of the standard covariance matrix

$$
\Sigma = \frac{1}{T} A A^{\dagger} = \sum_{i=1}^{K} \kappa_i u_i u_i^{\dagger}.
$$
 (3)

The $K \times T$ data matrix A contains mean-normalized time series as rows. Additionally, we apply a spectral decomposition to the standard covariance matrix. Eigenvalues are denoted by κ_i and eigenvectors are denoted by u_i . The largest eigenvalue and the corresponding eigenvector can be interpreted as market part of Σ , while the other larger eigenvalues correspond to industrial sectors. The smaller eigenvalues form a so-called bulk which contains to a large extent the noise in the time series. Their spectral density can be described by random matrix distributions [\[16,](#page-14-7) [22–](#page-14-9)[25,](#page-14-17) [29,](#page-14-10) [30,](#page-14-11) [42,](#page-15-2) [66,](#page-15-21) [67\]](#page-15-22). Now, we subtract the dyadic matrix corresponding to the largest eigenvalue

$$
\Sigma_B = \Sigma - \kappa_K u_K u_K^{\dagger} \tag{4}
$$

arriving at the matrix Σ_B as an intermediate quantity. We mention in passing that Σ_B is a well-defined covariance matrix [\[20\]](#page-14-16). Using the standard deviations ordered in the diagonal matrix

$$
\sigma_B = \text{diag}(\sigma_{B1}, \dots, \sigma_{BK}), \qquad (5)
$$

we define the reduced-rank correlation matrix in the covariance approach

$$
C_B = (\sigma_B)^{-1} \Sigma_B (\sigma_B)^{-1} . \tag{6}
$$

In Fig. $1(a)$, the correlation matrix in the covariance approach is depicted for the entire 16 year period. It shows positively correlated block-diagonal entries corresponding to eleven industrial sectors and anti-correlations in the inter-sector structure.

B. Correlation approach

Here, the starting point is the calculation of the standard correlation matrix

$$
C = \frac{1}{T} M M^{\dagger} = \sum_{i=1}^{K} \lambda_i x_i x_i^{\dagger}, \qquad (7)
$$

where M is a $K \times T$ data matrix whose rows are normalized to standard deviation one and mean value zero. Eigenvalues are denoted by λ_i and eigenvectors by x_i . Analogously to Eq. [\(6\)](#page-2-4), by means of the matrix

$$
\Sigma_L = C - \lambda_K x_K x_K^{\dagger} \tag{8}
$$

and the diagonal matrix of standard deviations

$$
\sigma_L = \text{diag}(\sigma_{L1}, \dots, \sigma_{LK}), \qquad (9)
$$

 $\overline{4}$

FIG. 2. Comparison of different fractions: (a) f_{Σ_n} , (b) $f_{\Sigma_B n}$, (c) $f_{\Sigma_L n}$, (d) f_{C_n} , (e) $f_{C_B n}$ and (f) $f_{C_L n}$ for $n = 1$ (black), $n = 2$ (blue), $n = 3$ (red), $n = 4$ (green). Each dot represents an interval of 42 trading days (Data from QuoteMedia via Quandl).

we define the reduced-rank correlation matrix of the correlation approach

DATA ANALYSIS AND RESULTS IV.

$$
C_L = (\sigma_L)^{-1} \Sigma_L (\sigma_L)^{-1} . \qquad (10)
$$

The reduced-rank correlation matrix in the correlation approach is depicted in Fig. $1(b)$. It looks very similar to the one in the covariance approach for the entire 16 year period in Fig. $1(a)$. As shown in Ref. [20], around the Lehman Brothers crisis, the reduced-rank correlation matrices for both approaches differ very much from each other for a one year time period.

In Sec. IVA, we briefly recapitulate our concept of market states. In Sec. IV B, we define mean values, distance matrices and averaged distances for the reducedrank correlation matrices and visualize their temporal evolution. We compare the time series of these mean values and averaged distances with historical and estimated events in Sec. IV C in order to study transitions of market states. Other precursors are identified in Sec. IVD. In Sec. IV E, we investigate market states for the dot-com bubble burst and the pre-phase of the Lehman Brothers crises. Importantly, we do not use post-crisis data.

FIG. 3. Comparison of different mean values: (a) mean covariance \overline{cov} , (b) mean covariance \overline{cov}_B , (c) mean covariance \overline{cov}_L , (d) mean correlation $\overline{\text{corr}}$, (e) mean correlation $\overline{\text{corr}}_B$ and (f) mean correlation $\overline{\text{corr}}_L$. The beginning of the dot-com bubble burst is highlighted by historical event (DC) and the Lehman Brothers crash is highlighted by (LB). Further label explanations for historical events (lower row) and estimated events (upper row) can be found in Tabs. II and III. Each dot represents an interval of 42 trading days (Data from QuoteMedia via Quandl).

