**Abstract:** Inferring the uncertainties in economic conditions are of significant importance for both decision makers as well as market players. In this paper, we propose a novel method based on Hidden Markov Model (HMM) to construct the Economic Condition Uncertainty (ECU) index that can be used to infer the economic condition uncertainties. The ECU index is a dimensionless index ranges between zero and one, this makes it to be comparable among sectors, regions and periods. We use the daily electricity consumption data of nearly 20 thousand firms in Shanghai from 2018 to 2020 to construct the ECU indexes. Results show that all ECU indexes, no matter at sectoral level or regional level, successfully captured the negative impacts of COVID-19 on Shanghai's economic conditions. Besides, the ECU indexes also presented the heterogeneities in different districts as well as in different sectors. This reflects the facts that changes in uncertainties of economic conditions are mainly related to regional economic structures and targeted regulation policies faced by sectors. The ECU index can also be easily extended to measure uncertainties of economic conditions in different fields which has great potentials in the future.

We declare that we have no conflict of interest.

# **1** Introduction

Inferring economic conditions timely is of significant importance for decision makers to make proper policy adjustments and for market players to understand the ongoing situations. Typically, decision makers and researchers use specific variables or construct quantitative indicators to reveal and understand the temporal and spatial economic conditions[1,2]. Appropriately designed economic condition indices can provide solid evidence for decision makers to stabilize the national and local economies under the economic fluctuations [3–5]. For example, statistical indicators such as gross domestic product (GDP), total export-import volume, gross investment that are released by national official statistics are often used to indicate economic conditions from different aspects. Furthermore, there has been a rising trend that composite indicators that are derived from existing statistical indicators are used to infer economic conditions. Since 1990, the Federal Reserve Bank of the United States released the Economic Conditions Index to measure the economic prosperities of metropolises[6]. This index attempts to measure economic activities in metropolitan area and is constructed by using a dynamic factor model with 12 traditional indicators including unemployment rate, per capita income, gross metropolis product, etc.[7]. The aforementioned Economic Conditions Index is a representative sample among other similar indices that are used to measure economic prosperities[8,9].

However, these traditional indicators have two main disadvantages in practice. Firstly, most of the existing economic condition indices are constructed with absolute values of different macroeconomic variables. This makes them able to measure the true economic activity levels and to detect real business cycles by using more complex modelling techniques[10]. Nevertheless, these indices can hardly identify rapid changes in economic conditions when facing unexpected exogeneous shocks such as earthquake, flood, epidemic, war, etc. As a result, impacts of these unexpected events on societies and economies will also be underestimated[11,12]. Policy makers need new indices that can provide effective information on economic condition uncertainties to facilitate the economic recovery[13,14]. Secondly, the existing indices are typically released with low frequencies like monthly, quarterly or even annually. This drawback reduces the applicability of using these indices to support decision makers to make prompt changes in policies. So, it is necessary to find a way to construct new indices with both high-frequency and high-resolution in order to make macro-control

more effectively.

The rise of big data in the past decade provides researchers with opportunities to measure the economic condition as well as its uncertainties through different perspectives[15]. For example, an ongoing project, namely Economic Tracker, uses high frequency economic activity data to track U.S. economy conditions including areas like business, employments, education and public health[16,17]. For other data sources, night light data has gained increasing popularities in measuring regional economic activities, especially for those underdeveloped regions [18,19]. Although new night lights data source such as VIIRS data can provide more unbiased estimates for economic activities than traditional DMSP data with a monthly basis, these practices still involve many unsolved debates that need to be answered in the future[20]. Similar satellite data have also been used in economics to infer conditions in specific topics such as agricultural developments, traffic conditions[21], predicting poverties[22], etc. Other big data applications also include using social media data[23], mobile phone data[24], etc. In order to track policy-related conditions, a news-based economic policy uncertainty (EPU) index is proposed[25]. The EPU index detects uncertainties of economic policies by extracting information from main stream newspapers and this method has been greatly extended so that larger scale datasets[26] and more advanced machine learning techniques[27] are used to improve the EPU index.

