Abstract

An oblivious subspace embedding (OSE), characterized by parameters $m, n, d, \epsilon, \delta$, is a random matrix $\Pi \in \mathbb{R}^{m \times n}$ such that for any d -dimensional subspace $T \subseteq \mathbb{R}^n$, $\Pr_{\Pi}[\forall x \in T, (1 - \epsilon)\|x\|_2 \leq \|\Pi x\|_2 \leq (1 + \epsilon)\|x\|_2] \geq 1 - \delta$. For ϵ and δ at most a small constant, we show that any OSE with one nonzero entry in each column must satisfy that $m = \Omega(d^2/(\epsilon^2\delta))$, establishing the optimality of the classical Count-Sketch matrix. When an OSE has $1/(9\epsilon)$ nonzero entries in each column, we show it must hold that $m = \Omega(\epsilon^{O(\delta)}d^2)$, improving on the previous $\Omega(\epsilon^2d^2)$ lower bound due to Nelson and Nguyễn (ICALP 2014).

1 Introduction

Subspace embedding is a fundamental technique in dimensionality reduction which has been successfully applied to a variety of tasks on large data sets, including clustering [BZMD15, CEM+15], correlation analysis [ABTZ14] and typical linear algebraic problems such as regression and low-rank approximation [CW17]. In general, the subspace embedding technique “compresses” a large-scale problem, which is computationally prohibitive, into a smaller one so that the result of the original problem can be obtained from the compressed version and the computation on the compressed version is affordable. A survey of subspace embedding techniques and their applications can be found in [Woo14].

More specifically, we define the notion of *oblivious subspace embedding* as follows.

Definition 1. An (n, d, ϵ, δ) -oblivious-subspace-embedding is a random matrix $\Pi \in \mathbb{R}^{m \times n}$ such that for any fixed d -dimensional subspace $T \subseteq \mathbb{R}^n$, it holds that

$$\Pr \{ \forall x \in T, (1 - \epsilon)\|x\|_2 \leq \|\Pi x\|_2 \leq (1 + \epsilon)\|x\|_2 \} \geq 1 - \delta. \quad (1)$$

When n and d are clear from the context, we abbreviate an (n, d, ϵ, δ) -oblivious-subspace-embedding to an (ϵ, δ) -oblivious-subspace-embedding. Very often, the subspace T is the column space of a matrix $A \in \mathbb{R}^{n \times d}$ and the subspace embedding property (1) thus becomes

$$\Pr \{ \forall x \in \mathbb{R}^d, (1 - \epsilon)\|Ax\|_2 \leq \|\Pi Ax\|_2 \leq (1 + \epsilon)\|Ax\|_2 \} \geq 1 - \delta. \quad (2)$$

A typical construction of Π is a random Gaussian matrix of i.i.d. $N(0, 1/m)$ entries with $m = \Theta((d + \log(1/\delta))/\epsilon^2)$. This target dimension m is known to be optimal up to a constant [NN14]. However, it is a dense matrix and computing ΠA could be computationally expensive. As a result, having a sparse matrix Π , which is commonly characterized by the maximum number of nonzero entries in each column, denoted by s , is highly desirable. OSNAP [NN13a, Coh16] and Count-Sketch [CW17] are two classical sparse constructions. In the OSNAP construction, $m = \Theta(d \log(d/\delta)/\epsilon^2)$ and Π has $s = \Theta(\log(d/\delta)/\epsilon)$ nonzeros per column, whose positions are chosen uniformly in each column and whose values are Rademacher variables; alternatively, $m = \Theta(d^{1+\gamma} \log(d/\delta)/\epsilon^2)$ and $s = \Theta(1/(\gamma\epsilon))$ for any constant $\gamma > 0$. The column sparsity allows for computing ΠA in $O(\text{nnz}(A) \cdot s)$ time, where $\text{nnz}(A)$ denotes the number of nonzero entries of A . The Count-Sketch construction is a special and extreme case of the OSNAP construction in which the column sparsity parameter $s = 1$. It has, however, $m = \Theta(d^2/(\delta\epsilon^2))$ rows, which is quadratic in d/ϵ . Despite this, the matrix Π is extremely sparse and computing ΠA takes only $O(\text{nnz}(A))$ time, making Count-Sketch indispensable in several fastest algorithms. A natural question is, therefore,

Is it possible to further reduce the target dimension m in the sparse constructions of Π ?

To answer the question, one can consider the lower bound for the target dimension m , that is, to show that an oblivious subspace embedding cannot exist if m is less than a certain threshold. So far only a few results have been known in this direction. Nelson and Nguyễn proved that for $s = 1$ and constant ϵ, δ , any (ϵ, δ) -oblivious-subspace-embedding must have $m = \Omega(d^2)$ [NN13b], showing the tightness of the quadratic dependence on d for Count-Sketch. When combined with the general (unconstrained column sparsity) lower bound of $m = \Omega(d/\epsilon^2)$, the best previously known lower bound for the case of $s = 1$ is $\Omega(d^2 + d/\epsilon^2)$, assuming that δ is a constant. This does not preclude a smaller dimension for Count-Sketch or, in general, extreme sparse constructions with $s = 1$. For larger s , the same authors showed that for δ a constant and $n = \Omega(d^2)$, any (ϵ, δ) -oblivious-subspace-embedding must have $m = \Omega(\epsilon^2 d^2)$ when $s \leq \alpha/\epsilon$ for some constant $\alpha > 0$ [NN14]. Recall the general $\Omega(d/\epsilon^2)$ bound without the sparsity constraint, the $\Omega(\epsilon^2 d^2)$ bound is stronger only when $d = \Omega(1/\epsilon^4)$. We also note that the sparsity constraint $s \leq \alpha/\epsilon$ is optimal up to a constant factor for the quadratic dependence on d due to the aforementioned OSNAP construction, where $s = \Theta(1/(\gamma\epsilon))$ and $m = \Theta(d^{1+\gamma}(\log d)/\epsilon^2)$.

Our contributions. We obtain the following improvements on the lower bounds on m for any (ϵ, δ) -oblivious-subspace-embedding.

- (i) When $s = 1$, we show a lower bound of $m = \Omega(d^2/(\epsilon^2\delta))$ for $n = \Omega(d^2/(\epsilon^2\delta))$, which implies that the target dimension of Count-Sketch is tight up to a constant factor.
- (ii) When $s \leq 1/(9\epsilon)$, we show a lower bound of $m = \Omega(\epsilon^{\Theta(\delta)}d^2)$ for $d = \Omega(1/\epsilon^2)$, $n = \Omega(d^2/\epsilon^2)$ and constant δ . This is almost a quadratic improvement on dependence on ϵ compared with the previous lower bound of $\Omega(\epsilon^2 d^2)$. Our result also reduces the effective constraint $d = \Omega(1/\epsilon^4)$ to $d = \Omega(1/\epsilon^{2+O(\delta)})$, again almost a quadratic improvement. Furthermore, we obtain a trade-off between m and s , namely $m = \Omega((\log s)^{-\Theta(1)}s^{-\Theta(\delta)}d^2)$, when $s \leq 1/(9\epsilon)$.

1.1 Our Techniques

We give a brief overview of the techniques for our new lower bounds, assuming that δ is a small constant. First of all, to show a lower bound of $m \geq M(d, \epsilon, \delta)$ for an (ϵ, δ) -oblivious-subspace-embedding, it suffices, by Yao’s minimax principle, to construct a distribution \mathcal{D} over $n \times d$ matrices (called the hard instance) and show that if a deterministic matrix $\Pi \in \mathbb{R}^{m \times n}$ is an (ϵ, δ) -subspace-embedding for $A \sim \mathcal{D}$, i.e., if (2) holds for probability taken over $A \sim \mathcal{D}$, then Π must have at least $M(d, \epsilon, \delta)$ rows. Without loss of generality, we may assume that \mathcal{D} is supported on isometries. Here, an isometry $U \in \mathbb{R}^{n \times d}$ has orthonormal columns.

1.1.1 Tight lower bound for $s = 1$

We first review an easy proof of the $m = \Omega(d^2)$ lower bound for $s = 1$. Intuitively, if Π is a subspace embedding for a deterministic isometry U , there cannot be a row l and two columns i, j of ΠU such that $|(\Pi U)_{l,i}|$ and $|(\Pi U)_{l,j}|$ are both large, because the “collision” would make the norm $\|\Pi U u\|_2$ not concentrate around 1 for some unit vector $u \in \mathbb{R}^d$. For example, consider the simple case of $s = 1$, $V = (I_d \ 0)^T$ and $U = S \cdot V$, where $S \in \mathbb{R}^{n \times n}$ is a diagonal matrix of i.i.d. Rademacher variables on its diagonal line, and suppose that $|(\Pi U)_{l,i}|, |(\Pi U)_{l,j}| \in [1 - \epsilon, 1 + \epsilon]$. Then for $u \triangleq (e_i + e_j)/\sqrt{2}$ we have $\|\Pi U u\|_2^2 \geq 2(1 - \epsilon)^2$ with probability 1/2 and $\|\Pi U u\|_2^2 \leq 2\epsilon^2$ with 1/2. Observe that $2(1 - \epsilon)^2$ and $2\epsilon^2$ are $2 - 4\epsilon$ apart from each other, which contradicts the fact that $\|\Pi U u\|_2^2$ falls in $[(1 - \epsilon)^2, (1 + \epsilon)^2]$, an interval of length $4\epsilon < 2 - 4\epsilon$.¹ Based on this observation, in the case of $s = 1$, one can choose the hard instance U to be $U = SV$, where S is as before but V is the induced distribution by randomly permuting the rows of $(I_d \ 0)^T$. Since ΠU behaves like hashing d coordinates into m buckets and the subspace embedding property implies that there should be no collision with a large probability, the lower bound of $m = \Omega(d^2)$ follows easily from the birthday paradox.

