ABSTRACT

Although the cosmic curvature has been tightly constrained in the standard cosmological model using observations of cosmic microwave background anisotropies, it is still of great importance to independently measure this key parameter using only late-universe observations in a cosmological model-independent way. The distance sum rule in strong gravitational lensing (SGL) provides such a way, provided that the three distances in the sum rule can be calibrated by other observations. In this paper, we propose that gravitational waves (GWs) can be used to provide the distance calibration in the SGL method, which can avoid the dependence on distance ladder and cover a wider redshift range. Using the simulated GW standard siren observation by the Einstein Telescope as an example, we show that this scheme is feasible and advantageous. We find that $\Delta\Omega_k \simeq 0.17$ with the current SGL data, which is slightly more precise than the case of using SN to calibrate. Furthermore, we consider the forthcoming LSST survey that is expected to observe many SGL systems, and we find that about 10^4 SGL data could provide the precise measurement of $\Delta\Omega_k \simeq 10^{-2}$ with the help of GWs. In addition, our results confirm that this method of constraining Ω_k is strongly dependent on lens models. However, obtaining a more accurate phenomenological model for lens galaxies is highly predictable as future massive surveys observe more and more SGL samples, which will significantly improve the constraint of cosmic curvature.

Key words: strong gravitational lensing – cosmological parameters – gravitational waves

1 INTRODUCTION

The question of whether the spacial geometry of our universe being open, flat, or closed, characterized by spatial curvature parameter Ω_k corresponding to $\Omega_k > 0$, $\Omega_k = 0$, and $\Omega_k < 0$, respectively, is a fundamental issue related to the origin and evolution of the universe. The inflationary cosmology predicts a flat universe, and this has been confirmed by the precise measurements of the cosmic microwave background (CMB) (Guth 1981; Linde 1982; Bennett et al. 1996). The latest Planck 2018 results reported a very stringent constraint on the curvature parameter, $\Omega_k = 0.001 \pm 0.002$, which is from the combination of CMB power spectra data and baryon acoustic oscillation (BAO) measurements in the framework of the Λ cold dark matter (Λ CDM) model (Aghanim et al. 2020).

Although there is a precise constraint on Ω_k indicating a flat universe, two points should be noticed. First, this tight constraint depends on a specific cosmological model and is based on the early-universe measurements. The Hubble tension problem (Riess et al. 2019; Di Valentino et al. 2021;

Vagnozzi 2020; Zhang 2019; Qi & Zhang 2020; Vattis et al. 2019; Zhang et al. 2014; Guo et al. 2019; Zhao et al. 2017; Guo & Zhang 2017; Guo et al. 2020; Feng et al. 2020), the most serious crisis in modern cosmology, implies the disagreements between the early universe and the late universe within the framework of modern cosmological theory (Verde et al. 2019; Riess et al. 2019; Di Valentino et al. 2021). Therefore, it is necessary to remeasure the curvature parameter using the late-universe observations and preferably cosmological model-independent methods. Second, recent studies (Di Valentino et al. 2019; Handley 2021) concerning the curvature parameter found that the Planck power spectra prefer a closed universe at more than 99% confidence level. However, combining the Planck data with BAO data prefers a flat universe, with a small error of 0.002. Conclusions regarding Ω_k from the combination of these data sets should be treated with suspicion. Thus, this further urges us to re-examine the constraints on Ω_k through a cosmological model-independent method and using low-redshift observations.