Compared to the aforementioned applications that use large-scale economic proxy data from different sources, electricity consumption data is often considered as the most appropriate indicators to reflect the economic condition[28,29]. Since electricity consumptions are closely related to the production activities[30], the economic condition fluctuates can be directly reflected by the changes in electricity consumption data[31,32]. The existing literature has demonstrated the statistical relationships between electricity consumptions and economic activities[33–38]. With the rapid development and deployment of smart meter technologies, nowadays large volume of electricity consumption data can be readily collected in real-time along with high data qualities. These features enhance the value of electricity big data in providing more accurate and timely information of economic conditions[39]. During the outbreak period of COVID-19, high-frequency electricity consumption data had made great contributions for understanding the impacts and recovery procedures of countries' economies[32,40]. For China, the Resumption Power Index[41] launched by the State Grid Zhejiang Electric Power Co. Ltd. considers the resumption of regional enterprises on the basis of their previous and current

electricity consumption. It once became an important indicator to measure the trends of the economic resumption after the COVID-19. However, since true economic conditions are difficult to be observed and companies' production pattern may slightly fluctuate, so simply comparing electricity consumptions in two periods may sometimes lead to biased estimates for economic conditions.

In this paper, we try to use electricity big data to construct a quantitative index that can reveal the changes of unobserved economic conditions. The index is called Economic Condition Uncertainty (ECU) index and is constructed by using a novel method proposed in this paper. The dynamic behaviors of unobserved economic conditions are modelled with Hidden Markov Model (HMM) and two unobserved conditions are stable condition and recession condition, respectively. Individual firm's production patterns are modelled to be different in different economic conditions. After estimating the HMM model, each unobserved economic condition will be assigned a probability which will be used to construct the aggregate ECU index. We use daily electricity consumption data from more than 18,000 firms in Shanghai from November 2018 to May 2020 to do empirical analyses. Results show that the ECU indexes constructed in this paper successfully capture the fluctuations in economy at both regional and sectoral level.

The rest of this paper is organized as follows. Section 2 is the research design that introduces the HMM and methods of constructing the ECU index. Section 3 describes the data used in this study. Section 4 shows the results of different ECU indexes. Section 5 concludes the paper.

# 2 Research design

## 2.1 Hidden Markov Model

In the real world, the economic condition may be prosperous or recessionary and it depends on a variety of factors. The most importantly, true economic condition cannot be readily observed since the impacts of economic condition changes may take a few times to take effect, so that economic conditions may not timely be reflected by firms' electricity consumptions. This time inconsistency may also be quite different for different sectors or firms. For example, a temporary drop or increase in a firm's electricity consumptions may just be the result of changes in weather conditions or this firm's temporary changes in production schedules.

To avoid misjudging the economic conditions, the empirical strategy should take two factors into

consideration to model firms' electricity consumption behavior. Firstly, each firm should set an electricity consumption benchmark and compare the current electricity consumption to this benchmark to see whether production has deviated from usual pattern or not. Secondly, the empirical models should allow the existence of unobserved economic conditions and firms have different production pattern in different economic conditions. To fulfill the above two targets, we choose Hidden Markov Model (HMM) [42,43] to set up the empirical models which can identify firms' production patterns as well as unobserved economic conditions to a large extent.