To obtain a better lower bound for $s = 1$, the hard instance U has to capture more than d dimensions in its rows. Hence, we replicate the identity matrix $1/(8\epsilon)$ times and normalize it, that is, let V be a row-permuted version of $(I_d \ I_d \ \cdots \ I_d \ 0)^T$ and $U = \sqrt{8\epsilon}SV$, so that every column of U has

¹In the case of $s = 1$, Nelson and Nguyễn proved $m = \Omega(d^2)$ by observing that the rank of ΠU would be less than d if a “collision” exists [NN13b]. Their argument seems difficult to apply to more complicated hard instances, while our type of contradiction is more amenable and plays a central role in proving higher lower bounds in our work.

exactly $1/(8\epsilon)$ nonzero entries, each being $\pm\sqrt{8\epsilon}$. Similarly to before, we seek to prove that no collisions should exist. Here, a collision means that Π has large values at some row $l \in [m]$ and some columns $i', j' \in [n]$ and, simultaneously, $U_{i',i}, U_{i',j} \neq 0$.² If there ever exists a “collision”, we would like to argue that we can find a unit vector u and a real number o such that $\|\Pi U u\|_2^2 > o + 2\epsilon$ with probability at least $1/4$ and $\|\Pi U u\|_2^2 < o - 2\epsilon$ with probability at least $1/4$ (over the randomness of S), and thus reach a contradiction. We still set $u \triangleq (e_i + e_j)/\sqrt{2}$. However, an important difference from before, thus the main difficulty, is that $\Pi U u$ now may have nonzero coordinates other than the l -th coordinate since U has more than one nonzero entry in each column, and so $\|\Pi U u\|_2^2$ cannot be easily controlled by observing the l -th coordinate with an easy bound or a concentration bound for the other coordinates. Even the l -th coordinate $(\Pi U u)_l$ itself may contain a hard-to-control contribution from columns other than columns i', j' in Π since there may exist $k' \neq i', j'$ such that $\Pi_{l,k'} U_{k',i} \neq 0$. Our key observation is the following. Conditioning on that $\Pi_{l,i'}, \Pi_{l,j'}, U_{i',i}, U_{j',j} \neq 0$, for any fixing of the random variables other than $S_{i',i'}, S_{j',j'}$, we can find a real number o such that $\|\Pi U u\|_2^2 > o + 2\epsilon$ with probability $1/4$ and $\|\Pi U u\|_2^2 < o - 2\epsilon$ with probability $1/4$. This suffices to derive a contradiction. Hence, all $d/(8\epsilon)$ nonzero entries of U must be isolated under the hashing matrix Π and the lower bound $m = \Omega(d^2/\epsilon^2)$ follows again from the birthday paradox.

1.1.2 New lower bound for $s \leq 1/(9\epsilon)$

Generalizing hard distribution. We generalize the hard instance U above with parameter β . Let \mathcal{D}_β be the distribution of random matrices U containing $1/\beta$ copies of I_d , normalized by $\sqrt{\beta}$ and multiplied by independent Rademacher variables, that is, V is a row-permuted version of $(I_d \ I_d \ \cdots \ I_d \ 0)^T$ and $U \triangleq \sqrt{\beta} S V$. A formal definition can be found in Definition 2.³ We observe that OSNAP with column sparsity $s \leq 1/(8\epsilon)$ requires $m = \Omega(d^2/\epsilon^2)$ rows for $U \sim \mathcal{D}_{8\epsilon s}$. This suggests the following conjecture: if Π has many entries of large absolute value, then \mathcal{D}_1 is a hard distribution. Therefore, we start by proving a lower bound for the hard instance $U \sim \mathcal{D}_1$ under an “abundance assumption” that Π has $\Omega(n/\epsilon)$ entries of absolute value $\Omega(\sqrt{\epsilon})$, and remove the assumption later at the cost of losing an $\epsilon^{O(\delta)}$ factor in the lower bound.

Generalizing the collision. To handle the case $s > 1$, we generalize the notion of collision of large entries. Instead of looking for two large entries in the same row, we look for two columns with a large inner product in absolute value. Assuming the large inner product, we can show, using an argument analogous to the case $s = 1$, a contradiction to the assumption that $\|\Pi U u\|_2^2$ is contained in an interval of length 4ϵ for some unit vector u (See Lemma 4 for a precise statement). Therefore, it suffices to show that, if m is small, with constant probability, there exist two columns of Π chosen by U whose inner product is at least 5ϵ in absolute value. Observe that the collision of two entries of absolute value at least $\sqrt{8\epsilon}$ contributes at least 8ϵ to the inner product. Thus, it suffices to prove that the inner product among the remaining entries does not cancel the 8ϵ by more than 3ϵ . To this end, we adopt an idea from Nelson and Nguyễn [NN14] and show that the inner product between two columns, after removing the two large colliding entries, is close to zero with good probability. Now, if we assume that $m = O(d^2)$, Π has sufficiently many entries of absolute value $\Omega(\sqrt{\epsilon})$ and $U \sim \mathcal{D}_1$, there will be many collisions of large entries with constant probability. For each such collision, as previously argued, with good probability, the inner product of the corresponding columns has absolute value at least 5ϵ . Therefore, with constant probability, we can find a pair of columns of Π chosen by U such that their inner product has absolute value at least 5ϵ , assuming that m is small and Π has many entries of large absolute values.

Finding colliding column pairs. The central work to prove the lower bound for $s = O(1/\epsilon)$, under the “abundance assumption”, lies in finding and analyzing the distributions of the random column pairs (i, j) of Π given the existence of a row l such that $|\Pi_{l,i}|, |\Pi_{l,j}|$ are both large. In fact, using Nelson and Nguyễn’s idea to obtain a stronger lower bound is highly non-trivial. (One can refer to Lemma 3 for the formal statement of a proposition akin to their idea.) This idea works only when columns i, j are drawn from the same set uniformly without replacement. However, this may indeed not be satisfied by a random colliding column pair. For instance, suppose that $\Pi_{l_1,i} = \Pi_{l_1,j} = \Pi_{l_2,j} = \Pi_{l_2,k} = \sqrt{8\epsilon}$ and the remaining entries are zero, then $(i, j), (j, k)$ are colliding pairs but (i, k) is not.

²Throughout this paper, we let $[n] \triangleq \{1, \dots, n\}$.

³The distribution of U in Definition 2 is not strictly supported on isometries but is an isometry with an overwhelming probability, which suffices for our purpose.

A simple workaround is to limit the collisions between a column i and other columns to some fixed row $l(i)$. Let $l(i)$ be such that $\Pi_{l(i),i}$ has the largest absolute value among the m entries in column i and consider only the collisions between column i and columns j where $l(j) = l(i)$. Under this restriction, the columns are partitioned into disjoint groups based on $l(i)$'s, and the distribution of colliding column pair can be viewed as sampling a group followed by sampling uniformly at random two columns i, j in the group. A critical drawback of this solution is that we can merely find $\approx \sqrt{d^2/m}$ colliding column pairs, and each pair yields large inner product with probability $\approx \epsilon$, so Nelson and Nguyễn obtained a lower bound of $m = \Omega(\epsilon^2 d^2)$ only.

To obtain a higher lower bound, we shall balance (i) the number of colliding column pairs we examine and (ii) the probability of each pair having a large inner product in absolute value, so that we can maximize the probability that we find a pair of columns whose inner product is large in absolute value. To maximize (i), we adopt the following greedy strategy. Recall that the matrix U in the definition of \mathcal{D}_1 has d nonzero rows at random positions and let $C_1, \dots, C_d \in [n]$ be the indices of these rows. Initialize $S \triangleq [d]$. We iterate over $i \in [d]$. If $i \in S$, we find $j \in S \setminus \{i\}$ such that the columns C_i and C_j collide, output a pair (C_i, C_j) and remove i, j from S . Indeed, this greedy strategy would result in a large number of colliding pairs, but the problem is how to show (ii) is large. A challenge is that the distribution of the column pairs found by the greedy strategy is rather involved. To see this, let ϕ_c denote the conditional probability of a random C_j collides with C_i given that $C_i = c$, then the marginal distribution of C_i of a random colliding pair (C_i, C_j) has probability mass function $p(c) = \phi_c / \sum_c \phi_c$. The greedy strategy, on the other hand, induces a marginal probability $q(c) = \psi_c / \sum_c \psi_c$ for C_1 , conditioned on that C_1 collides with C_j for some $j > 1$, where $\psi_c \triangleq 1 - (1 - \phi_c)^{d-1}$ is the probability that there exists $j > 1$ such that C_j collides with $C_1 = c$. Thus, the colliding pair found by the greedy strategy has a different distribution from the true distribution \mathcal{D}' of a colliding pair (C_1, C_j) . To overcome this challenge, we observe that (i) if $\phi_c = \Omega(1/d)$ for some c , there will exist a row l such that $|\Pi_{l,i}|$ is large for $\Omega(1/(sd))$ -fraction of columns $i \in [n]$ and we can then apply Nelson and Nguyễn's idea on row l ; (ii) if $\phi_c = O(1/d)$ for all c , then $\psi_c = \Theta(d \cdot \phi_c)$ and $q(c) = \Theta(p(c))$ for all c , hence the distribution of a colliding column pair found by the greedy strategy is close to the true distribution \mathcal{D}' . Assuming that $\phi_c = O(1/d)$ for all c , it is sufficient to analyze \mathcal{D}' , which is another technical innovation of this work. Below we assume that it always holds $\phi_c = O(1/d)$ for all c and analyze the pairs found in this case.