Based on the distance sum rule, Räsänen et al. (2015) presented a cosmological model-independent method to constrain the cosmic curvature parameter with the combination of strong gravitational lensing (SGL) observations and Type

^{*} E-mail: zhangxin@mail.neu.edu.cn

Ia supernovae (SN Ia) data and obtained a Ω_k value close to zero but with poor precision. Subsequently, this method has been fully implemented with larger SGL and SN Ia samples (Liu et al. 2020; Xia et al. 2017; Li et al. 2018; Wang et al. 2020b; Zhou & Li 2020) as well as other distance indicators such as intermediate luminosity quasars (Qi et al. 2019c). However, the results of these previous works on the constraints of Ω_k are not consistent. For instance, with a prior from CMB observations, $\Omega_k \leq -0.1$, Räsänen et al. (2015) and Xia et al. (2017) obtained that Ω_k is close to zero. However, without the prior from CMB, Li et al. (2018) constrained Ω_k with a larger SN Ia sample and found that a closed universe is preferred. The reason for this inconsistency is probably the addition of the CMB prior. Alternatively, the bias of estimation for Ω_k could also be caused by the limited number of available SGL samples bringing unknown systematic errors. Specifically, to constrain Ω_k using the distance sum rule requires calibrating the distances of lenses and sources in SGL systems by using other distance indicators. The maximum redshift of the distance indicators determines the number of SGL systems that can be calibrated. At present, the maximum redshift of sources in the observed SGL sample is about 3.6, while the maximum redshift of the SN Ia sample used commonly as a distance indicator is only about 2.3, which means that some SGL systems cannot be calibrated. Therefore, we need other distance probes capable of detecting higher redshifts. On the other hand, a disadvantage of SN Ia is that it cannot provide absolute distance unless calibrated by the distance ladder. Therefore, it is necessary to develop other reliable cosmological probes to constrain Ω_k .

The successful detections of gravitational waves (GWs) (Abbott et al. 2016, 2017) bring us into the era of GW astronomy and multi-message astronomy. The absolute luminosity distance can be determined by analysing GW's waveform, which is referred to as standard siren (Schutz 1986). For a comparison, for SN Ia, only relative distances can be obtained. If the redshift of GW event is obtained through the electromagnetic (EM) counterpart or its host galaxy, the distance-redshift relation can be established, which is of importance for cosmological studies (Qi et al. 2019b,a; Zhao et al. 2011; Wang et al. 2018; Zhang 2019; Wang et al. 2020a; Zhang et al. 2019a, 2020; Zhao et al. 2020; Jin et al. 2022a,b, 2020; Wang et al. 2022; Jin et al. 2021; Bian et al. 2021). According to the conservative estimates, the third-generation ground-based GW observatory, such as the Einstein Telescope (ET) with one order of magnitude more sensitive than the current GW detectors, can detect 1000 GW events with the redshift information from the binary neutron star (BNS) mergers in a ten-year observation (Nissanke et al. 2010; Zhao et al. 2011; Cai & Yang 2017; Zhao & Wen 2018; Chen et al. 2021). Moreover, the detectable redshifts of GWs could reach much higher. It is no doubt that the observations of GWs will become an important tool for cosmological studies in the near future.

Considering the above model-independent constraints on Ω_k based on the method of distance sum rule, GW observation could provide a perfect complement to traditional cosmological probes. Therefore, in this paper, we will investigate how GWs as a distance indicator will affect the constraints on Ω_k in the near future of GW astronomy. Our investigation includes two parts. First, based on ET in its 10-year observation, we simulate 1000 GW standard sirens and constrain Ω_k in combination with the latest observed SGL sample. Since this method is dependent strongly on the lens models characterizing the mass distribution of lens galaxies (Qi et al. 2019c), we will perform the constraint on Ω_k in three lens models extensively used in strong lensing studies. Next, we consider the possible developments of next decades. During the construction and subsequent observation of ET, the ongoing and future massive surveys like Large Synoptic Survey Telescope (LSST) or Dark Energy Survey will provide a large sample of well-measured SGL systems. For example, according to the prediction of Collett (2015), the LSST survey could potentially observe 1.2×10^5 SGL systems. In this paper, we also make a forecast for what constraints on Ω_k can be obtained with such a significant increase of the number of SGL systems.