In the HMM setting, we denote the unobservable economic condition in period t as  $S_t$  and  $S_t \in \{S^p, S^r\}$ , where  $S^p$  stands for prosperous condition and  $S^r$  stands for recessionary condition. The economic condition is not independent in period t, it depends on the economic condition in last period and follows a first order Markov chain as follows:

$$\boldsymbol{P} = \begin{pmatrix} P(S_t = S^p | S_{t-1} = S^p) & P(S_t = S^r | S_{t-1} = S^p) \\ P(S_t = S^p | S_{t-1} = S^r) & P(S_t = S^r | S_{t-1} = S^r) \end{pmatrix} = \begin{pmatrix} q_{pp} & q_{pr} \\ q_{rp} & q_{rr} \end{pmatrix}$$
(1)

where **P** is the transition matrix. Besides,  $q_{ij} = P(S_t = S^j | S_{t-1} = S^j)$  is the conditional probability that  $S_t$  equals  $S^j$  when  $S_{t-1}$  equals  $S^i$ . The conditional probabilities are called transition probabilities and are assumed to be constant which satisfy the constraints  $q_{pp} + q_{rp} = 1$  and  $q_{pr} + q_{rr} = 1$ .

In this paper, we focus on the differences of firms' electricity consumption between period in this year and corresponding period in the last year which is the benchmark year. Here we assume that firms' productions show periodic patterns on an annual basis. Let  $y_t$  be the difference of 7-day smoothed electricity consumption data in period t and in the corresponding period. The specifications of the regression model for two economic conditions are as follows:

$$\begin{cases} y_t = \alpha_p t + \beta_p + \varepsilon_{p,t} & \text{if } S_t = S^p \\ y_t = \alpha_r t + \beta_r + \varepsilon_{r,t} & \text{if } S_t = S^r \end{cases}$$
(2)

where  $\alpha$  and  $\beta$  are coefficients, and subscripts p and r are economic condition indicator.  $\varepsilon_t$  is the i.i.d. normal distribution with mean zero and variance  $\sigma^2$ , which is conditional on the unobserved economic condition. Then the conditional density of  $y_t$  is:

$$f(y_t|S_t = S^i) = \frac{1}{\sqrt{2\pi}\sigma_i} exp\left\{\frac{-(y_t - \alpha_i t - \beta_i)^2}{2\sigma_i^2}\right\}$$
(3)

The unobserved economic condition  $\{S_t\}$  is presumed to be generated by some probability distribution and the unconditional probability that  $S_t$  equals to different economic condition is

denoted  $\mu$ . The unconditional probability  $\mu_p$  and  $\mu_r$  are as follows:

$$P(S_t = S^p) = \mu_p, P(S_t = S^r) = \mu_r \text{ and } \mu_p + \mu_r = 1$$
(4)

Combining formula (1) to (4), then the unconditional density of  $y_t$  is the weighted average of all possible values for different economic conditions:

$$f(y_t) = \frac{\mu_p}{\sqrt{2\pi}\sigma_p} exp\left\{\frac{-(y_t - \alpha_p t - \beta_p)^2}{2\sigma_p^2}\right\} + \frac{\mu_r}{\sqrt{2\pi}\sigma_r} exp\left\{\frac{-(y_t - \alpha_r t - \beta_r)^2}{2\sigma_r^2}\right\}$$
(5)

All parameters including  $\alpha$ ,  $\beta$ ,  $\sigma$ ,  $\mu$  can then be estimated by maximizing the following log likelihood function for all observed data by using Algorithm[44]:

$$L(\alpha,\beta,\sigma,\mu) = \sum_{t=1}^{T} logf(y_t)$$
(6)

Next step after fitting the HMM is to identify the attributes of two hidden states. For each firm, we need to determine which state stands for prosperous economic condition and which one stands for recessionary economic condition (see more details in Appendix A.1). According to previous analyses and model assumptions, when a firm operates normally then its  $y_t$  series should fluctuate around zero and be irrelevant to time trend t. This means  $\beta_p$  should be close to zero and  $\alpha_t$  should not be significantly different from zero. When a firm is experiencing negative shocks then its  $y_t$  series should have a dramatic drop at the beginning follows by a recovery process. This means  $\beta_r$  should be significantly less than zero and  $\alpha_r$  should have a positive value.