Analyzing random colliding column pairs. Recall that Nelson and Nguyễn's idea works only when columns i, j are drawn from the same set uniformly without replacement, and \mathcal{D}' may not be such a distribution. Our idea is to examine a distribution \mathcal{D}'' which is close to \mathcal{D}' and is a linear combination of distributions that sample column pairs without replacement. Specifically, we assign to each colliding column pair (i, j) a weight which is equal to the number of rows l such that $\Pi_{l,i}, \Pi_{l,j}$ are both large in absolute value, and let $\mathcal{D}''(i, j)$ be proportional to the weight of (i, j) . Under this construction, \mathcal{D}'' can be viewed as sampling a row l from some distribution, followed by sampling two columns i, j uniformly without replacement from the set of large entries in row l . Note that for any (i, j) , it holds that $\mathcal{D}'(i, j) = \Omega(\epsilon \cdot \mathcal{D}''(i, j))$, since the column sparsity $s = O(1/\epsilon)$. Invoking Nelson and Nguyễn's idea, we can show that a colliding column pair $(i, j) \sim \mathcal{D}''$ has a large inner product with probability $\Omega(\epsilon)$. Consequently, a column pair $(i, j) \sim \mathcal{D}'$ has a large inner product with probability $\Omega(\epsilon^2)$. Since an average colliding column pair can collide in $\Omega(1/\epsilon)$ rows, we have to set $m = O(\epsilon d^2)$ to ensure $\Omega(1/\epsilon^2)$ colliding column pairs, and thus obtain a lower bound of $m = \Omega(\epsilon d^2)$ only.

Our final solution is to further consider a quantity Δ of Π , which is the expected number of rows l such that $|\Pi_{l,i}|, |\Pi_{l,j}|$ are simultaneously large for $(i, j) \sim \mathcal{D}'$. We take Δ along with \mathcal{D}'' as a pivot for our proof. We show that we can find $\Omega(d^2/(\epsilon^2 m \Delta))$ colliding column pairs with high probability and, informally, that a random pair of colliding columns $(i, j) \sim \mathcal{D}'$ has a large inner product with probability $\Omega(\epsilon^2 \Delta)$. Therefore, if $m \leq d^2$, we find a column pair with a large inner product with constant probability, leading to the lower bound $m = \Omega(d^2)$.

Removing the assumption. The key argument for removing the “abundance assumption” is the following claim. If m is small, then for every $\ell \in \{0, 1, \dots, L\}$ ($L \triangleq \log(1/\epsilon) - 3$), the matrix Π cannot have too many entries of absolute value at least $\sqrt{2}^\ell$. This claim would imply that the ℓ_2 -norm of an average column of Π is less than $1 - \epsilon$ and thus Π cannot be a subspace embedding for $U \sim \mathcal{D}_1$.

To prove the claim, we propose a new hard distribution: with probability $1/2$, it is \mathcal{D}_1 ; with probability $1/2$, it is $\mathcal{D}_{2^{-\ell'}}$ for ℓ' uniformly chosen from $\{0, 1, \dots, L\}$. By the law of total probability, Π must be a subspace embedding for $U \sim \mathcal{D}_1$ and also a subspace embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$ for $(1 - O(\delta))$ -fraction of $\ell' \in \{0, \dots, L\}$. Hence, for each $\ell \in \{0, \dots, L\}$, there exists an ℓ' among the $(1 - O(\delta))$ -fraction such

that Π is a subspace embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$ and $\ell + \ell' \approx L$ up to an additive error of $O(\delta L)$, matching our conjecture that $U \sim \mathcal{D}_{2^{-L+\ell}}$ is hard for the subspace embedding Π with column sparsity $s = 2^\ell$. We can then follow the proof of the lower bound with the ‘‘abundance assumption’’ to show that Π cannot have $\approx \epsilon^{O(\delta)} 2^\ell n$ entries of absolute value at least $\sqrt{2^\ell}$, where the additional $\epsilon^{O(\delta)}$ factor is incurred by the aforementioned additive error $O(\delta L)$. Thus, the average squared ℓ_2 -norm of column vectors of Π is $\epsilon^{O(\delta)} \log(1/\epsilon) < (1-\epsilon)^2$ for small enough ϵ , contradicting the assumption that Π is a subspace embedding for $U \sim \mathcal{D}_1$.

2 Preliminaries

For $x, y \in \mathbb{R}$ and $\theta > 0$, we write $x = y \pm \theta$ if $x \in [y - \theta, y + \theta]$. For a matrix A , we denote its i -th column vector by $A_{*,i}$. For a finite set S , we denote by $\text{Unif}(S)$ the uniform distribution on S . For a random variable X and a probability distribution \mathcal{D} , we write $X \sim \mathcal{D}$ to denote that X follows \mathcal{D} .

When d and ϵ are clear from the context, we abbreviate the event in the probability of (2) to ‘‘ Π is a subspace embedding for A ’’.

The following distribution \mathcal{D}_β on $n \times d$ matrices, parameterized by β , is fundamental in the hard instances for the lower bounds.

Definition 2 (Distribution \mathcal{D}_β). *The distribution \mathcal{D}_β ($0 < \beta \leq 1$) is defined on matrices $U \in \mathbb{R}^{n \times d}$ as follows. The matrix U is decomposed as $U = VW$, where $V \in \mathbb{R}^{n \times d/\beta}$ and $W \in \mathbb{R}^{d/\beta \times d}$. The matrix V has i.i.d. columns, each $V_{*,i}$ ($i = 1, \dots, d/\beta$) is uniformly distributed among the n canonical basis vectors in \mathbb{R}^n . The matrix W is distributed as follows: For each $i = 1, \dots, d$, set $W_{j,i} \triangleq \sigma_j \sqrt{\beta}$ for $j = (i-1)/\beta + 1, \dots, i/\beta$, where $\sigma_j \in \{-1, 1\}$ are independent Rademacher variables; set the remaining entries of W to zero.*

Let \mathcal{B} denote the event that V has two identical columns. Since $U = VW$ may not be an isometry when \mathcal{B} happens, we shall only consider the subspace embedding property of Π for U conditioned on $\bar{\mathcal{B}}$. Note that when $n \geq Kd^2/(\beta^2\delta)$, it holds that $\Pr[\mathcal{B}] \leq \delta/(2K)$, which can be made an arbitrarily small fraction of δ by setting K large enough. We shall thus assume K is large enough and ignore the event \mathcal{B} hereafter and pretend that V has independent columns and the full column rank.

Our strategy is to show that there are two columns i, j of ΠV such that their inner product $\langle (\Pi V)_{*,i}, (\Pi V)_{*,j} \rangle$ deviates from zero and that the large deviation implies that Π cannot be a subspace embedding for U . We shall need the following lemmata.

The first lemma, inspired by Lemmata 8 and 9 in [NN14], shows that in a finite collection of vectors of length at most 1 there always exists a small fraction of vector pairs whose inner product is not too small. We shall use this lemma to look for an inner product away from zero.

Lemma 3. *Let $\epsilon \in (0, 1/9)$ and $\kappa = 3$. Suppose that S is a finite subset of the unit ℓ_2 -ball and u, v are independent samples from $\text{Unif}(S)$. Then $\langle u, v \rangle \geq -\kappa\epsilon$ with probability at least 2ϵ .*

Proof. Note that

$$0 \leq \left\| \sum_{u \in S} u \right\|_2^2 = \sum_{u, v \in S} \langle u, v \rangle.$$

Thus

$$\mathbb{E}_{u, v} [\langle u, v \rangle] \geq 0.$$

Since $\|u\|_2 \leq 1$ for all $u \in S$, it holds that $\langle u, v \rangle \leq 1$. If $\Pr[\langle u, v \rangle \geq -\kappa\epsilon] \leq 2\epsilon$ for some $\kappa > 0$, then

$$0 \leq \mathbb{E}_{u, v} [\langle u, v \rangle] \leq 2\epsilon + (1 - 2\epsilon)(-\kappa\epsilon)$$

which is true only if $\kappa < 2/(1 - 2\epsilon)$. That is, when $\kappa = 3$ and $\epsilon \in (0, 1/9)$, the inequality above will not hold and therefore $\Pr[\langle u, v \rangle \geq -\kappa\epsilon] > 2\epsilon$. \square

The next lemma states that, if two columns of ΠV have a large inner product, then this large deviation implies the anti-concentration of $\|\Pi U v\|_2^2$ for some v , which refutes the existence of a good Π .