2 METHODS AND DATA

2.1 Distance sum rule

According to the cosmological principle that the universe is homogeneous and isotropic at large scales, the spacetime geometry can be described by the Friedmann-Lemaître-Robertson-Walker (FLRW) metric, so we have

$$ds^{2} = -dt^{2} + a^{2}(t) \left\{ \frac{dr^{2}}{1 - kr^{2}} + r^{2}(d\theta^{2} + \sin^{2}\theta d\phi^{2}) \right\}, \quad (1)$$

where a(t) denotes the cosmic scale factor, and k is a constant associated with the spatial curvature. Considering a SGL system in the FLRW metric, the angular diameter distance between the lens galaxy at redshift z_l and the source at redshift z_s can be represented as $D_A(z_l, z_s)$. The dimensionless comoving distance d(z) between the lens and the source can be described as

$$d(z_l, z_s) = (1+z_s)H_0 D_A(z_l, z_s)$$

= $\frac{1}{\sqrt{|\Omega_k|}} \operatorname{sinn}\left[\sqrt{|\Omega_k|} \int_{z_l}^{z_s} \frac{H_0 dz'}{H(z')}\right],$ (2)

where

$$\operatorname{sinn}(x) = \begin{cases} \sin(x), & \Omega_k < 0, \\ x, & \Omega_k = 0, \\ \sinh(x), & \Omega_k > 0. \end{cases}$$
(3)

Here, H(z) is the Hubble parameter, and H_0 is the Hubble constant. $\Omega_k = -k/(H_0^2 a_0^2)$ $(a_0 = a(0))$ is the spatial curvature parameter. For convenience, we define $d_l = d(0, z_l)$, $d_s = d(0, z_s)$, and $d_{ls} = d(z_l, z_s)$. These three dimensionless distances in the FLRW universe and cosmic curvature Ω_k satisfy the distance sum rule (Bernstein 2006; Räsänen et al. 2015):

$$\frac{d_{ls}}{d_s} = \sqrt{1 + \Omega_k d_l^2} - \frac{d_l}{d_s} \sqrt{1 + \Omega_k d_s^2}.$$
(4)

Obviously, we obtain $d_s = d_l + d_{ls}$ if the universe is spatially flat ($\Omega_k = 0$). Simultaneously, $d_s < d_l + d_{ls}$ and $d_s > d_l + d_{ls}$ correspond to a spatially closed ($\Omega_k < 0$) and open ($\Omega_k > 0$) universe, respectively. On the basis of Equation (4), if we obtain the distances d_l , d_s , and d_{ls} from observations, the spatial curvature Ω_k can be directly derived without any assumption regarding the specific cosmological model. In this

2.2 Data simulation for gravitational wave standard sirens

All the GW events considered in this work are assumed to be produced by the mergers of binary neutron stars (BNSs). The neutron star (NS) mass distribution is randomly sampled in the interval [1, 2] M_{\odot} , where M_{\odot} is the solar mass, the same as in the literature (Cai et al. 2018; Zhang et al. 2019b; Wang et al. 2018). The redshift distribution of GW sources takes the form (Zhao et al. 2011; Cai & Yang 2017)

$$P(z) \propto \frac{4\pi d_C^2(z) R(z)}{H(z)(1+z)},$$
(5)

where $d_C(z)$ represents the comoving distance at the redshift z. R(z) indicates the time evolution of the burst rate, which is given by (Schneider et al. 2001; Cutler & Holz 2009)

$$R(z) = \begin{cases} 1+2z, & z \le 1, \\ \frac{3}{4}(5-z), & 1 < z < 5, \\ 0, & z \ge 5. \end{cases}$$
(6)

After knowing the redshift and mass distributions described above, we can generate the mock catalog of the GW standard sirens. The luminosity distance D_L can be extracted from the GW amplitude, and its value in this simulation can be obtained by

$$D_L(z) = (1+z) \int_0^z \frac{dz'}{H(z')}.$$
(7)

In this simulation, the fiducial cosmological model we choose is the flat Λ CDM universe and the values of parameters are taken from Planck 2018 results (Aghanim et al. 2020).