A. Concept of market states

We identify quasi-stationary structures in the timedependent correlation matrices. We refer to them as market states. In previous works $[9, 16-21, 36-40, 49]$, time periods of several decades are divided into so-called epochs (see Sec. II). Epochs are usually disjoint, *i.e.* nonoverlapping intervals. The fixed length of each epoch is typically one or two trading months. For each epoch, we calculate a correlation matrix, a standard one or a reduced-rank one. We group correlation matrices of the same kind by employing a clustering algorithm, the k means clustering algorithm $[31-35]$. We identify these

groups as market states which comprise correlation matrices of a similar structure. Wo do that for the standard and for the reduced-rank correlation matrices which show striking differences. In particular, we find longer life times in the latter ones. The market operates in a state for a certain time, then jumps to another one and yet another one and also might return to a state. Put differently, the states emerge, exist for some time, reappear and eventually disappear.

FIG. 4. Mean covariance $\overline{\text{cov}}$ plotted on a logarithmic scale in order to visualize the increasing and decreasing mean covariances around crisis listed in Tabs [II.](#page-8-2) The other events can be found in Tab. [III](#page-8-3) [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

B. Mean values, distance matrices and averaged distances

Since we want to scrutinize what happens at the transitions of the market states we use overlapping $T_{\text{ep}} =$ 42 trading days to find signals in our data potentially being connected to such transitions. Relevant signals may be found in the mean values of all reduced-rank correlation matrices elements and in the distance matrices derived from the reduced-rank correlation matrices. Investigating time series with a moving interval of T_{ep} = 42 trading days involves noise in the corresponding observables such as volatilites, covariances or correlations. Numerous analysis especially in the past decade showed that this is justified by revealing dynamics in financial markets which otherwise would stay hidden (see Ref. [\[15\]](#page-14-5)). Kenett et al. [\[68\]](#page-15-23) analyzed the US stock markets in a period from 2002 to 2009. These authors found that 22 trading days are approximately the lowest bound for a trade-off between noise and a smoothed dynamics for so-called normalized correlation matrices.

We set up $K \times T_{ep}$ data matrices A and M where $K = 250$ is the number of stocks and $T_{ep} = 42$ trading days is the length of one interval. The matrices are computed on a 42 trading day sliding window which is shifted forward by one trading day and moved over the 4026 trading days of the return time series. In total, we compute 3984 data matrices A and 3984 data matrices M. According to Sec. [III,](#page-1-1) we calculate the standard covariance matrix Σ , the covariance matrix Σ_B , the reduced-rank correlation matrix C_B in the covariance approach, the standard correlation matrix C , the covariance matrix Σ_L in the covariance approach and the reducedrank correlation matrix C_L in the correlation approach. The latter matrices are singular and their elements are strongly influenced by noise.

However, it is quite difficult to separate the dynamics and noise introduced on such short time windows. To make statements about the system-relevant dynamics for matrices Σ , Σ_B C_B , C , Σ_B and C_L with $T_{ep} = 42$ trading days we assume that the ten largest

eigenvalues for each matrix contain almost all of the information on the industrial sectors. We take into account only the ten largest eigenvalues similar to a cut-off from the noise-dressed bulk for matrices with $T \gg K$ [\[16,](#page-14-7) [22–](#page-14-9) [25,](#page-14-17) [29,](#page-14-10) [30,](#page-14-11) [42,](#page-15-2) [66,](#page-15-21) [67\]](#page-15-22). We define the fraction

$$
f_{\Sigma n} = \frac{\sum_{i=1}^{n} \kappa_{K+1-i}}{\sum_{i=1}^{10} \kappa_{K+1-i}} ,
$$
\n(11)

for the covariance matrix Σ (cf. Ref. [\[69\]](#page-15-24)). The fraction $f_{\Sigma n}$ describes how much variance of all 250 time series correspond to the n largest eigenvalues related to the variance of the ten largest eigenvalues.

Figure [2](#page-3-7) depicts the fractions $n = 1, \ldots, 4$ for all six matrices. For Σ and C in Figs. [2a](#page-3-1) and [2d,](#page-3-4) the four largest eigenvalues contain at least 53 % and on average 74 % of the variance of the ten largest eigenvalues. After 2007/2008, the dynamics of the selected stocks is dominated by the largest eigenvalues of Σ and C. Subtracting the dyadic matrix corresponding to the largest eigenvalue reveals a completely different dynamics in Figs. [2b,](#page-3-2) [2c,](#page-3-3) [2e](#page-3-5) and [2f.](#page-3-6) The four largest eigenvalues contain at least 46 % and on average 55 % of the variance of the ten largest eigenvalues. The dynamics is not dominated by the largest eigenvalues of Σ_B , Σ_L , C_B and C_L after 2007/2008. The time evolution of the curves show a certain stability in time indicating a stable correlation structure and corroborating our results for the market state analysis from Ref. [\[20\]](#page-14-16). Remarkably, the four curves in Figs. [2b,](#page-3-2) [2c,](#page-3-3) [2e](#page-3-5) and [2f](#page-3-6) feature a similar time evolution for the entire time period reflecting the coherent behavior of the industrial sectors.