### 2.2 Economic Condition Uncertainty Index

The results of HMM provide us estimated probabilities of two unobserved economic conditions for each firm in very period. These estimated probabilities are then used to construct the ECU index. The ECU index is a weighted average probability of recessionary economic condition which takes firm's daily electricity consumption data as the weight. The formula to calculate the aggregate ECU index is as follows:

$$ECU_t = \left(\sum_{k=1}^N ele_k \times \tilde{\mu}_{k,r,t}\right) / \sum_{k=1}^N ele_k \tag{7}$$

where  $\tilde{\mu}_{k,r,t}$  is the estimated probability of recessionary condition of firm k in period t.  $ele_k$  is the electricity consumption of firm k in period t. The ECU index ranges between zero and one which is a dimensionless index that can be used to measure uncertainties of economic conditions. On the one hand, when firms' electricity consumptions deviate from their previous normal patterns, their probabilities of recessionary condition will increase. This will lead to the increase in ECU index. On the other hand, when firms operate in a similar pattern of the past, their probabilities of recessionary

condition will be kept at low levels. This will reduce the ECU index.

Furthermore, if samples are separated into different groups, then we can also define the ECU indexes at regional and sectoral level as follows:

$$ECU_{sector,t} = \left(\sum_{k=1}^{N_{sector}} ele_k \times \tilde{\mu}_{k,r,t}\right) / \sum_{k=1}^{N_{sector}} ele_k \tag{8}$$

$$ECU_{region,t} = \left(\sum_{k=1}^{N_{region}} ele_k \times \tilde{\mu}_{k,r,t}\right) / \sum_{k=1}^{N_{region}} ele_k \tag{9}$$

where subscript sector stands for different sectors and subscript region stands for different regions. The regional and sectoral ECU indexes can be interpreted similarly as the aggregate ECU index. They also range from zero to one, and higher index values means higher uncertainties in regional or sectoral economic conditions. Due to the dimensionless feature, ECU indexes can be used to make consistent comparisons among different regions or sectors.

## 3 Data

This paper uses daily electricity consumption data provided by State Grid Shanghai Electric Power Company of 18348 large firms in Shanghai from November 2018 to May 2020<sup>2</sup>. Firms are categorized into different sectors such as manufacturing, real estate, wholesale and retail, finance, hotel and catering, etc. according to the Industrial Classification for National Economic Activities[45]. Table 1 summarizes the ratios of different sectors in the sample and the average daily electricity consumption data for each sector.

Table 1: Summary of the sample data			
Sector	Ratio	Average daily electricity consumption (kWh)	
Primary sectors			
Agriculture, forestry, husbandry and fishery	0.34%	2008.40	
Secondary sectors			
Mining	0.09%	18439.20	
Manufacturing	42.47%	8382.90	
Electricity, heat, gas and water production and supply	1.13%	12466.27	

<sup>&</sup>lt;sup>2</sup> Daily electricity data are preprocessed by using 14-day mean average value to interpolate the missing data and outliers. Data is considered to be an outlier when its value exceeds twice the standard deviation beyond the mean value of a 15 days window period.

Construction	2.36%	4746.94
Tertiary sectors		
Wholesale and retail	8.69%	5223.96
Transportation, storage and postal services	4.13%	12611.17
Hotel and catering	2.31%	6045.01
Information transmission, software and information technology services	2.15%	10262.70
Finance	1.58%	8079.91
Real estate	16.68%	8020.08
Leasing and business services	4.04%	10424.84
Scientific research and technology	1.48%	9993.31
Water conservancy, environment and public facilities management	3.37%	2019.75
Residential services, repair and other services	0.35%	2311.36
Education	0.78%	8137.42
Health and social work	1.53%	10377.33
Culture, sports and entertainment	1.48%	3291.20
Public administration, social security and social organizations	2.37%	3964.79
Others	2.67%	4670.22