For the estimation of the luminosity distance error ΔD_L , it depends on the sensitivity of the GW detector and the signalto-noise ratio (SNR) of a GW event. The strain h(t) in GW interferometers quantifies the difference of two optical paths due to the passing of GW, following Sathyaprakash & Schutz (2009) and Zhao et al. (2011), which can be denoted as

$$h(t) = F_{+}(\theta, \phi, \psi)h_{+}(t) + F_{\times}(\theta, \phi, \psi)h_{\times}(t),$$
(8)

where ψ is the polarization angle, and (θ, ϕ) describe the source-location angles relative to the detector. Here, the antenna pattern functions F_+ and F_{\times} of the ET are written as (Cai & Yang 2017)

$$F_{+}^{(1)}(\theta,\phi,\psi) = \frac{\sqrt{3}}{2} \left[\frac{1}{2} (1 + \cos^{2}(\theta)) \cos(2\phi) \cos(2\psi) - \cos(\theta) \sin(2\phi) \sin(2\psi) \right],$$

$$F_{\times}^{(1)}(\theta,\phi,\psi) = \frac{\sqrt{3}}{2} \left[\frac{1}{2} (1 + \cos^{2}(\theta)) \cos(2\phi) \sin(2\psi) + \cos(\theta) \sin(2\phi) \cos(2\psi) \right].$$
(9)

There are three interferometers with 60° inclined angles for each other, with $F_{+,\times}^{(2)}(\theta,\phi,\psi) = F_{+,\times}^{(1)}(\theta,\phi+\frac{2\pi}{3},\psi)$ and $F_{+,\times}^{(3)}(\theta,\phi,\psi) = F_{+,\times}^{(1)}(\theta,\phi+\frac{4\pi}{3},\psi).$

Then, the Fourier transform $\mathcal{H}(f)$ of the time domain waveform h(t) can be derived as (Zhao et al. 2011)

$$\mathcal{H}(f) = \mathcal{A}f^{-7/6} \exp[i(2\pi f t_0 - \pi/4 + 2\Psi(f/2) - \varphi_{(2.0)})].$$
(10)

Here, the definitions of the functions Ψ and $\varphi_{(2,0)}$ can be found in Zhao et al. (2011). The Fourier amplitude \mathcal{A} is defined as

$$\mathcal{A} = \frac{1}{D_L} \sqrt{F_+^2 (1 + \cos^2(\iota))^2 + 4F_\times^2 \cos^2(\iota)} \times \sqrt{5\pi/96} \pi^{-7/6} \mathcal{M}_c^{5/6},$$
(11)

where $\mathcal{M}_c = (1+z)M\eta^{3/5}$ is chirp mass. Here, M is the total mass of the coalescing binary with component masses m_1 and m_2 , namely $M = m_1 + m_2$, and $\eta = m_1 m_2 / (m_1 + m_2)^2$. The parameter ι is the inclination angle of the binary's orbital angular momentum with the line of sight, which can be obtained from the accompanying EM counterpart of the GW event like short gamma-ray bursts (SGRBs). SGRBs are believed to be strongly beamed phenomena (Nakar et al. 2006; Abdo et al. 2009; Rezzolla et al. 2011). Once SGRBs are observed, it means that the binaries should be aligned nearly face on (i.e., $\iota \simeq 0$). We take the maximal inclination to be $\iota = 20^{\circ}$. In general, one would need to compute all the Fisher matrices with random inclination angles and then select the sources above the detection threshold that happen to have an EM counterpart. However, according to the analysis of Li (2015), averaging the Fisher matrix over the inclination ι and the polarisation ψ with the constraint $\iota < 20^{\circ}$ is approximately equivalent to taking $\iota = 0$. Moreover, in the previous simulation of GW (Zhao et al. 2011; Cai et al. 2018; Zhang et al. 2019b; Wang et al. 2018), the inclination ι was also treated in the same way. Following them, therefore, we set $\iota = 0$ in the simulation of GW data.