Lemma 4. *Suppose that $|\langle A_{*,p}, A_{*,q} \rangle| \geq \lambda\epsilon/\beta$ for some distinct columns p, q of a matrix $A \in \mathbb{R}^{m \times d/\beta}$, where $\lambda > 2$. Then there exists a unit vector $u \in \mathbb{R}^d$ such that with probability at least $1/4$ (over W)*

$$\|AWu\|_2^2 \notin [(1-\epsilon)^2, (1+\epsilon)^2].$$

Proof. Let p', q' be the columns of W such that $W_{p,p'} \neq 0$ and $W_{q,q'} \neq 0$. First we assume that $p' \neq q'$. Let $u \triangleq (e_{p'} + e_{q'})/\sqrt{2}$, $S \triangleq \{i \in [d/\beta] : W_{i,p'} \neq 0 \text{ or } W_{i,q'} \neq 0\}$ and $\nu \triangleq \sum_{i \in S \setminus \{p,q\}} \sigma_i A_{*,i}$. Then

$$\|AW(e_{p'} + e_{q'})\|_2^2 / \beta = \|\sigma_p A_{*,p} + \sigma_q A_{*,q} + \nu\|_2^2 = \|A_{*,p}\|_2^2 + \|A_{*,q}\|_2^2 + \|\nu\|_2^2 + 2(X + Y + Z), \quad (3)$$

where

$$X \triangleq \sigma_p \sigma_q \langle A_{*,p}, A_{*,q} \rangle, \quad Y \triangleq \sigma_p \langle A_{*,p}, \nu \rangle, \quad Z \triangleq \sigma_q \langle A_{*,q}, \nu \rangle.$$

The assumption states that $|X| \geq \lambda\epsilon/\beta$ and thus $\max\{|X|, |Y|, |Z|\} \geq \lambda\epsilon/\beta$. We arbitrarily fix σ_i 's for all $i \in S \setminus \{p, q\}$ and then apply the following fact.

Fact 5. *Suppose that $x_1, x_2, x_3 \in \mathbb{R}$ satisfy $|x_1| \geq |x_2| \geq |x_3|$ and $|x_1| \geq a$. Let σ_1, σ_2 be independent Rademacher variables. Then $\Pr[\sigma_1 x_1 + \sigma_2 x_2 + \sigma_1 \sigma_2 x_3 \geq a] \geq 1/4$ and $\Pr[\sigma_1 x_1 + \sigma_2 x_2 + \sigma_1 \sigma_2 x_3 \leq -a] \geq 1/4$.*

Note that $O \triangleq \|A_{*,p}\|_2^2 + \|A_{*,q}\|_2^2 + \|\nu\|_2^2$ is constant conditioned on $\{\sigma_i\}_{i \in S \setminus \{p,q\}}$. We conclude that

$$\Pr \left[\|AWu\|_2^2 \geq \frac{O\beta}{2} + \lambda\epsilon \mid \{\sigma_i\}_{i \in S \setminus \{p,q\}} \right] \geq \frac{1}{4} \quad \text{and} \quad \Pr \left[\|AWu\|_2^2 \leq \frac{O\beta}{2} - \lambda\epsilon \mid \{\sigma_i\}_{i \in S \setminus \{p,q\}} \right] \geq \frac{1}{4}. \quad (4)$$

Observe that $[(1 - \epsilon)^2, (1 + \epsilon)^2]$ is an interval of length $4\epsilon < 2\lambda\epsilon$, it follows that

$$\Pr \left\{ \|AWu\|_2^2 \notin [(1 - \epsilon)^2, (1 + \epsilon)^2] \mid \{\sigma_i\}_{i \in S \setminus \{p,q\}} \right\} \geq 1/4.$$

The claimed result then follows from the law of total probability. This completes the proof for the case $p' \neq q'$.

Next we consider the case $p' = q'$. Let $u \triangleq e_{p'}$ and $S \triangleq \{i \in [d/\beta] : W_{i,p'} \neq 0\}$. Then the preceding argument goes through almost identically as $\|AWe_{p'}\|_2^2 / \beta$ has exactly the same expansion as in (3). Instead of (4) we shall have

$$\Pr \left[\|AWu\|_2^2 \geq O\beta + 2\lambda\epsilon \mid \{\sigma_i\}_{i \in S \setminus \{p,q\}} \right] \geq \frac{1}{4} \quad \text{and} \quad \Pr \left[\|AWu\|_2^2 \leq O\beta - 2\lambda\epsilon \mid \{\sigma_i\}_{i \in S \setminus \{p,q\}} \right] \geq \frac{1}{4}. \quad \square$$

3 Lower Bound for $s = 1$

Our hard instance \mathcal{D} is \mathcal{D}_1 with probability $1/2$ and $\mathcal{D}_{8\epsilon}$ with probability $1/2$, where \mathcal{D}_β is defined in Definition 2.

Lemma 6. *If $\Pi \in \mathbb{R}^{m \times n}$ is an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}$ with column sparsity $s = 1$, then $(1 - 2\delta/d)$ -fraction of the column vectors of Π has ℓ_2 -norm of $1 \pm \epsilon$, i.e. $(1 - 2\delta/d)$ -fraction of the nonzero entries of Π have absolute value $1 \pm \epsilon$.*

Proof. By the law of total probability,

$$\begin{aligned} 1 - \delta &\leq \Pr[\Pi \text{ is a subspace embedding for } U] \\ &= \frac{1}{2} \Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_1] + \frac{1}{2} \Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}]. \end{aligned}$$

Thus we have $\Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_1] \geq 1 - 2\delta$.

Suppose that σ fraction of the nonzero entries of Π have the absolute value outside $[1 - \epsilon, 1 + \epsilon]$, then we have $\Pr[\|\Pi U e_i\|_2 \in [1 - \epsilon, 1 + \epsilon] \mid U \sim \mathcal{D}_1] = 1 - \sigma$ for each $i \in [d]$. Hence,

$$\Pr[\forall i \in [d], \|\Pi U e_i\|_2 \in [1 - \epsilon, 1 + \epsilon] \mid U \sim \mathcal{D}_1] = (1 - \sigma)^d,$$

and consequently, it must hold that $\sigma \leq 1 - (1 - 2\delta)^{1/d} \leq 2\delta/d$. \square

For each $i \in [m]$, let B_i denote the number of distinct $j \in [n]$ such that $|\Pi_{i,j}| \in [1 - \epsilon, 1 + \epsilon]$ and $\Pi_{i,j} V_{j,l} \neq 0$ for some $l \in [d]$. Since Π can be viewed as a hashing matrix of hashing n items into m buckets, B_i can be viewed as the number of distinct dimensions which are hashed into the i -th bucket with small distortion (multiplied by $1 \pm \epsilon$ or $-(1 \pm \epsilon)$).

Lemma 7. *Let $\epsilon \in (0, 1/8)$, $\delta \in (0, 1/4)$ and $n \geq Kd^2/(\epsilon^2\delta)$ for some absolute constant $K > 0$ large enough. If $\Pi \in \mathbb{R}^{m \times n}$ is an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}$ with column sparsity $s = 1$, then conditioned on $U \sim \mathcal{D}_{8\epsilon}$, with probability at most $2\delta/(1 - 4\delta)$, there exists an i such that $B_i > 1$.*

Proof. A similar argument to the beginning of the proof of Lemma 6 yields that

$$\Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}] \geq 1 - 2\delta.$$

We define an event \mathcal{E} to be that $B_i > 1$ for some $i \in [m]$. Let $\sigma \triangleq \Pr[\overline{\mathcal{E}} | U \sim \mathcal{D}_{8\epsilon}]$. Again by the law of total probability,

$$\begin{aligned} 1 - 2\delta &\leq \Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}] \\ &= \Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}, \overline{\mathcal{E}}] \cdot \sigma \\ &\quad + \Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}, \mathcal{E}] \cdot (1 - \sigma). \end{aligned}$$

It follows that

$$\Pr[\Pi \text{ is a subspace embedding for } U | U \sim \mathcal{D}_{8\epsilon}, \mathcal{E}] \geq \frac{1 - 2\delta - \sigma}{1 - \sigma} =: 1 - \sigma'.$$

It suffices to show that Π cannot be a subspace embedding for $U \sim \mathcal{D}_{8\epsilon}$, conditioning on \mathcal{E} and an arbitrarily fixed V , with large probability. When \mathcal{E} happens, there exist $i \neq j$ such that $|\langle (\Pi V)_{*,i}, (\Pi V)_{*,j} \rangle| \geq (1 - \epsilon)^2 > 3/4$. Invoking Lemma 4, we conclude that Π is not a subspace embedding for U with probability at least $(1 - \sigma')/4$.

