

$$f_{max} \times A = \frac{\Delta}{2\pi \times 2T_{clk}} \quad (2)$$

$$\hat{t}_{OFF} = \frac{3 \times T_{clk}}{2} \quad (3)$$

$$P_{ADC}^{average} = P_{ADC}^{ON} \times \left(1 - \frac{N_{cross}}{t} \times \hat{t}_{OFF}\right) + P_{ADC}^{OFF} \times \left(\frac{N_{cross}}{t} \times \hat{t}_{OFF}\right) \quad (4)$$

The first intuition we can build from the expressions is the fact that the effectiveness of the technique for power reduction is better if the signal is more active, thus increasing the number of crossings per unit of time. To further guide the design choices for clock speed, some curves were build based on macro models of the converter and the control circuit. Figure 5 shows the optimal clock choice for a full-scale sine wave driving the input of the converter at given frequency. Note that, for a full-scale signal, the converter cannot correctly handle frequencies higher that what is bounded by the clock value. At that maximum frequency, the percentage of off time of the comparators converge to a value close to 45.5%, where small variations are expected given the random distribution of the crossing moment and the time of the simulation.

If the clock frequency is sized and then fixed by design, then one can expect a decrease of the percentage of off time of the comparators, thus an increase in average power consumption given a smaller sine wave frequency at the input, as shown in Figure 6. However, as small as the power reduction may be, the converter is always saving power for a clock frequency smaller than 201kHz. This is due to the fact that the power overhead created by turning on and off the comparators and propagating the REQ signal in the simulations is smaller than the energy saved during the 5μs off time of the given clock.

Finally, in Figure 7, one can see the bandwidth trade-off with respect to the chosen clock frequency. The top line is the limit set by the comparator input, the curves are then shaped by the Equation 2. Note the contrast with the brick-wall shaped bandwidth of Nyquist converters, here the bandwidth is hyperbolic shaped (trapezoidal in a logarithmic scale), thus bigger frequencies can be correctly converted if the amplitude of the input signal is correctly scaled. The power reduction gained from bandwidth trade-off is not straightforward since it is also dependent on the input signal. Table 1 presents a summary of the power performance of the proposed level crossing ADC under the power reduction technique.

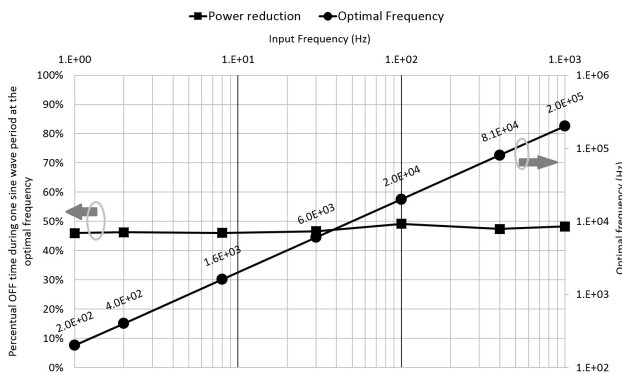

Fig. 5 Optimal clock frequency for the maximum off time for the comparator at given input signal.

Table 1: Summary of level crossing ADC simulation.

Parameter	Value
P_{ADC}^{ON}	2.6μW
P_{ADC}^{OFF}	0.2μW
$P_{ADC}^{average}$ at opt. clock frequency	1.5μW
Max. average power reduction (sine wave)	42%
Bandwidth (full scale input and 201kHz clock)	1kHz

Fig. 6 Decrease of off time for the comparators as input frequency decreases given reduction of the number of crossings at a fixed clock frequency.

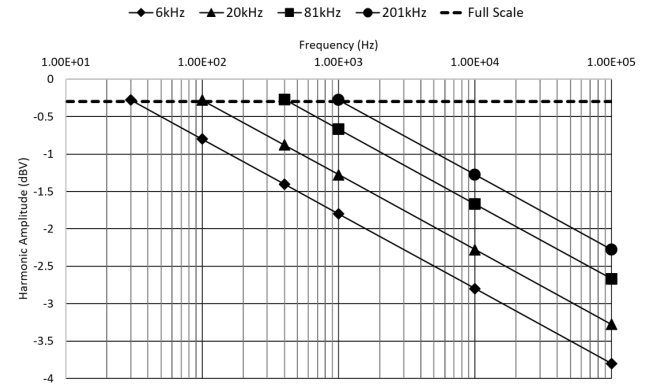

Fig. 7 Bandwidth boundary for the proposed level crossing ADC given different clock frequencies.

Conclusion: A modified architecture for level crossing ADC was presented and simulated. The comparator was designed to prevent glitches when powering up and a control circuit was built to define the time the comparators would be off after a level crossing. This enables the ADC to trade bandwidth with power savings by simply changing an input clock frequency. The free running ADC would consume an average power of 2.6μW and with the new input dependent power consumption it could achieve an average power consumption 42% smaller.