After knowing a waveform of GW, one can calculate its signal-to-noise ratio (SNR). For the ET detector, a GW event is confirmed only when the SNR reaches at least 8. The combined SNR of the network including three equivalent independent interferometers can be written as

$$\rho = \sqrt{\sum_{i=1}^{3} (\rho^{(i)})^2},\tag{12}$$

where $\rho^{(i)} = \sqrt{\langle \mathcal{H}^{(i)}, \mathcal{H}^{(i)} \rangle}$, and the inner product is denoted as

$$\langle a,b\rangle = 4 \int_{f_{\text{lower}}}^{f_{\text{lopper}}} \frac{\tilde{a}(f)\tilde{b}^*(f) + \tilde{a}^*(f)\tilde{b}(f)}{2} \frac{df}{S_h(f)},$$
(13)

where a tilde represents the Fourier transform of the function. Here, $S_h(f)$ is the one-side noise power spectral density, and its form for ET is taken to be the same as in Freise et al. (2011); Zhao et al. (2011); Cai et al. (2018). For the detection rate of GW from BNS mergers with redshift measurements enabled by EM counterparts, according to the recent studies (Yu et al. 2021; Chen et al. 2021) by investigating various models of the short γ -ray bursts and afterglows, a rough estimation of about 1000 GW standard sirens for the 10-year observation of ET is achievable. Although the approximation of $\iota = 0$ we take above could increase the SNR, it does not increase our estimated detection rate, which is based on more robust studies about the short γ -ray bursts. Therefore, we simulate 1000 GW standard sirens based on a 10-year observation of ET.

4 Yan-Jin Wang et al.

Applying the Fisher information matrix, the instrument error of D_L could be given by

$$\Delta D_L^{\text{inst}} \simeq \sqrt{\left\langle \frac{\partial \mathcal{H}}{\partial D_L}, \frac{\partial \mathcal{H}}{\partial D_L} \right\rangle^{-1}}.$$
 (14)

Due to $\mathcal{H} \propto D_L^{-1}$ as shown in Equations (10) and (11), we have

$$\frac{\partial \mathcal{H}}{\partial D_L} = -\frac{\mathcal{H}}{D_L}.$$
(15)

By substituting Equation (15) into Equation (14), we can obtain

$$\Delta D_L^{\text{inst}} \simeq \sqrt{\frac{D_L^2}{\langle \mathcal{H}, \mathcal{H} \rangle}} \simeq \frac{D_L}{\rho}.$$
 (16)

Note that the uncertainty of the inclination ι would affect the SNR, and the maximal effect of the inclination on the SNR is a factor of 2 ($0^{\circ} < \iota < 90^{\circ}$). Then, the instrumental error on the luminosity distance can be written as

$$\Delta D_L^{\text{inst}} \simeq \frac{2D_L}{\rho}.$$
(17)

Besides, the error from the weak lensing should be taken into account as well, wherein $\Delta D_L^{\text{lens}} = 0.05 z D_L$ (Sathyaprakash et al. 2010). Finally, the total error of D_L can be expressed as

$$\Delta D_L = \sqrt{(\Delta D_L^{\text{inst}})^2 + (\Delta D_L^{\text{lens}})^2}$$
$$= \sqrt{\left(\frac{2D_L}{\rho}\right)^2 + (0.05zD_L)^2}.$$
(18)

In this way, we generate a catalogue of GW standard sirens with the redshift z, the luminosity distance D_L , and the error of the luminosity distance ΔD_L .

2.3 Gaussian process

Using the distance sum rule to constrain Ω_k requires the knowledge of the distances in SGL systems, which usually could be implemented by the distance calibration using other distance indicators, such as GWs, as done in this paper. However, one key difficulty is that there is no one-to-one correspondence between the redshifts of SGL data and GW data. In the previous works, there are two effective ways to do this, the polynomial fitting and Gaussian process (GP). In this paper, we adopt the GP method based on GaPP Python code (Seikel et al. 2012a,b) to reconstruct a smooth distance-redshift curve of D_L from GWs so that we can calibrate the distances in SGL data.