Thus we have $(1 - \sigma')/4 \leq \delta$, which implies that $1 - \sigma \leq 2\delta/(1 - 4\delta)$. \square

Theorem 8. *Let $\epsilon \in (0, 1/8)$, $\delta \in (0, 1/8)$, and $n \geq Kd^2/(\epsilon^2\delta)$ for some absolute constant $K > 0$ large enough. If $\Pi \in \mathbb{R}^{m \times n}$ is an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}$ with column sparsity $s = 1$, then $m = \Omega(d^2/(\epsilon^2\delta))$.*

Proof. It follows from Lemma 6, together with linearity of expectation and Markov's inequality, that when conditioned on $U \sim \mathcal{D}_{8\epsilon}$, with probability at least $1 - 4\delta/d$, there are $d/(16\epsilon)$ entries of U which are multiplied by $1 \pm \epsilon$ or $-(1 \pm \epsilon)$ in ΠU . By Lemma 7 and a union bound, with probability at least $1 - 2\delta/(1 - 4\delta) - 4\delta/d \geq 1 - 8\delta$, for any two distinct columns i, j among the $d/(16\epsilon)$ columns of V , there does not exist $k \in [m]$ such that $(\Pi V)_{k,i} \neq 0$ and $(\Pi V)_{k,j} \neq 0$. The folklore lower bound for the birthday paradox immediately implies that the matrix Π must have $\Omega(d^2/(\epsilon^2\delta))$ rows. \square

4 Lower Bound for $s = 1/(9\epsilon)$ with Abundance Assumption

In this section we shall show an $\Omega(d^2)$ lower bound for all Π with column sparsity $1/(9\epsilon)$ and an additional ‘‘abundance assumption’’ that Π has many large entries in most columns (formalized as Assumption (ii) in Theorem 9). We shall remove this assumption in the next section and obtain an $\Omega(\epsilon^{O(\delta)}d^2)$ lower bound.

For these lower bounds, we use the same distribution \mathcal{D}_β in Definition 2 and consider a constant δ . As explained after Definition 2, we pretend that V has independent columns and the full column rank by assuming $n \geq Kd^2/(\beta^2\delta)$ for some K large enough.

We say that a matrix entry is θ -heavy if its absolute value is at least θ . We define the *average number of θ -heavy entries* of a matrix A of n columns as $\mathbb{E}_j[|\{i : |A_{i,j}| \geq \theta\}|]$, where $j \sim \text{Unif}([n])$. We say that two columns i, j of A share k θ -heavy rows if there exist k distinct values $l \in [m]$ such that both $A_{l,i}$ and $A_{l,j}$ are θ -heavy.

Below is the main theorem of the section.

Theorem 9. *There exist absolute constants $\epsilon_0, \delta_0, K_0 > 0$ such that the following holds. For all $\epsilon \in (0, \epsilon_0)$, $\delta \in (0, \delta_0)$, $d \geq 1/\epsilon^2$ and $n \geq K_0d^2/\delta$, if (i) the column sparsity of Π is at most $1/(9\epsilon)$, (ii) the average number of $\sqrt{8\epsilon}$ -heavy entries of Π is at least $1/(12\epsilon)$, and (iii) Π is an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}_1$, then Π must have more than d^2 rows.*

Remark 10. *The d^2 lower bound is tight up to a constant factor, demonstrated by the following example. Let H be a Hadamard matrix of order $1/(8\epsilon)$. We define Π to be the horizontal concatenation of copies of an $m \times m$ block diagonal matrix, where $m = O(d^2)$ and each diagonal block is $\sqrt{8\epsilon}H$. Clearly each column of Π contains $1/(8\epsilon)$ entries of absolute value $\sqrt{8\epsilon}$. It can be easily verified that Π is a $(0, \delta)$ -subspace-embedding for $U \sim \mathcal{D}_1$ and constant δ .*