As a next step, the mean value of all matrix elements for every matrix is computed. For the covariance matrix Σ , we take the average of all covariance matrix elements

$$
\overline{\text{cov}} = \frac{1}{K^2} \sum_{i,j=1}^{K} \Sigma_{ij} . \tag{12}
$$

Correspondingly, we define the mean covariance $\overline{\text{cov}}_B$ in the covariance approach and the mean covariance \overline{cov}_L in the correlation approach. Since we include the diagonal elements in the average in Eq. [\(12\)](#page-5-1), we analogously define the average for the standard correlation matrix C as

$$
\overline{\text{corr}} = \frac{1}{K^2} \sum_{i,j=1}^{K} C_{ij} \,. \tag{13}
$$

For the reduced-rank correlation matrix C_B and C_L , the mean correlation is denoted by $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$, respectively. Finally, we generate time series of the mean covariances $\overline{\text{cov}}$, $\overline{\text{cov}}_B$, $\overline{\text{cov}}_L$ and the mean correlations $\overline{\text{corr}}$, $\overline{\text{corr}}_B$, $\overline{\text{corr}}_L$. Each of these time series comprises 3984 mean values.

In Figs. $3(a)$, $3(b)$ and $3(e)$, the time evolutions of the mean values $\overline{\text{cov}}_B$, $\overline{\text{cov}}_B$ and $\overline{\text{corr}}_B$ belonging to the covariance approach are displayed on a linear scale. This is compared to the time evolutions of the mean values

FIG. 5. [\(a\)](#page-6-0) Covariance approach: (top) distance matrix $\zeta_B^{\text{Eucl}}(t_a, t_b)$ and (bottom) averaged distance $\overline{\zeta}_B^{\text{ Eucl}}(t_a)$; [\(b\)](#page-6-1) Correlation approach: (top) distance matrix $\zeta_L^{\text{Eucl}}(t_a, t_b)$ and (bottom) averaged distance $\overline{\zeta}_L^{\text{Eucl}}(t_a)$. For the averaged distances, values smaller than 0.22 are excluded. Marks along margins of distance matrices indicate trading years. Events in brackets are listed in Tabs. [II](#page-8-2) and [III](#page-8-3) [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

corr, $\overline{\text{cov}}_L$ and $\overline{\text{corr}}_L$ in Figs. [3\(d\),](#page-4-4) [3\(c\)](#page-4-3) and [3\(f\)](#page-4-6) corresponding to the correlation approach on a linear scale as well. Each data matrix, correlation matrix and mean value receive a time stamp which corresponds to the center of a 42 trading day interval and which is represented by a black dot in Fig. [3.](#page-4-7) A logarithmic scale in Fig. [4](#page-5-2) for mean covariance $\overline{\text{cov}}$ facilitates a comparison with its peaks. Both mean covariances \overline{cov} and \overline{cov}_B are positive for the entire 16 year time period. In contrast to the mean correlation $\overline{\text{corr}}$, the mean covariance $\overline{\text{cov}}$ shows no trend to larger mean values. Larger mean values in the covariance and correlation approach correspond to reduced-rank correlation matrices in which a sector such as the financial sector or a subgroup of stocks show sometimes strong anti-correlation to the other industrial sec-tors (cf. Ref. [\[20\]](#page-14-16)). For smaller mean covariances \overline{cov} and correlations $\overline{\text{corr}}$, we usually find larger peaks in $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$, respectively. Although the mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ can be small in contrast to $\overline{\text{corr}}$, this does not imply that these are artifacts due to noise as we effectively take the average of $K(K-1)/2 = 31125$ correlation matrix elements, taking the symmetry and the

unities on the diagonals of correlation matrices into account. For the mean covariances, the variances (squared volatilities) are on the diagonals and are time-dependent quantities.

We now turn to measuring distances between correlation matrices. As we use k-means clustering in our market state analysis which employs the Euclidean metric [\[31–](#page-14-12)[35\]](#page-14-13), we introduce a distance matrix – as defined for the standard correlation matrix in Refs. $[9, 16]$ $[9, 16]$ – by calculating the pairwise distance between two reducedrank correlation matrices in the covariance approach

$$
\zeta_B^{\text{Eucl}}(t_a, t_b) = \frac{\sqrt{\sum_{i,j} (C_{Bij}(t_a) - C_{Bij}(t_b))^2}}{K}.
$$
 (14)

Correspondingly, in the correlation approach, we define the Euclidean distance $\zeta_L^{\text{Eucl}}(t_a, t_b)$. Rows and columns are labeled by the indices $t_a = 1, \ldots, 3984$ and $t_b =$ 1, . . . , 3984. Thus, we obtain distance matrices of dimension 3984 \times 3984. Due to the normalization with K in Eq. [\(14\)](#page-6-2) we may compare distance matrices for another selection of stocks.

In Figs. [5\(a\)](#page-6-0) and [5\(b\)](#page-6-1) the distance matrices calculated according to Eq. [\(14\)](#page-6-2) are displayed. The larger the distance, the more dissimilar are two reduced-rank correlation matrices. The distance matrices derived from the standard correlation matrices show their highest values for financial crashes [\[9\]](#page-14-6). We observe a completely different dynamics for the distance matrices $\zeta_B^{\text{Eucl}}(t_a, t_b)$ and $\zeta_L^{\text{Eucl}}(t_a, t_b)$. Quasi-stationary periods of distances with values of approximately 0.24 are followed by less stable periods of larger distances with values larger than 0.26. The distance matrix $\zeta_B^{\text{Eucl}}(t_a, t_b)$ for the covariance approach shows a much more pronounced structure than that for the correlation approach $\zeta_L^{\text{Eucl}}(t_a, t_b)$.