This reconstruction method has been widely used in cosmology (Seikel et al. 2012a,b; Zhang & Li 2018; Zhang & Xia 2016; Cai et al. 2020; Wang et al. 2021; Seikel & Clarkson 2013), by which the reconstructed function f(z) is a Gaussian distribution at each point z, and its values at different points z and \tilde{z} are connected by a covariance function $k(z, \tilde{z})$. There are various forms for the covariance function. According to the analysis in Seikel & Clarkson (2013), the squared exponential form with the Matérn ($\nu = 9/2$) covariance function can lead to more reliable results than all others. So we

Figure 1. Reconstruction of the dimensionless comoving distances from the 1000 simulated GW standard siren data. The red points with error bars represent the simulated data. The blue shaded area and the blue solid line denote the 1σ confidence level errors and best-fit values of the reconstruction by using the GP method.

take it here and its expression is

$$k(z, \tilde{z}) = \sigma_f^2 \exp(-\frac{3|z-\tilde{z}|}{\ell}) \times (1 + \frac{3|z-\tilde{z}|}{\ell} + \frac{27(z-\tilde{z})^2}{7\ell^2} + \frac{18|z-\tilde{z}|^3}{7\ell^3} + \frac{27(z-\tilde{z})^4}{35\ell^4}), \quad (19)$$

where σ_f and ℓ are hyperparameters which can be optimized by the GP itself via the observational data. To determine the dimensionless distances, d_l and d_s , in Equation (4), firstly we convert the luminosity distances of GWs into the dimensionless distances via the following relation

$$d(z) = \frac{H_0 D_L(z)}{(1+z)}.$$
(20)

With the simulated GW data with redshift measurements enabled by EM counterparts, we can use the smoothing technique of GP to reconstruct the distance-redshift curve with 1σ confidence region as shown in Figure 1. In this way, the dimensionless comoving distances corresponding to the source and lens for an SGL system could be determined by the reconstructed distance-redshift curve, as well as the errors of distances.

2.4 Strong gravitational lensing systems

In this subsection, we briefly introduce the SGL system and the observational SGL sample we used. For SGL systems, the measurements of lens velocity dispersion σ could be used commonly as a statistical quantity to constrain cosmological parameters and density profiles of lens galaxies. In general, early-type galaxies are more massive and dominant in most SGL samples. Moreover, they also could be characterized by a general mass model because most of them satisfy the spherical symmetry distribution (Chen et al. 2019). With strict criteria to ensure the validity of the assumption of spherical symmetry on the lens galaxies, Chen et al. (2019) compiled a sample of SGL including 161 galaxy-scale strong lensing systems from the following surveys: the Sloan Lens ACS (SLACS) survey (Bolton et al. 2006, 2008; Auger et al. 2009, 2010; Shu et al. 2015, 2017), the Baryon Oscillation Spectroscopic Survey (BOSS) Emission-Line Lens Survey (BELLS) (Brownstein et al. 2012), the BELLS for GALaxy-Ly γ EmitteR sYstemsGALLERY (Shu et al. 2016a,b). In this SGL sample, 130 SGL systems have the measurements of the luminosity density slope δ for lens galaxies which is obtained by fitting the two-dimensional power-law luminosity profile to the high-resolution imaging data from the Hubble Space Telescope. Chen et al. (2019) found that treating δ as an observable for individual lens galaxy rather than treating it as a universal parameter for all lens galaxies is necessary to get an unbiased cosmological estimate. Therefore, in this paper, we also use this truncated SGL sample including 130 SGL systems with the measurements of δ , for which the redshift range of lenses is $0.0624 < z_l < 0.7224$ and the redshift range of sources is $0.1970 \le z_s \le 2.8324$.