Algorithm 1: Finding disjoint good column pairs

47  end
48   $k \leftarrow k + 1$ ;
49 end

```

We shall prove Theorem 9 by contradiction. Assume that Π has $m = d^2$ rows in the rest of this section.

We say that two columns i, j collide with each other, denoted by $i \leftrightarrow j$, if they share at least one $\sqrt{8\epsilon}$ -heavy row. We call a column good if it has at least $1/(16\epsilon) \sqrt{8\epsilon}$ -heavy entries and its ℓ_2 -norm is $1 \pm \epsilon$. Let $G \subseteq [n]$ be the set of indices of the good columns of Π . It follows from an averaging argument together with Lemma 6 that at least $(1/3)$ -fraction of the columns of Π are good.

We are going to adopt the idea of the proof of Theorem 7 in [NN14] to show that there is a pair of columns (i, j) of ΠV such that $|\langle (\Pi V)_{*,i}, (\Pi V)_{*,j} \rangle| = \Omega(\epsilon)$ with probability at least a constant. To this end, we are going to find colliding column pairs and analyze their distributions.

4.1 Finding colliding column pairs

This subsection is devoted to analyzing Algorithm 1 and proving Lemmas 12 and 13, i.e. showing that Algorithm 1 finds many colliding pairs and they are well distributed.

For a sequence of column indices $(C_1, C_2, \dots) \in [n]^*$, we say that two column pairs $(C_a, C_b), (C_c, C_d) \in [n]^2$ are disjoint if a, b, c, d are distinct. We select disjoint good column pairs among the good columns chosen by V using the random process presented in Algorithm 1, in which we set $\eta \triangleq 3$. Our goal is to show that with constant probability, there is a column pair (C_i, C_j) , found by Algorithm 1, such that $|\langle \Pi_{*,C_i}, \Pi_{*,C_j} \rangle| = \Omega(\epsilon)$.

Suppose that the output of Algorithm 1 are $Y_1, \dots, Y_{d/16}$. Each Y_i is a random pair over $(\{\perp\} \cup [n]) \times (\{\perp\} \cup [n])$. We have the following lemma on the guarantee of Algorithm 1.

Lemma 11. *The set sequences $\{G_k\}$ and $\{S_k\}$ are both decreasing and nonempty. Furthermore, conditioned on Y_1, \dots, Y_{k-1} , the set G_k is determined and the random variables $\{C_i\}_{i \in S_k}$ are independent and uniformly distributed over G_k .*

Proof. It is clear from the algorithm that G_k is determined by Y_1, \dots, Y_{k-1} and both $\{G_k\}$ and $\{S_k\}$ are non-increasing and nonempty. It remains to show that $\{C_i\}_{i \in S_k}$ are i.i.d. $\text{Unif}(G_k)$, which we shall prove by induction on k .

The base case is $k = 1$. Indeed, all the g C_i 's are independent and uniformly distributed over G . Since $G_1 = G$, the base case is verified.

For the induction step, we fix a k such that $1 \leq k$. We also fix Y_1, \dots, Y_{k-1} .

If there exists $c \in G_k$ such that $\phi_{k,c} > \eta/d$ and $Y_k = (\cdot, \perp)$, then we know that $S_{k+1} = S_k \setminus S'_k$ and $G_{k+1} = G_k \setminus G_k^c$, where G_k^c and S'_k are as defined in Lines 8 and 10. For each $i \in S_{k+1} = S_k \setminus S'_k$, we know that Π_{ℓ, C_i} is not heavy and thus $C_i \notin G_k^c$. Since C_i is uniform on G_k given Y_1, \dots, Y_{k-1} , we know that C_i is uniform on $G_k \setminus G_k^c$ when further conditioned on that $C_i \notin G_k^c$. The induction hypothesis also implies that $\{C_i\}_{i \in S_{k+1}}$ are independent.

If there exists $c \in G_k$ such that $\phi_{k,c} > \eta/d$ and $Y_k \neq (\cdot, \perp)$, we know that $G_{k+1} = G_k$ and $S_{k+1} \subset S_k$. Since $\{C_i\}_{i \in S_{k+1}}$ is a subset of $\{C_i\}_{i \in S_k}$, which are i.i.d. $\text{Unif}(G_k)$ by the induction hypothesis, it is clear that $\{C_i\}_{i \in S_{k+1}}$ are i.i.d. $\text{Unif}(G_k)$.

Now we assume that $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$. When $Y_k = (\perp, \perp)$, then we know $j \notin S_k$. Since $G_{k+1} = G_k$ and $S_{k+1} = S_k$, it follows immediately from the induction hypothesis that $\{C_i\}_{i \in S_{k+1}}$ are i.i.d. $\text{Unif}(G_{k+1})$. When $Y_k \in [n] \times [n]$, we know that $G_{k+1} = G_k$ and $S_{k+1} \subset S_k$, thus it follows from the induction hypothesis that $\{C_i\}_{i \in S_{k+1}}$ are i.i.d. $\text{Unif}(G_{k+1})$. When $Y_k \in \{\perp\} \times [n]$, for each $i \in S_{k+1}$, it must hold that C_i does not collide with C_j and thus $C_i \notin \{c \in G_k : c \leftrightarrow C_j\}$ by the Line 45. Since C_i is uniform on G_k given Y_1, \dots, Y_{k-1} , we know that C_i is uniform on G_{k+1} when further conditioned on that $C_i \in G_{k+1}$. The induction hypothesis also implies that $\{C_i\}_{i \in S_{k+1}}$ are independent.

The proof of the inductive step is now complete. \square

Let \mathcal{E} denote the event that at least $7d/24$ columns of ΠV are good. By a Chernoff bound, we know that $\Pr(\mathcal{E}) \geq 1 - \exp(-\Omega(d))$. When \mathcal{E} happens, the set S_1 in Algorithm 1 contains at least $7d/24$ good column indices with high probability in d .

For each k and each $c \in G_k$ (where G_k is as guaranteed by Lemma 11), we define

$$\phi_{k,c} \triangleq \Pr_{c' \sim \text{Unif}(G_k)} [c' \leftrightarrow c]. \quad (5)$$

Observe that the while-loop never shrinks S_k and the for-loop remove at least one and at most two elements from S_k during each iteration. It is clear that $|S_k \setminus \{j\}| \geq (7d/24) - 2 \cdot (d/16) = d/6$ for all $j \leq k$. Furthermore, it is easy to see that the while-loop will also be broken. We shall discuss two cases based on the breaking conditions of the while-loop.

Lemma 12. *Assume that \mathcal{E} happens. For each $j \in [d/16]$, if the while-loop is broken by the event $S'_k \neq \emptyset$, then with probability at least $\delta' \epsilon$, Algorithm 1 outputs a column pair $(C_{j'}, C_{j''}) \sim \text{Unif}(G_k^\ell \times G_k^\ell)$, where $\delta' > 0$ is an absolute constant.*

Proof. When the while-loop is broken by event $S'_k \neq \emptyset$, it must happen that $\phi_{k,c} > \eta/d$ for some $c \in G_k$. Let $M \triangleq \{l \in [m] : |\Pi_{l,c}| \geq \sqrt{8\epsilon}\}$. Note that $\{c' \in G_k : c' \leftrightarrow c\} = \bigcup_{l \in M} G_k^l$. The choice of ℓ implies that $|G_k^\ell| \geq |\{c' \in G_k : c' \leftrightarrow c\}|/|M_c|$. Since the column sparsity of Π is s , $|M_c| \leq s = 1/(9\epsilon)$ and so $|G_k^\ell| \geq (\phi_{k,c} \cdot |G_k|)/|M_c| \geq \eta\epsilon/(9d) \cdot |G_k|$. Let $p \triangleq |G_k^\ell|/|G_k|$, so $p \geq \eta\epsilon/(9d)$.

Observe that at most two elements are removed from S_k during each iteration of the for-loop. Since \mathcal{E} happens, it always holds that $|S_k| \geq d/6$. By Lemma 11, the elements in S'_k are sampled independently from G_k with sampling probability p . Hence,

$$\begin{aligned} \Pr[|S'_k| \geq 2 \mid S'_k \neq \emptyset] &= 1 - \frac{\Pr[|S'_k| = 1]}{\Pr[S'_k \neq \emptyset]} = 1 - \frac{|S_k| p (1-p)^{|S_k|-1}}{1 - (1-p)^{|S_k|}} \\ &\geq 1 - \frac{|S_k| p (1-p)^{|S_k|-1}}{p |S_k|} \\ &= 1 - (1-p)^{|S_k|-1}. \end{aligned}$$

Observe that the rightmost side above is increasing w.r.t. p . When $p \cdot |S_k| \leq 1$,

$$\Pr[|S'_k| \geq 2 \mid S'_k \neq \emptyset] \geq \left(1 - \frac{1}{e}\right) p (|S_k| - 1) \geq \left(1 - \frac{1}{e}\right) \frac{\eta}{54} \epsilon.$$

Therefore, it always hold that $\Pr[|S'_k| \geq 2 \mid S'_k \neq \emptyset] \geq \delta' \cdot \epsilon$, where $\delta' = (1 - 1/e)\eta/54$. \square

Now we assume that the while-loop is broken by the event that “ $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$ ”. We further define $T_k \triangleq \{(i, i') \in G_k \times G_k : i \leftrightarrow i'\}$, i.e., the set of good column pairs in G_k which collide with each other. Let \mathcal{D}'_k denote the distribution of the output $(C_{j'}, C_j)$ in Line 39 of Algorithm 1. Let Δ_k be a random variable representing the conditional expected number of $\sqrt{8\epsilon}$ -heavy rows shared by two random good columns from T_k given Y_1, \dots, Y_{k-1} . Note that $\forall c \in G_k, (c, c) \in T_k$, hence $T_k \neq \emptyset$, and thus Δ_k is well-defined.

Lemma 13. *Assume that \mathcal{E} happens. For each $j \in [d/16]$, if the while-loop is broken by event “ $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$ ” and if $j \in S_k$, then with probability at least $d/(K\epsilon^2 m \Delta_k)$, Algorithm 1 outputs a column pair $(C_{j'}, C_j)$, where $K > 0$ is an absolute constant. Furthermore, the probability mass function of \mathcal{D}'_k differs from that of $\text{Unif}(T_k)$ by at most a factor of an absolute constant.*

Proof. We claim that

$$\sum_{c \in G_k} \frac{\phi_{k,c}}{|G_k|} = \Pr_{c, c' \sim \text{Unif}(G_k)}[c' \leftrightarrow c] \geq \frac{1}{256\epsilon^2 m \Delta_k}. \quad (6)$$

Indeed, let X denote the number of $\sqrt{8\epsilon}$ -heavy rows shared by two random good columns $i, i' \sim \text{Unif}(G_k)$. Note that

$$\begin{aligned} \mathbb{E}[X] &= \sum_{l \in [m]} \Pr[\Pi_{l,i}, \Pi_{l,i'} \text{ are } \sqrt{8\epsilon}\text{-heavy}] \\ &= \sum_{l \in [m]} \Pr[\Pi_{l,i} \text{ is } \sqrt{8\epsilon}\text{-heavy}]^2 \\ &\geq \frac{1}{m} \left(\sum_{l \in [m]} \Pr[\Pi_{l,i} \text{ is } \sqrt{8\epsilon}\text{-heavy}] \right)^2 \quad (\text{Cauchy-Schwarz}) \\ &\geq \frac{1}{m} \cdot \left(\frac{1}{16\epsilon} \right)^2 = \frac{1}{256\epsilon^2 m}. \end{aligned}$$

Since $X \geq 0$, applying the law of total expectation gives that

$$\mathbb{E}[X] = \mathbb{E}[X|X=0] \cdot \Pr[X=0] + \mathbb{E}[X|X>0] \cdot \Pr[X>0] = \Delta_k \cdot \Pr[X>0],$$

which implies that $\Pr[X>0] = \mathbb{E}[X]/\Delta_k \geq 1/(256\epsilon^2 m \Delta_k)$. This establishes (6).

Observe that at most two elements are removed from S_k during each iteration of the for-loop. Since \mathcal{E} happens, it always holds that $|S_k| > d/6$. Thus, C_j collides with some $C_{j'} \in G_j$, where $j' \in S_k \setminus \{j\}$, with probability at least

$$\sum_{c \in G_k} \Pr[C_j = c] \left(1 - (1 - \phi_{k,c})^{\frac{d}{6}}\right) \geq \sum_{c \in G_k} \frac{1}{|G_k|} \cdot \left(1 - \frac{1}{e}\right) \cdot \phi_{k,c} \cdot \frac{d}{6} \geq \frac{d}{K} \cdot \frac{1}{256\epsilon^2 m \Delta_k}.$$

for some absolute constants $K > 0$. Here, the first inequality follows from the fact that $\phi_{k,c} \cdot d/6 \leq \eta/6 \leq 1$ and the second inequality from (6).

Next we analyze the distribution of the colliding pair $(C_{j'}, C_j)$. Given that there is such an output, the distribution of $(C_{j'}, C_j)$ can be obtained by first sampling $C_j = c \in G_k$ with probability $p_{k,c} \triangleq \phi'_{k,c} / \sum_{c \in G_k} \phi'_{k,c}$, where

$$\phi'_{k,c} \triangleq \Pr[\exists c' \in \{C_i\}_{i \in S_k \setminus \{j\}}, c' \leftrightarrow c] = 1 - (1 - \phi_{k,c})^{|S_k| - 1},$$

and then independently sampling $j' \sim \text{Unif}(S'_k)$. Since we are conditioning on that the algorithm outputs a column pair, the second step is equivalent to choosing $C_{j'} \sim \text{Unif}(M_{C_j})$, where $M_c \triangleq \{c' \in G_k : c' \leftrightarrow c\}$.

Now we examine $(C', C) \sim \text{Unif}(T_k)$. Then $\text{Unif}(T_k)$ can be obtained from first sampling $C = c \in G_k$ with probability $q_{k,c} \triangleq \phi_{k,c} / \sum_{c \in G_k} \phi_{k,c}$ and then independently sampling $C' \sim \text{Unif}(M_c)$.

The result follows from the fact that

$$p_{k,c} = \frac{\phi'_{k,c}}{\sum_{c \in G_k} \phi'_{k,c}} = \Theta\left(\frac{\phi_{k,c}}{\sum_{c \in G_k} \phi_{k,c}}\right) = \Theta(q_{k,c}), \quad \forall c \in G_k. \quad \square$$

4.2 Looking for large inner product

In this subsection, we shall show that (informally)

1. (Lemma 16) every column pair (i, j) , found by Algorithm 1 in Line 39, satisfies that $|\langle \Pi_{*,i}, \Pi_{*,j} \rangle| = \Omega(\epsilon)$ with probability $\Omega(d/m)$;
2. (Corollary 17) Algorithm 1 finds a column pair whose inner product is $\Omega(\epsilon)$ with probability $\Omega(d^2/m)$.