We introduce a new time series – the *averaged distance* – to analyze the market state transitions in more detail. Due to the characteristic stripes in Figs. $5(a)$ and $5(b)$, it is beneficial to take the average of the rows of a distance matrix since these stripes might contain information on possible market state transitions. Using the distance matrix $\zeta_B^{\text{Eucl}}(t_a, t_b)$ in Eq. [\(14\)](#page-6-2), we calculate the averaged distance as

$$
\overline{\zeta}_{B}^{\text{Eucl}}(t_a) = \frac{1}{t_c} \sum_{t'_b=1}^{t_c} \zeta_{B}^{\text{Eucl}}(t_a, t'_b) . \tag{15}
$$

keeping the row index t_a fixed and summing up to a specific column index t_c . The column index $t'_b = 1$ corresponds to the trading date 1997-01-31 and $t_c = 484$ to the trading date 1998-12-31. Thus, we obtain a side profile for each distance matrix mapping important structural information into a one-dimensional plot. The averaged distance facilitates the comparison with historical events. We do not analyze $\overline{\zeta}_{B}^{\text{ Eucl}}(t_a)$ in dependence of t_c . Analogously, we define the averaged distance $\overline{\zeta}_L^{\mathrm{Eucl}}(t_a)$ for the correlation approach. The averaged distances are depicted in Figs. [5\(a\)](#page-6-0) for the covariance approach and in Fig. [5\(b\)](#page-6-1) for the correlation approach.

In Figs. $5(a)$ and $5(b)$, we cut off distance matrix elements with values smaller than 0.22. Thereby, we exclude distances between overlapping reduced-rank correlation matrices in Eq. [\(15\)](#page-7-1). By including values smaller than 0.22 we would calculate systematically lower values for the averaged distance in Eq. [\(15\)](#page-7-1) from $t'_b = 1$ to t_c compared to the time period from t_c to $t_d = 3984$. We would create an artificial jump at t_c .

C. Historical and estimated events

We wish to compare the time evolution of the mean values and averaged distances with events which are on the one hand historical crisis events listed in Tab. [II](#page-8-2) and on the other hand events in Tab. [III](#page-8-3) estimated from the averaged distances in Sec. [IV B.](#page-5-0) Those estimated events are connected to market state transitions and are highlighted as dashed lines in Figs. [3,](#page-4-7) [4](#page-5-2) and [5.](#page-6-3)

The mean covariance $\overline{\text{cov}}$ in Fig. [3\(a\)](#page-4-1) shows its highest peaks for the Lehman Brothers crash (LB) whereas the mean correlation \overline{corr} in Fig. [3\(d\)](#page-4-4) has its largest value for the August 2011 stock market fall (AF). We want to emphasize that the trading day when the NASDAQ Composite stock market index peaked is labeled by (DC) [\[70\]](#page-15-25). Shortly after this event, the dot-com bubble bursted.

Our new analysis corroborates our results in Ref. [\[20\]](#page-14-16): Using reduced-rank correlation matrices, in covariance or correlation approach, exogenous effects are likely to be efficiently separated from endogenous ones. This affects all stocks and appears in $\overline{\text{cov}}$ and $\overline{\text{corr}}$ as crisis events (cf. Tab. [II\)](#page-8-2). The mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ show a non-stationary behavior with sometimes even high values, especially in the case of the covariance approach (cf. Figs. $3(e)$ and $3(f)$). We additionally calculated the mean covariances $\overline{\text{cov}}_B$ and $\overline{\text{cov}}_L$ which both show a separation from the historical events in their temporal behavior as well (cf. Figs. $3(b)$ and $3(c)$).

The averaged distances in Figs. [5\(a\)](#page-6-0) and [5\(b\)](#page-6-1) facilitate the identification of signals in the distance matrix which are connected to market state transitions. The market state transitions occur for the dot-com bubble burst roughly between (DC1) and (DC2) and for the prephase of the Lehman Brothers crash between (LB1) and (LB2) (cf. Tab. [III\)](#page-8-3). The duration of the market state transition period in the vicinity of historical event (DC) is 73 trading days and prior to (LB) 74 trading days. The market state transition for the Lehman Brothers crisis market state appears in mid-2007 as it was observed in Ref. [\[59\]](#page-15-14) for the absolute changes of the largest eigenvalues of the standard correlation matrices. The presumable cause was the freezing of the Interbank market [\[71\]](#page-15-26). This is a precursor signal exclusively for (LB).

The dashed lines (LB1) and (LB3) around (LB) show a high agreement with the recession period of December 2007 - June 2009 [\[72\]](#page-15-27). Information on such recession periods is provided by the National Bureau of Economic Research (NBER) for the US economy. Apparently, we are able to detect connections to this recession period using reduced-rank correlation matrices on US stock markets. It is possible that the observables in our study are influenced by the recession period from March 2001 - November 2001 as well.