As mentioned above, the velocity dispersion of intervening galaxies is the statistical quantity for cosmological fitting, and its measurement could be obtained from the spectroscopic data. To eliminate the effect of the aperture size on measurements of velocity dispersions, $\sigma_{\rm ap}$ measured within a circular aperture with the angular radius $\theta_{\rm ap}$ should be normalized to a typical physical aperture within a circular aperture of radius $R_{\rm eff}/2$ (the half-light radius of the lens galaxy), according to the aperture correction formula (Jorgensen et al. 1995),

$$\sigma_0 = \sigma_{\rm ap} \left(\frac{\theta_{\rm eff}}{2\theta_{\rm ap}} \right)^{\xi},\tag{21}$$

where $\theta_{\text{eff}} = R_{\text{eff}}/D_A(z_l)$, and ξ is adopted as $\xi = -0.066 \pm 0.035$ (Cappellari et al. 2006). It should be noted that the uncertainty of ξ is going to feed into the total error of σ_0 . In addition, considering the extra mass contribution from matters along the line of sight and the fractional uncertainty of the Einstein radius, 5% uncertainty of velocity dispersion will be taken as the systematic error (Wang et al. 2020b).

For a SGL system, the gravitational mass $M_{\rm grl}^{\rm E}$ should equal to the dynamical mass $M_{\rm dyn}^{\rm E}$ within the Einstein radius $\theta_{\rm E}$. If the lens model and the cosmological distances are determined, $M_{\rm dyn}^{\rm E}$ could be inferred from the velocity dispersion, and $M_{\rm grl}^{\rm E}$ can also be inferred from the measurement of the Einstein radius. As mentioned above, although this constraint of Ω_k is independent of cosmological models, it strongly depends on the lens models. Therefore, we will consider three lens models widely used in strong lensing studies for full analysis.

• Singular isothermal sphere (SIS) model

For the simplest SIS model, the velocity dispersion can be expressed as (Cao et al. 2015)

$$\sigma_0^{\rm SIS} = \sqrt{\frac{\theta_{\rm E}}{4\pi f_{\rm E}^2}} \frac{d_s}{d_{ls}},\tag{22}$$

where $f_{\rm E}$ is a phenomenological coefficient, which reflects the uncertainty due to the difference between the observed stellar velocity dispersion and the underlying dark matter, and other systematic effects. In terms of standard SIS model, the coefficient $f_{\rm E}$ is strictly equal to 1. In this paper, $f_{\rm E}$ is treated as a free parameter and it takes the range $0.8 < f_{\rm E}^2 < 1.2$ according to some observations (Kochanek et al. 2000; Ofek et al. 2003).

• Extended power-law (EPL) lens model

Considering a more complex mass model, we assume that the luminosity density profile v(r) differs from the total-mass density profile $\rho(r)$, and they take the forms (Cao et al. 2015)

$$\rho(r) = \rho_0 \left(\frac{r}{r_0}\right)^{-\gamma}, \quad \upsilon(r) = \upsilon_0 \left(\frac{r}{r_0}\right)^{-\delta}, \tag{23}$$

where r is the spherical radius from the lens galaxy center, γ is the power law index of the total mass density profile treated as a free parameter, and δ is the power law index of the luminosity density profile, which has been measured for each lens in SGL sample we used in this paper. In addition, we also consider the anisotropy of the stellar velocity dispersion $\beta(r)$, which is given by

$$\beta(r) = 1 - \frac{\sigma_{\theta}^2}{\sigma_r^2},\tag{24}$$

where σ_{θ} and σ_r are the tangential and radial components of the velocity dispersion, respectively. According to the constraint on β from a well-studied sample of nearby elliptical galaxies, we will treat it as a nuisance parameter and marginalize over it with a Gaussian distribution, $\beta =$ 0.18 ± 0.13 (Schwab et al. 2010). In this lens model, the velocity dispersion can be expressed as (Chen et al. 2019)