Recall that the column sparsity is at most $s = 1/(9\epsilon)$. We further define for each $x \in [s]$

$$\begin{cases} Q_{x,k} \triangleq \{(i, i') \in T_k : i \text{ and } i' \text{ share exactly } x \sqrt{8\epsilon}\text{-heavy rows}\}, \\ P_{x,k} \triangleq \{(i, i') \in Q_{x,k} : \langle \Pi_{*,i}, \Pi_{*,i'} \rangle \geq (8 - \kappa)\epsilon\}. \end{cases}$$

Let $q_{x,k} = |Q_{x,k}|/|T_k|$ and $p_{x,k} = |P_{x,k}|/|T_k|$. Note that $\{q_{x,k}\}_x$ forms a probability distribution on $[s]$ and $\sum_x x \cdot q_{x,k} = \Delta_k$.

To analyze \mathcal{D}'_k , which is close to $\text{Unif}(T_k)$, we consider an analogous distribution \mathcal{D}''_k . Instead of sampling a good column pair uniformly at random over T_k , \mathcal{D}''_k is obtained by sampling a good column pair (i, i') with probability proportional to the number of $\sqrt{8\epsilon}$ -heavy rows shared by columns i and i' .

We need the following observation.

Lemma 14. *Let $\epsilon \in (0, 1/9)$. Suppose that a matrix A has a row l such that $S \triangleq \{i : |A_{l,i}| \geq \theta\}$ is nonempty. Further suppose that $\|A_{*,i}\|_2^2 \leq 1 + \theta^2$ for all $i \in S$. Let $u, v \sim \text{Unif}(S)$ be independently sampled. Then $\langle A_{*,u}, A_{*,v} \rangle \geq \theta^2 - \kappa\epsilon$ with probability at least $\epsilon/2$, where κ is as in Lemma 3.*

Proof. We partition S into two groups $S^- = \{i : A_{l,i} < 0\}$ and $S^+ = \{i : A_{l,i} > 0\}$. Without loss of generality, we assume that $|S^-| \geq |S^+|$. With probability at least $1/4$, we have $u, v \in S^-$. Condition on this event. It is clear that we have $A_{l,u}A_{l,v} \geq \theta^2$ and u, v are independent uniform samples over S^- .

Let S' be the set of column vectors consisting of all the column vectors in S^- with the l -th entry removed. Applying Lemma 3 to S' yields that $\langle A_{*,u}, A_{*,v} \rangle - A_{l,u}A_{l,v} \geq -\kappa\epsilon$ with probability larger than 2ϵ . Unconditioning on $u, v \in S^-$, the claim follows. \square

The following is an immediate corollary of the preceding lemma.

Corollary 15. *It holds that $(\sum_{x=1}^s x \cdot p_{x,k}) / (\sum_{x=1}^s x \cdot q_{x,k}) \geq \epsilon/2$.*

Proof. Note that \mathcal{D}_k'' can be rephrased as samples some row l , then sample two good columns (i, i') such that $|\Pi_{l,i}|, |\Pi_{l,i'}| \geq \sqrt{8\epsilon}$. Lemma 14 implies the advertized result. \square

Let $\hat{p}_k \triangleq \sum_x p_{x,k}$, then \hat{p}_k has the combinatorial interpretation that

$$\hat{p}_k = \Pr_{(i,i') \sim \text{Unif}(T_k)} [\langle \Pi_{*,i}, \Pi_{*,i'} \rangle \geq (8 - \kappa)\epsilon].$$

For the true distribution \mathcal{D}'_k , define correspondingly

$$\tilde{p}_k = \Pr_{(i,i') \sim \mathcal{D}'_k} [\langle \Pi_{*,i}, \Pi_{*,i'} \rangle \geq (8 - \kappa)\epsilon].$$

Recall that \mathcal{D}'_k is different from $\text{Unif}(T_k)$ by a constant factor, we have $\tilde{p}_k = \Theta(\hat{p}_k)$. We shall show that if $j \in S_k$ and $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$, with probability at least $\Omega(d/m)$, Algorithm 1 in Line 39 outputs a pair $(C_{j'}, C_j)$ such that $\langle \Pi_{*,C_{j'}}, \Pi_{*,C_j} \rangle \geq (8 - \kappa)\epsilon$.

Lemma 16. *There exists an absolute constant $\delta' > 0$ such that the following holds. Assume that \mathcal{E} happens. Suppose that $\epsilon \in (0, 1/9)$, the while-loop is broken by event “ $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$ ”, and $j \in S_k$. With probability at least $\delta'd/m$, Algorithm 1 in Line 39 outputs a pair $(C_{j'}, C_j)$ such that $\langle \Pi_{*,C_{j'}}, \Pi_{*,C_j} \rangle \geq (8 - \kappa)\epsilon$, where κ is as in Lemma 3.*

Proof. Since $\Delta_k \leq s = 1/(9\epsilon)$, Algorithm 1 in Line 39 outputs a pair $(C_{j'}, C_j)$ with probability at least $9d/(K\epsilon m)$ by Lemma 13. When $\hat{p}_k \geq \epsilon/12$, we have that $\tilde{p}_k = \Theta(\hat{p}_k) = \Omega(\epsilon)$ and the desired result follows.

Next we assume that $\hat{p}_k \leq \epsilon/12$. Let $\epsilon' \triangleq \epsilon/2$, $w_k \triangleq (\sum_x x \cdot p_{x,k})/\hat{p}_k$ and $\Delta'_k \triangleq \sum_x x(q_{x,k} - p_{x,k})$. It is clear that $w_k \leq (\sum_x s \cdot p_{x,k})/\hat{p}_k = s$. Note that $\Delta_k = \Delta'_k + w_k \cdot \hat{p}_k = \sum_x x \cdot q_{x,k} \geq \sum_x q_{x,k} = 1$, we know that $\Delta'_k \geq 1 - s \cdot \hat{p}_k \geq 107/108 \geq s \cdot \hat{p}_k \geq w_k \cdot \hat{p}_k$, so $\Delta'_k \geq \Delta_k/2$. The inequality in Corollary 15 can be written as

$$\frac{w_k \hat{p}_k}{\Delta'_k + w_k \hat{p}_k} \geq \epsilon'.$$

Thus,

$$\hat{p}_k \geq \frac{\epsilon' \Delta'_k}{(1 - \epsilon')w_k} \geq \frac{\epsilon' \Delta'_k}{s} = \frac{(\epsilon/2)\Delta'_k}{1/(9\epsilon)} = \frac{9\epsilon^2 \Delta'_k}{2} \geq \frac{9\epsilon^2 \Delta_k}{4}.$$

The conclusion then follows from Lemma 13 and the fact that $\tilde{p}_k = \Theta(\hat{p}_k)$. \square

Corollary 17. *There exist absolute constants $\delta'', K > 0$ such the following holds. Suppose that $d \geq 1/\epsilon^2$ and $\epsilon \in (0, 1/9)$. Assume that \mathcal{E} happens. Then, with probability at least $\delta'' \cdot \min\{d^2/m, 1\}$, Algorithm 1 outputs a pair $(C_i, C_{i'})$ such that $\langle \Pi_{*,C_i}, \Pi_{*,C_{i'}} \rangle \geq (8 - \kappa)\epsilon$, where κ is as in Lemma 3.*

Proof. Observe that the while-loop never shrinks S_k and the for-loop always removes one or two elements from S_k during each iteration. We claim that, assuming \mathcal{E} happens, either (i) “the while-loop is broken by event $S'_k \neq \emptyset$ ” happens for at least $d/96$ times, or (ii) “the while-loop is broken by event $\forall c \in G_k, \phi_{k,c} \leq \eta/d$ ” and “ $j \in S_k$ ” happens simultaneously for at least $d/64$ times. We analyze the two cases separately.

In case (i), by Lemma 12, Line 23 of Algorithm 1 outputs a distinct column pair with probability $\Omega(\epsilon)$. Let \mathcal{F} denote the event that Line 23 outputs $\Omega(\epsilon d)$ distinct pairs over the entire execution, then $\Pr[\overline{\mathcal{F}}] \leq \exp(-\Omega(\epsilon d))$ by a Chernoff bound. By Lemma 14, each pair has a desired large inner product with probability $\epsilon/2$. Hence, when \mathcal{F} happens, since $d \geq 1/\epsilon^2$, one of the pairs has a desired large inner product with probability at least $1 - (1 - \epsilon/2)^{\Omega(\epsilon d)} \geq 1 - e^{-c\epsilon^2 d} \geq 1 - e^{-c}$ for some constant $c > 0$. One can choose ϵ_0 to be small enough such that $\Pr[\overline{\mathcal{F}}] \leq \exp(-\Omega(1/\epsilon)) \leq (1 - e^{-c})/2$ so that the overall success probability in case (i) is at least $(1 - e^{-c})/2$.

For case (ii), immediately by Lemma 16 we obtain that the desired probability is lower bounded by

$$1 - \left(1 - \frac{\delta' d}{m}\right)^{d/64} \geq \frac{\delta'' d^2}{m}$$

for some absolute constant $\delta'' > 0$. \square

4.3 Putting everything together

Now we are ready to complete the proof of Theorem 9.

Proof of Theorem 9. Since $n \geq K_0 d^2 / \delta$, V does not have the full column rank with probability at most $\delta / (2K_0) \leq \delta''$ for large enough constant $K_0 > 0$, where δ'' is as in Corollary 17. Suppose that d is at least a sufficiently large constant d_0 such that $\Pr[\mathcal{E}] \leq \exp(-\Omega(d)) < \delta''$.

Let $\delta_0 = \delta''/5$ and $\epsilon_0 = \min\{1/\sqrt{d_0}, 1/9\}$. When conditioned on \mathcal{E} , it follows from Corollary 17 that with probability at least δ'' there is a pair (i, j) such that $\langle (\Pi V)_{*,i}, (\Pi V)_{*,j} \rangle \geq (8 - \kappa)\epsilon$. Noting that $8 - \kappa > 2$, we invoke Lemma 4 and conclude that Π cannot be an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}_1$, whenever $\delta < \delta_0 \leq (\delta''/4) \cdot (1 - 2\delta'')$. Therefore, Π must have more than d^2 rows. \square

5 Removing the Abundance Assumption

In this section, we remove the ‘‘abundance assumption’’, i.e. Assumption (ii) in Theorem 9, and prove the Theorem 18.

Consider a distribution $\tilde{\mathcal{D}}$ over $\mathbb{R}^{n \times d}$: with probability 1/2, it is \mathcal{D}_1 ; with probability 1/2, it is $\mathcal{D}_{2^{-\ell}}$ for an uniformly chosen $\ell \in [L]$, where $L \triangleq \log(1/\epsilon) - 3$.

Theorem 18. *There exist absolute constants $\epsilon_0, \delta_0, c_0, K_0, K_1 > 0$ such that the following holds. For all $\epsilon \in (0, \epsilon_0)$, $\delta \in (0, \delta_0)$, $d \geq 1/\epsilon^2$ and $n \geq K_0 d^2 / (\epsilon^2 \delta)$, if (i) the column sparsity of Π is at most $1/(9\epsilon)$, and (ii) Π is an (ϵ, δ) -subspace-embedding for $U \sim \tilde{\mathcal{D}}$, then Π must have more than $c_0 \log^{-4}(1/\epsilon) \epsilon^{K_1 \delta} d^2$ rows.*

The rest of the section is devoted to the proof of Theorem 18. Let

$$\delta' \triangleq \frac{\log \log(1/\epsilon^{72})}{\log(1/\epsilon)},$$

then $4\epsilon^{\delta'} \log(1/\epsilon) \leq 1/18$.

We start by assuming there is a matrix $\Pi \in \mathbb{R}^{m \times n}$ which is an (ϵ, δ) -subspace-embedding of $U \sim \tilde{\mathcal{D}}$ for $m = \epsilon^{4\delta' + K_1 \delta} d^2$.

By the law of total probability and the averaging principle, Π is an $(\epsilon, 2\delta)$ -subspace-embedding for $U \sim \mathcal{D}_1$, and by Markov’s inequality, for $(1 - \gamma)$ -fraction of $\ell' \in [L]$, Π is an $(\epsilon, 2\delta/\gamma)$ -subspace-embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$, where $\gamma \triangleq K_1 \delta / 2 < 1$. Hence, for all $\ell \in [L]$, there exists an

$$\ell' \in [\max\{0, (1 - \gamma)L - \ell\}, L - \ell] \text{ such that } 2^{-\ell - \ell'} \in [2^{-L}, (2^{-L})^{1 - \gamma}]$$

and Π is an $(\epsilon, 2\delta/\gamma)$ -subspace-embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$.

Let $G_0 \subseteq [n]$ denote the set of the column indices $i \in [n]$ such that $\|\Pi_{*,i}\|_2 = 1 \pm \epsilon$. By Lemma 6, $|G_0| \geq (1 - 2\delta/d)n$. Let Π' be the submatrix of Π which consists of all the columns in G_0 .

Note that the following lemma implies that the average squared ℓ_2 -norm of the columns of Π' is at most $4\epsilon^{\delta'} \log(1/\epsilon) + s(8\epsilon) \leq 17/18 < (1 - \epsilon)^2$. Therefore, it suffices to prove the following lemma to refute Π .

Lemma 19. *Suppose that $\epsilon \in (0, 1/9)$, $d \geq 1/\epsilon^2$, $n \geq K_0 d^2 / (\epsilon^2 \delta)$ and Π is an (ϵ, δ) -subspace-embedding for $U \sim \tilde{\mathcal{D}}$. For every $\ell \in [L]$, the average number of $\sqrt{2^{-\ell}}$ -heavy entries of Π' is at most $\epsilon^{\delta'} 2^\ell$.*

Proof sketch. We prove the lemma by contradiction. Fix an arbitrary $\ell \in [L]$ and suppose that the average number of $\sqrt{2^{-\ell}}$ -heavy entries of Π' is at least $\epsilon^{\delta'} 2^\ell$. By the arguments preceding Lemma 19, Π is an $(\epsilon, 2\delta/\gamma)$ -subspace-embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$.

We say that two columns i, j collide with each other, denoted by $i \leftrightarrow j$, if they share at least one $\sqrt{2^{-\ell}}$ -heavy row. We call a column good if it has at least $\epsilon^{\delta'} 2^\ell / 3$ $\sqrt{2^{-\ell}}$ -heavy entries and its ℓ_2 -norm is $1 \pm \epsilon$.

Recall that every column of Π' has the ℓ_2 -norm within $[1 - \epsilon, 1 + \epsilon]$. Hence, in each column of Π' , the number of $\sqrt{2^{-\ell}}$ -heavy entries is at most $2^\ell (1 + \epsilon)^2$. We claim that at least $(\epsilon^{\delta'} / 2)$ -fraction of the columns of Π are good. Indeed, let θ be the fraction of good columns of Π' , then we have

$$\epsilon^{\delta'} 2^\ell \leq \theta 2^\ell (1 + \epsilon)^2 + (1 - \theta) \frac{\epsilon^{\delta'} 2^\ell}{3} \leq \frac{100}{81} \theta 2^\ell + (1 - \theta) \frac{\epsilon^{\delta'} 2^\ell}{3},$$

Algorithm 2: Finding disjoint good column pairs