Additionally, Figs. [5\(a\)](#page-6-0) and [5\(b\),](#page-6-1) also make visible the historical events (AC), (RC), (S11) and (AF) and potentially (ED) in the averaged distances. The difference to the dot-com bubble burst and the Lehman Brothers crisis is that these four to five crises are not accompanied by larger outburst in the mean covariances $\overline{\text{cov}}_B$, $\overline{\text{cov}}_L$ and the mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_B$ in their direct vicinity (see Fig. [3\)](#page-4-7). In spite of removing to a large extent exogenous contributions in the mean covariances $\overline{\text{cov}}_B$ and $\overline{\text{cov}}_L$ and mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ we find that the averaged distances still contain exogenous information of several financial crises.

TABLE II. Historical events taken from [\[73\]](#page-16-0).

Label Crisis	Date $(Year-Month-Day)$
(AC) Asian financial crisis	1997-10-27
(RC) Russian financial crisis	1998-08-17
(DC) Dot-com bubble (before burst)	2000-03-10
(S11) September 11th	2001-09-11
(MD) Stock market downturn of 2002	2002-10-09
(CB) Chinese stock bubble	2007-02-27
(LB) Lehman Brothers crash	2008-09-16
(ED) European debt crisis	2010-04-27
(AF) August 2011 stock markets fall	2011-08-01

TABLE III. Dates for events estimated from the averaged distances introduced in Sec. [IV B.](#page-5-0) First to fourth label highlight dates for begin and end of market state transitions [\(Data](https://www.quandl.com/) [from QuoteMedia via Quandl\)](https://www.quandl.com/).

D. Other long-term precursors

The periods of the dot-com bubble burst between (DC1) and (DC2) and the pre-phase of the Lehman Brothers crash between (LB1) and (LB2) start with very low values of $\overline{\text{corr}}_B$ accompanied by an increasing mean covariance $\overline{\text{cov}}$ for (LB), also depicted on a logarithmic scale in Fig. [4.](#page-5-2) These very low values of $\overline{\text{corr}}_B$ coincide with market state transitions. In the case of the dotcom bubble burst a sudden mean correlation outburst in $\overline{\text{corr}}_B$ appears at (DC1). For the Lehman pre-phase, however, the outburst of $\overline{\text{corr}}_B$ does not happen at (LB1) but shortly before (LB). The low values for the mean correlation $\overline{\text{corr}}_B$ are precursor signals for (DC) and (LB).

The sudden decreases in the mean covariances $\overline{\text{cov}}_B$ and $\overline{\text{cov}}_L$ and in the mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ at (LB) indicate a connection to the Lehman Brothers crash whereas the mean covariance $\overline{\text{cov}}$ as a measure for the entire market risk and the mean correlation \overline{corr} have peaks. The financial sector crisis spread over to the entire market, leading to a market-wide crash. This can be interpreted as a spill-over effect. Therefore, $\overline{\text{cov}}_B$, $\overline{\text{cov}}_L$, $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ show features of potential measures for systemic risk. We do not observe such a spill-over effect for the dot-com bubble. The largest peaks in the averaged distances in Figs. $5(a)$ and $5(b)$ at (LB) coin-

cide with lower mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$. This spill-over effect is a precursor signal exclusively for (LB).

Comparing the averaged distances in Figs. [5\(a\)](#page-6-0) and [5\(b\)](#page-6-1) and the time evolution of the mean correlations $\overline{\text{corr}}_B$ and $\overline{\text{corr}}_L$ in Figs. [3\(e\)](#page-4-5) and [3\(f\)](#page-4-6) we see that changes in the averaged distances occur prior to the changes in the mean correlation at a market state transition to the crisis period for (LB). In the pre-phase of the Lehman Brothers crisis, the mid-2007 peak discussed in Sec. [IV C](#page-7-0) does not coincide with a larger change in mean correlations. The spill-over effect appears later. In the case of the dot-com bubble burst, we observe for the correlation approach between (DC1) and (DC2) that a change in the averaged distance is accompanied by an outburst of the mean correlation $\overline{\text{corr}}_B$.

E. Market state transitions as long-term precursors of financial crises

In Ref. [\[20\]](#page-14-16), we divided a 15 year time period into epochs (time periods of equal length) with $T_{ep} = 42$ trading days and set up a $K \times T_{ep}$ data matrix A and M with $K = 262$ and $T_{ep} = 42$ for each epoch. Then we calculated the reduced-rank correlation matrices for these epochs and clustered all reduced-rank correlation matrices by the k-means algorithm $[31-35]$ $[31-35]$, resulting in different market states. According to Secs. [III A](#page-2-2) and [IV B,](#page-5-0) we predominantly cluster information on the industrial sectors. The market state analysis reveals much more clearly major structures hidden in the distance matrices as we strongly reduce the information of the reduced-rank correlation matrices to the market states.

Here, we follow a different method which we want to explain in the case of the Lehman Brothers crash (LB) by means of Figs. $6(a)-6(e)$ $6(a)-6(e)$ for the covariance approach. We divide a time period of several years before the Lehman Brothers crash (LB) into epochs with $T_{ep} = 42$ trading days. Figs. $6(a)-6(e)$ have in common that the starting epoch of the time period is fixed. In Fig. [6\(a\),](#page-9-0) the last epoch is seven epochs before (LB) and in Fig. [6\(e\)](#page-9-1) one epoch before (LB). For each epoch, we calculate a reduced-rank correlation matrix of dimension 250×250 and cluster all reduced-rank correlation matrices employing the k-means clustering algorithm for $k = 2$. We refer to Figs. $6(a)$ – $6(e)$ as "snapshots". All snapshots together for one approach form a sequence of snapshots.