Shanghai is dominated by the secondary and tertiary. In 2019, the primary, secondary and tertiary sectors have accounted for 0.27%, 26.99% and 72.73% of Shanghai's GDP[46]. In our sample data, total number of firms in these three sectors accounted for 0.34%, 46.16% and 53.50% respectively. Among them, manufacturing alone accounted for 42.47%, followed by real estate, which accounted for 16.68%. From the regional perspective, Shanghai's 16 districts have quite different economic. As shown in Fig.1, central urban districts such as Hongkou, Changning, Putuo, Xuhui, Jingan, Yangpu and Huangpu have very high proportion of tertiary industry. For those suburban districts such as Baoshan, Qingpu, Fengxian, Minhang, Jinshan, Pudong, Songjiang, Jiading and Chongming, their proportions of secondary industry are nearly 50 percent or even higher.

Fig.1: Distribution of primary, secondary and tertiary sectors

The outbreak of COVID-19 started from January 2020 and immediately followed by large-scale lockdowns in China. Both lockdown period and recovery period are included in our data sample period. Since the pandemic has caused significant negative impacts to the whole world, thus we can take the outbreak of COVID-19 as a special exogenous shock to check whether the ECU indexes can capture the resultant uncertainties in Shanghai's economy. For Shanghai's local policies, in order to control the spread of the pandemic, Chinese government extended the length of Spring Festival holiday for three days, and firms reopened their businesses gradually since February 9<sup>3</sup>. The time of Spring Festival holiday regularly changes every year and this holiday has significant impacts on the whole economy. By considering these two issues, we choose the New Year's Eve in 2019 and 2020 as the base points (denoted day zero) and 95 consecutive days before and after the base points are chosen to conduct the HMM estimation. The final periods of the experimental samples included are: November 1, 2018 to May 10, 2019 (New Year's Eve: February 4, 2019) and October 20, 2019 to April 28, 2020 (New Year's Eve: January 24, 2020).

## **4 Results**

### 4.1 Economic Condition Uncertainty index of Shanghai

<sup>&</sup>lt;sup>3</sup> The original period for Spring Festival is from 24th to 30th January. It was extended to end on 2th February.

Fig.2 shows the aggregate ECU index of Shanghai from October 20, 2019 to April 28, 2020. In the fourth quarter of 2019, the overall economic condition of Shanghai was very stable, with ECU index maintained at around 43%, and the market did not fluctuate sharply. Since January 8, 2020, the uncertainty of Shanghai's economic condition began to decline gradually. During the Spring Festival holiday (gray shadow), aggregate ECU index reached the lowest level that was about 18% lower than previous average level.

According to the regular patterns in the previous year, firms will restart production after the Spring Festival holiday. However, due to the implementation of a variety of control policies for COVID-19, firms' electricity consumption did not follow the previous pattern to rise after the holiday. This led to the rapid rise of ECU in Shanghai after the Spring Festival holiday. Although firms were allowed to resume production from February 9 (gray dotted line), the whole society was still in fear of COVID-19. Most people are reluctant to go back to office immediately and preferred to work online, and most firms were also not well prepared to reopen their businesses. These uncertainties of the economic conditions are directly reflected in the aggregate ECU index that the index continues to rise and gradually decreases after nearly 10 days. The peak ECU index occurred on February 18 (yellow line) that was 27.31% higher than the average level in the fourth quarter in 2019.

In order to restore the overall economic condition as soon as possible, the government had released a series of economic incentive policies such as financial subsidies and support, tax reduction, consumer coupons, etc. It took around 20 days for the aggregate ECU index of Shanghai to drop from the peak to the average level before COVID-19. After the end of March, Shanghai's economy had

recovered to a more stable situation and the aggregate ECU index was about 14.6% lower than the average level in the fourth quarter in 2019.