```

Let  $g$  be the number of good columns chosen by  $V$  and let  $S_1 \leftarrow [g]$ ;
Let  $(C_1, C_2, \dots, C_g) \in [n]^g$  be the good columns among the  $\epsilon^{\delta'} d \cdot 2^{\ell'}$  columns chosen from  $[n]$  by
 $V$  in the order they are sampled;
 $G_1 \leftarrow G$ ;
 $k \leftarrow 1$ ;
foreach  $j \in [\epsilon^{\delta'} d \cdot 2^{\ell'} / 16]$  do
     $\vdots$ 
    (the same as Lines 6–10 of Algorithm 1)
     $\vdots$ 
    if  $\phi_{k,c} \leq \eta / (\epsilon^{\delta'} d 2^{\ell'})$  for all  $c \in G_k$  then
         $\vdots$ 
        (the same as Lines 12–48 of Algorithm 1)
         $\vdots$ 
    end

```

whence we can solve that $\theta \geq \epsilon^{\delta'} \cdot (2/3) / (100/81 - \epsilon^{\delta'} / 3) \geq \epsilon^{\delta'} / 2$.

Recall that V has $d' \triangleq d 2^{\ell'}$ columns. Since $d \geq 1/\epsilon^2$ and $2^{\ell'} \geq 1$, it holds that $\epsilon^{\delta'} d' \geq 1/(\epsilon^2 \text{polylog}(1/\epsilon))$. By a Chernoff bound, with probability at least $1 - \exp(-1/\epsilon^{2-o(1)})$, there exist $\epsilon^{\delta'} d' / 4$ good columns in IV .

We follow the proof of Lemma 12 to show that if the while-loop is broken by event $S'_k \neq \emptyset$, then Algorithm 2 in Line 23 outputs a pair $(C_{j'}, C_j)$ with probability $\Omega(\epsilon)$.

We follow the proof of Lemma 13 to show that if the while-loop is broken by event “ $\phi_{k,c} \leq \eta/d$ for all $c \in G_k$ ” and if $j \in S_k$, then Algorithm 2 in Line 39 outputs a pair $(C_{j'}, C_j)$ with probability $\Omega(\epsilon^{3\delta'} d \cdot 2^{2\ell'+\ell'} / (m \Delta_{\ell,j}))$.

Then, following the proof of Corollary 17, we conclude that Algorithm 2 finds a pair $(C_{j'}, C_j)$ such that $\langle \Pi_{*,C_{j'}}, \Pi_{*,C_j} \rangle \geq 2^{-\ell} - \kappa\epsilon$ with probability $\Omega(\min\{\epsilon^{4\delta'+2\gamma} d^2 / m, 1\}) \geq \delta''$ for some absolute constant $\delta'' > 0$, provided that $K_1 \delta \geq 2\gamma$.

Recall that $2^{-\ell-\ell'} \geq 8\epsilon$ and $2^{-\ell'} \leq 1$, we conclude that there is a pair of columns of IV whose inner product is at least $(8 - \kappa)\epsilon / 2^{-\ell'}$ with probability at least δ'' . This contradicts Lemma 4 since Π is an $(\epsilon, 2\delta/\gamma)$ -subspace-embedding for $U \sim \mathcal{D}_{2^{-\ell'}}$, whenever $2\delta/\gamma < \delta''/6$, so we let $\gamma \triangleq 12.5\delta/\delta''$ and $K_1 \triangleq 25/\delta''$. \square

Setting $L \triangleq s$, we can obtain the following generalized lower bound.

Theorem 20. *There exist absolute constants $\epsilon_0, \delta_0, K_0, K_1 > 0$ such that the following holds. For all $\epsilon \in (0, \epsilon_0)$, $\delta \in (0, \delta_0)$, $d \geq 1/\epsilon^2$, $s \leq 1/(9\epsilon)$ and $n \gtrsim K_0 d^2 / (\epsilon^2 \delta)$, if (i) the column sparsity of Π is s , and (ii) Π is an (ϵ, δ) -subspace-embedding for $U \sim \mathcal{D}$, then Π must have $\Omega((\log^{-4} s) s^{-K_1 \delta} d^2)$ rows.*