For the first snapshot in Fig. $6(a)$, we divide the time period from 2004-01-15 to 2007-07-18 into 21 epochs. The last epoch is in the vicinity of where we observe a small value of the mean value $\overline{\text{corr}}_B$ (see Sec. [IV D\)](#page-8-0), *i.e.* between $(LB1)$ and $(LB2)$ (see Tab. [III\)](#page-8-3). In Fig. $6(b)$, we divide the time period from 2004-01-15 to 2007-09-17 into 22 epochs. We cluster 22 reduced-rank correlation matrices, i.e. additionally, we cluster one more reduced-rank correlation matrix corresponding to an epoch of 42 trading days. In contrast to Fig. $6(a)$, we observe in Fig. $6(b)$ a drastic change in the market state evolution. For the

FIG. 6. Snapshots of the market state analysis for the reduced-rank correlation matrices in the [\(a\)-](#page-9-0)[\(e\)](#page-9-1) covariance approach and [\(f\)-](#page-9-3)[\(j\)](#page-9-4) correlation approach compared to estimated events around the Lehman Brothers crash (LB) (for lower row, see Tab. [II\)](#page-8-2). For all snapshots, the first epoch is fixed. The clustered period starts for all snapshots at 2004-01-15. The estimated events in the upper row (LB1), (LB2) and (LB3) can be found in Tab. [III.](#page-8-3) Every dot stands for an epoch of 42 trading days. From subplots [\(a\)](#page-9-0) to [\(j\),](#page-9-4) the number of the remaining epochs before (LB) is specified [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

FIG. 7. Typical second market states ($K = 250$ stocks) corresponding to the snapshots before the Lehman Brothers crash marked by historical event (LB) (cf. Fig. [6\)](#page-9-5) for the reduced-rank correlation matrices in the [\(a\)-](#page-10-0)[\(c\)](#page-10-1) covariance approach and (d) [-\(f\)](#page-10-3) correlation approach. From subplots [\(a\)](#page-10-0) to [\(f\),](#page-10-3) the number of the remaining epochs before (LB) is specified. A typical market state is obtained by taking the element-wise average of the correlation matrices of the respective market state. Capital Letters indicate industrial sectors (see Tab. [I\)](#page-1-2) [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

first 21 epochs, all reduced-rank correlation matrices are clustered into the first market state. The second market state consists of one reduced-rank correlation matrix located between $(LB1)$ and $(LB2)$. In Fig. $6(c)$, we consider 25 epochs, i.e. three more reduced-rank correlation matrices compared to Fig. [6\(b\).](#page-9-2) The two remaining reduced-rank correlation matrices in Figs. $6(d)$ and $6(e)$ are assigned to the second market state as well, revealing a certain stability in the market states.

The sequence of snapshots for the correlation approach in Figs. $6(f)-6(j)$ $6(f)-6(j)$ looks very similar compared to the one for the covariance approach in Figs. $6(a)$ – $6(e)$. For both approaches, there are three epochs between the last epoch in Figs. $6(c)$ and $6(h)$ and event (LB) which is half of a trading year. We are able to detect such a structural change without using post-crash data, thereby demonstrating precursor properties of the reduced-rank correlation matrices.

We obtain very similar results for the covariance and the correlation approach which is supported by the plots in Fig. [7.](#page-10-4) Here, we show so-called typical market states [\[9,](#page-14-6) [20\]](#page-14-16) as element-wise average of all reduced-

rank correlation matrices of a single market state for the second market state and for different snapshots. Corresponding typical second market states for the covariance and the correlation approach are very similar.

For dot-com bubble burst in Fig. [8,](#page-11-0) we are not able to identify a market state transition before (DC). Major correlation structure changes appear afterwards. The clustered period starts for all snapshots at 1997-01-13. Estimated events (DC1) and (DC2) (see Tab. [III\)](#page-8-3) highlight the market state transition and small values of mean value $\overline{\text{corr}}_B$ (cf. Sec. [IV D\)](#page-8-0). Instead, we take into account epochs after (DC) and analyze for which snapshots the market state transitions can be detected. In contrast to the Lehman Brothers crash, the temporal evolutions of the typical market states within the snapshots for the covariance approach differ qualitatively from those of the correlation approach in the case of the dot-com bubble burst. It is intriguing that we are able to detect a first market state transition after two epochs in Fig. [8\(b\)](#page-11-1) which is much earlier than the six epochs after (DC) for the correlation approach in Fig. $8(g)$.