## 4.2 Sectoral ECU indexes

Fig.3 shows the ECU indexes of three sectors which are primary sector, secondary sector and tertiary sector. The green solid line in the figure represents the aggregate sectoral ECU index and the light green solid lines are sub-sectoral ECU indexes. We can see from Fig.3 that before the Spring Festival holiday, ECU index of primary sector fluctuated greatly. The index occurred two small peaks caused by New Year's Day and weather conditions that reached 72.70% and 64.31%, respectively. In contrast, the aggregate ECU indexes of secondary and tertiary sector were more stable. Similar to the aggregate ECU index of Shanghai, two aggregate sectoral ECU indexes decreased by 15%-40% before the Spring Festival holiday (gray shadow) which represented the small uncertainties in economic conditions.

(a) Primary sectors

#### (c) Tertiary sectors

#### Fig.3: Sector-level ECUs in Shanghai

Although all three sectors' aggregate ECU indexes had similar trend that increased first and then decreased to their normal level, they still presented different patterns in the duration of affected period. Unlike secondary sector that uncertainties decreased quickly after reaching the peak level, tertiary sector had experienced a much longer period of being affected by the COVID-19. The reason is mainly three-fold. Firstly, most works in tertiary sector are more easily to be moved online, so electricity consumptions of firms in tertiary sector still kept in relatively low level during the recovery period. Secondly, places such as cinemas, shopping malls, music halls, stadiums, etc. are typically involve large-scale population flows, so lock-down regulations for businesses in these places were much stricter and lasted much longer. Thirdly, the long-lasting travel bans had greatly affected the tourism and related businesses. These businesses are mainly related to the tertiary sector. With the combination

of all aforementioned reasons, ECU indexes of tertiary sector kept at a high level for about 25 days, and the average level in this period was 26% higher than that in fourth quarter in 2019. After the Qingming holiday (April 5, 2020), ECU indexes of all three sectors gradually became stable and economic conditions gradually returned to the level before the outbreak of the COVID-19.

### 4.3 Regional ECU indexes

Fig.4 illustrates the three sectoral ECU indexes of all 16 districts in Shanghai. The overall trends of ECU indexes in these districts are similar to aggregate sectoral ECU indexes in Shanghai, but there still existed differences. There were mainly two features of the regional ECU indexes. Firstly, during the pandemic period, tertiary sectors' ECU indexes of several districts are higher than secondary sectors' ECU indexes of these districts. Take Jingan district as an example, its tertiary sector's ECU index had increased significantly, with 20.68% higher than that of the secondary sectors' ECU indexes. These results are quite similar to the results of sectoral aggregate ECU indexes. Shanghai government had imposed stricter restrictions on offline stores, hotels, restaurants and entertainment places during the COVID-19 period. Most tertiary sector services were forced to close down or must limit visitor flows. As a result, ECU indexes of tertiary sectors increased earlier than that of secondary sectors in most districts. This phenomenon in Hongkou district is most obvious. The peak value of its tertiary sector is ECU index appeared on February 7, 24 days ahead of the peak time of its secondary sector.

Considering that the restriction policies were equally implemented in all districts in Shanghai, so the different patterns of each district's ECU indexes are mainly caused by their economic structure. We find that for districts with higher industrial diversities and more complex economic structures, their ECU indexes would increase less during the COVID-19 period. For example, Minhang and Pudong have higher sector coverages as well as large numbers of big firms in the secondary sector. Their ECU indexes increased by smaller values under the impacts of COVID-19 than other districts. Moreover, sectoral ECU indexes in these districts were also more stable in normal periods which means they generally have more stable economic conditions. For districts with relatively simple or concentrated economic structures, such as Chongming, the economic conditions were more easily affected by exogenous shocks. Since large-scale farming is not the dominant economic businesses in Shanghai, there exist only very few numbers of large firms in the primary sector. For the same reason, primary sectors' ECU indexes in all districts presented very weird patterns.