We aim to compare the mean correlation $\overline{\text{corr}}_B$ with a

FIG. 8. Snapshots of the market state analysis for the reduced-rank correlation matrices in the [\(a\)-](#page-11-3)[\(e\)](#page-11-4) covariance approach and [\(f\)-](#page-11-5)[\(h\)](#page-11-6) correlation approach compared to estimated events at the beginning of the dot-com bubble burst marked by historical event (DC) (for lower row, see Tab. [II\)](#page-8-2). For all snapshots, the first epoch is fixed. The clustered period starts for all snapshots at 1997-01-13. The estimated events in the upper row (DC1) and (DC2) can be found in Tab. [III.](#page-8-3) Every dot stands for an epoch of 42 trading days. From subplots [\(a\)](#page-11-3) to [\(h\),](#page-11-6) the number of the epochs after (DC) is specified [\(Data from QuoteMedia](https://www.quandl.com/) [via Quandl\)](https://www.quandl.com/).

FIG. 9. Self-constructed index as average of the adjusted daily closing prices (see Sec. [II\)](#page-1-0) of the 27 IT stocks (see Tab. [I](#page-1-2) and Tab. [IV](#page-17-0) in App. [A\)](#page-17-1). The dates for the end of the epochs are for $(EP2)$ 2000-07-11 (two epochs after (DC)) and for $(EP4)$ 2000-11-07 (four epochs after (DC)) [\(Data from QuoteMedia](https://www.quandl.com/) [via Quandl\)](https://www.quandl.com/).

time series mimicking the NASDAQ index [\[74\]](#page-16-1). We construct this time series by taking the average of the adjusted daily closing prices belonging to the 27 IT stocks (cf. Fig. [I\)](#page-1-2). In Fig. [9,](#page-12-1) this self-constructed index is displayed (cf. Tab. [I](#page-1-2) and Tab. [IV](#page-17-0) in App. [A\)](#page-17-1). The end date of the second epoch after (DC) is 2000-07-11 and highlighted by the label (EP2); the end date of the fourth epoch after (DC) is 2000-11-07 and highlighted by the label (EP4). Event (EP2) lies before a major drop of the dot-com bubble burst in Fig. [9.](#page-12-1) It is interesting to compare this observation with the temporal evolution of the mean values in Sec. [IV B.](#page-5-0) In Fig. [3\(e\)](#page-4-5) the mean correlation $\overline{\text{corr}}_B$ remains at a relatively high level whereas the mean covariance $\overline{\text{cov}}$ is decreasing in Fig. [3\(a\)](#page-4-1) and Fig. [4](#page-5-2) on a logarithmic scale. The mean correlation $\overline{\text{corr}}_B$ seems to indicate that there is still an endogenous risk in the IT sector which finally results in the market drop. This is another result which adds to the observation of Sec. [IV D](#page-8-0) that the mean correlation $\overline{\text{corr}}_B$ is a potential measure for systemic risk.

We can also observe in the correlation structure of the typical second market states in Fig. [10](#page-13-0) that both market state transitions are different for the two approaches. The anti-correlations from the IT sector with the other ten sectors as in Fig. $10(c)$ also appear as a feature of the reduced-rank correlation matrices in the covariance approach around the Lehman Brothers crash according to Ref. [\[20\]](#page-14-16). Based on this observation and the historical events during the time period, the second market state in the time period of the dot-com bubble burst can be referred to as "crisis state" as well.

V. CONCLUSION

We studied the dynamics of reduced-rank correlation matrices in the covariance and the correlation approach and found long-term precursor properties. The dynamics of the correlation structure was analyzed in two different

ways. On the one hand we looked at the market states of the reduced-rank correlation matrices, on the other hand we were able to relate the market state transitions to sometimes large peaks or drastic changes in the mean values of covariance and correlation approach and in the corresponding averaged distances.

Analyzing the variance of the largest four eigenvalues for standard and reduced- rank matrices we corroborated the quasi-stationary behavior of the market states based on the reduced-rank correlation matrices from Ref. [\[20\]](#page-14-16). Moreover, we found that the industrial sectors show a coherent behavior over the entire time period.

We have introduced a new method for analyzing market states. With our technique of snapshots for the market state analysis, we can follow the market state transitions by adding reduced-rank correlation matrices of new epochs to the market state analysis, thereby following the trajectories of the reduced-rank correlation matrices before or within crises periods. Our market state analysis is able to detect market state transitions belonging to the Lehman Brothers crash occurred. We exclusively used pre-crises data. The snapshots for the covariance and correlation approach look very much alike. For the dot-com bubble burst both approaches reveal differences concerning the market state dynamics.

We identified structures in the averaged distances which coincide with market state transitions in our cluster analysis. The mid-2007 event (freezing of the Interbank market) is the very first precursor signal starting the Lehman Brothers crisis state. The burst of the dotcom bubble marks the beginning of a crisis state as well.

The market state transition prior to the Lehman crash occurred at the time of the Interbank lending freeze. In the averaged distances, the influence of this event dampened. Nevertheless, we still detect the second market state shortly before the Lehman crash. Hence we observe a hysteresis effect, i.e. the second market state shortly before the Lehman crash was not directly caused by the Interbank lending freeze. Nonetheless the market stayed in the crisis market state meaning that the market was still in a period not necessarily but potentially leading to a crash.

By comparing the mean correlations in the covariance and correlation approach with historical events we saw that the mean correlations (especially in the covariance approach) reflect the dynamics of an endogenous risks for both crises. Points of minimum correlations in the covariance approach indicate the beginning of two crises periods. From these points onwards, the endogenous risk builds up. Thus it is conceivable that a market state transition takes place since a new economic period begins in terms of the endogenous risk dynamics.

Our new market state method relates precursors of different kinds. In the market state analysis, transitions into a crises market state are connected to low mean correlations in the covariance approach and sudden changes in the averaged distances.

Furthermore, we found a period around the Lehman

FIG. 10. Typical second market states $(K = 250$ stocks) corresponding to the snapshots of the dot-com bubble burst marked by historical event (DC) (cf. Fig. [6\)](#page-9-5) for the reduced-rank correlation matrices in the $(a)-(c)$ $(a)-(c)$ covariance approach and $(d)-(f)$ $(d)-(f)$ correlation approach. A typical market state is obtained by taking the element-wise average of the correlation matrices of the respective market state. From subplots [\(a\)](#page-13-2) to [\(f\),](#page-13-4) the number of the epochs after (DC) is specified. Capital Letters indicate industrial sectors (see Tab. [I\)](#page-1-2) [\(Data from QuoteMedia via Quandl\)](https://www.quandl.com/).

Brothers crash coinciding with a recession. Usually, recession periods are calculated with the gross domestic product (GDP) and techniques such as the Hodrick-Prescott filter [\[75](#page-16-2)[–77\]](#page-16-3). Analogously, by subtracting the dyadic matrix corresponding to the largest eigenvalue, we also separated the quickly changing market motion from the more stable sectoral one.

For the Lehman Brothers crisis state, changes in the averaged distances build up prior to the changes in the mean correlation at a market state transition. The interpretation for this phenomenon might be that economic changes like the freezing of the Interbank market [\[71\]](#page-15-26) are first visible which is supported by our identification of a "recession market state". The endogenous risk increases as some kind of "economic tension" in the market which builds up and finally dissipates. This risk is potentially contagious for the entire market. In the case of the Lehman Brothers crash it might be viewed as a spill-over effect. All our observations lead to the conclusion that the mean correlations for the reduced-rank correlation matrices in both approaches describe to some extent the fragility of the market being exposed to a po-

tentially larger risk initialized by an industrial sector. In the covariance approach, we observed anti-correlations between the IT-sector and the other ten sectors during the dot-com bubble burst. Such anti-correlations are also visible in the Lehman Brothers crash pre-phase between the financial sector and the other ten sectors in Ref. [\[20\]](#page-14-16). Therefore, the above mentioned endogenous risks, visible in the mean correlations in the covariance and correlation approach, are potential measures for systemic risk.

Appendix A: List of selected stocks

	Number Symbol Security	Sector	Sub-Industry
$\mathbf{1}$	CVX Chevron Corp.	Energy	Integrated Oil & Gas
$\overline{2}$	HES Hess Corporation	Energy	Integrated Oil & Gas
3	XOM Exxon Mobil Corp.	Energy	Integrated Oil & Gas
4	BKR Baker Hughes Co	Energy	Oil & Gas Equipment & Services
5	HAL Halliburton Co.	Energy	Oil & Gas Equipment & Services
6	SLB Schlumberger Ltd.	Energy	Oil & Gas Equipment & Services
7	APA Apache Corporation	Energy	Oil & Gas Exploration & Production
8	COG Cabot Oil & Gas	Energy	Oil & Gas Exploration & Production
9	COP ConocoPhillips	Energy	Oil & Gas Exploration & Production
10	EOG EOG Resources	Energy	Oil & Gas Exploration & Production
11	MRO Marathon Oil Corp.	Energy	Oil & Gas Exploration & Production
12	NBL Noble Energy	Energy	Oil & Gas Exploration & Production
13	OXY Occidental Petroleum	Energy	Oil & Gas Exploration & Production
14	VLO Valero Energy	Energy	Oil $\&$ Gas Refining & Marketing
15	OKE ONEOK	Energy	Oil & Gas Storage & Transportation
16	WMB Williams Companies	Energy	Oil $\&$ Gas Storage & Transportation
17	VMC Vulcan Materials	Materials	Construction Materials
18	FMC FMC Corporation	Materials	Fertilizers & Agricultural Chemicals
19	MOS The Mosaic Company	Materials	Fertilizers & Agricultural Chemicals
20	NEM Newmont Corporation	Materials	Gold
21	APD Air Products & Chemicals Inc	Materials	Industrial Gases
22	BLL Ball Corp	Materials	Metal & Glass Containers
23	AVY Avery Dennison Corp	Materials	Paper Packaging
24	IP International Paper	Materials	Paper Packaging
25	SEE Sealed Air	Materials	Paper Packaging
26	ECL Ecolab Inc.		Specialty Chemicals
27	IFF International Flavors & Fragrances	Materials Materials	Specialty Chemicals
	PPG PPG Industries		
$\sqrt{28}$		Materials	Specialty Chemicals
$\,29$	SHW Sherwin-Williams	Materials	Specialty Chemicals
$30\,$	NUE Nucor Corp.	Materials	Steel
31	BA Boeing Company	Industrials	Aerospace & Defense
$32\,$	GD General Dynamics	Industrials	Aerospace & Defense