Fig.4: ECU indexes of 16 districts in Shanghai

# **5** Conclusions and policy implications

# 5.1 Brief summary of the ECU index

There are many examples in both academic and practice field that people attempt to infer the economic conditions timely[35]. However, in the real world, economic conditions can be hardly observed and using absolute value of different variables to infer the economic conditions may lead to biases. Moreover, it is the uncertainty of economic condition, not the absolute level of certain economic condition index, plays the core role in decision-making process. In this paper, we propose a novel method to construct the ECU index that can be used to infer the economic condition uncertainties. This method uses the hidden Markov process to describe the changing pattern of different economic conditions, and focuses on the deviations of electricity consumptions that are used to describe the uncertainties. The ECU index is then constructed by calculating the weighted average of all individual firms' probabilities in recessionary economic conditions. The ECU index is a dimensionless index ranges between zero and one, this makes it to be comparable among sectors, regions and periods.

We use the daily electricity consumption data of nearly 20 thousand firms in Shanghai from 2018 to 2020 to construct the ECU indexes of Shanghai. Results show that all ECU indexes, no matter at sectoral level or regional level, successfully captured the negative impacts of COVID-19 on Shanghai's economic conditions. Besides, the ECU indexes also presented the heterogeneities in different districts as well as in different sectors. This reflects the facts that changes in uncertainties of economic conditions are mainly related to regional economic structures and targeted regulation policies faced by sectors. Districts with more complex economic structures typically suffered less during the COVID-19 period and had relatively stable and low uncertainties in economic conditions. From the sector perspective, tertiary sector faced strictest regulation policies and businesses in this sector are the easiest to move online, so ECU index of the tertiary sector typically rose higher and last longer (see Appendix A.2).

#### 5.2 Policy implications

The ECU index has been demonstrated to be capable in referring economic condition uncertainties. So, it can be seen as an eligible candidate to be used in decision-making procedure to understand the risks and conditions of the economy. Moreover, the ECU index proposed in this paper can be further extended in two ways to facilitate the decision-making procedures. Firstly, the method based on HMM estimation can be extended to include more than two hidden statuses. Then a set of indexes can be constructed to reflect those more complicated economic conditions. This extension will be quite useful when decision-making procedures are sensitive to true economic conditions. Secondly, the ECU index can not only be constructed by using electricity consumption data. All data that have high frequencies and present regular periodic patterns can be used to construct different ECU indexes. For example, custom data can be used to construct the ECU index to measure uncertainties in international trade, macro financial data can be used to construct the ECU index to measure uncertainties in financial market, etc. These extensions are not subject to a specific region or specific field, which provides huge potentials for future researches.

# **Appendix A**

### Appendix A.1 Illustration of a sample firm's estimation results

Fig.A1 shows the electricity consumption behavior characteristics of one firm in 191 days. Fig. A1(a) describes the differences of electricity consumptions between two periods before and after smoothing. It can be seen that differences fluctuated around zero before the Spring Festival holiday. Differences were significantly negative due to the lockdown policies within two months after the Spring Festival holiday. Fig.a1(b) shows the probabilities of recessionary condition (dark blue line) and prosperous condition (yellow line) estimated by HMM. Obviously, the model can accurately identify the abnormal production behavior during the lockdown period in 2020. During this period, the probabilities of recessionary condition were close to one, and the probabilities of prosperous condition were close to zero. These results are consistent to the trends shown in Fig.A1(a).

(a) Differences of electricity consumptions
 (b) Probabilities of two unobserved economic conditions
 Fig.A1: Electricity consumption data and estimated probabilities of a sample firm

### Appendix A.2 Major subsectors' ECU indexes in Shanghai

Fig.A2 shows ECU indexes (green curves) of nine major subsectors in Shanghai, including manufacturing, construction, wholesale and retail, hotel & catering, finance, real estate, scientific research & technology, transportation & storage & postal services, and education. The Spring Festival holiday (gray shadow) and reopen time (gray dotted line) are marked in each subfigure. Sample sizes and maximum ECU indexes for each subsector are shown in subfigures.