$$\sigma_0^{\rm EPL} = \sqrt{\frac{\theta_{\rm E}}{2\sqrt{\pi}} \frac{d_s}{d_{ls}} \frac{3-\delta}{(\xi-2\beta)(3-\xi)} \left(\frac{\theta_{\rm eff}}{2\theta_{\rm E}}\right)^{2-\gamma} \left[\frac{\lambda(\xi) - \beta\lambda(\xi+2)}{\lambda(\gamma)\lambda(\delta)}\right]},$$
(25)

where $\xi = \gamma + \delta - 2$, and $\lambda(x) = \Gamma\left(\frac{x-1}{2}\right)/\Gamma\left(\frac{x}{2}\right)$. It is worth noting that if $\gamma = \delta = 2$ and $\beta = 0$, the EPL model will be reduced to the standard SIS model. According to the studies of previous works (Ruff et al. 2011; Bolton et al. 2012; Cao et al. 2016; Cui et al. 2017; Holanda et al. 2017), the dependence of total mass density slope γ on the redshift is possible. Therefore, we consider two scenarios of γ to further explore the issues we are interested in, i.e.,

- (i) EPL1: $\gamma = \gamma_0$,
- (ii) EPL2: $\gamma = \gamma_0 + \gamma_1 z_l$,

where γ_0 and γ_1 are free parameters.

The distance ratio d_{ls}/d_s can be inferred from the distance sum rule, once the distances d_l and d_s are calibrated by GWs, in which the spatial curvature Ω_k is involved. Thus, the values of σ_0 in three lens models can be obtained. Ω_k can be constrained by maximizing the likelihood function $\mathcal{L} \propto e^{-\chi^2/2}$. The χ^2 function is defined as

$$\chi^{2}(\boldsymbol{p},\Omega_{k}) = \sum_{i=1}^{N} \frac{[\sigma_{0}^{\text{lens}}(z_{i},\boldsymbol{p},\Omega_{k}) - \sigma_{0}^{\text{obs}}(z_{i})]^{2}}{(\Delta\sigma_{0}^{\text{tot}})^{2}},$$
(26)

where N denotes the number of SGL data points, and \boldsymbol{p} is the parameters of lens models. It should be noted that the total uncertainty σ_0^{tot} not only has the contribution from the measurements of SGL systems, but also contains the uncertainties from distance calibrations of d_l and d_s .

3 RESULTS AND DISCUSSION

By using the emcee Python module (Foreman-Mackey et al. 2013) based on the Markov Chain Monte Carlo (MCMC) method, we obtain the cosmological model-independent constraint on Ω_k in the framework of three lens models. Different from previous work (Räsänen et al. 2015; Xia et al. 2017) considering a prior of $\Omega_k > -0.1$ from the CMB observation (Vonlanthen et al. 2010; Audren et al. 2013; Audren 2014), we do not take this prior because our motivation is to measure Ω_k using only the late-universe observations. Firstly, we present the constraint results from the current data sets of 130 SGL systems combined with the simulated GW data. Secondly, considering the upcoming LSST survey with a large sample of SGL as expected, we also forecast what constraint on Ω_k could be achieved.

3.1 Results from current SGL data

For the simplest SIS model, the constraints on Ω_k and $f_{\rm E}$ are shown in Figure 2 and Table 1. By using the combination of 1000 GW simulation data and 130 SGL observational data, the spatial curvature parameter is constrained to be $\Omega_k = 0.550^{+0.313}_{-0.256}$, wherein a zero value of Ω_k is ruled out at 2σ confidence level. It should be noted that while the 1000 GW data are simulated in a flat universe, the 130 SGL data are actually observed, so the constraint result of Ω_k is still instructive. For the parameter $f_{\rm E}$ reflecting the mass distribution of the lens galaxies, we obtain a result of $f_{\rm E} = 1.016 \pm 0.009$ at 1σ confidence level, which is in good agreement with the standard SIS model ($f_{\rm E} = 1$) at 2σ confidence level.

Now we focus on the constraint errors of parameters. Compared with the previous results using SN Ia as distance indicators to calibrate the distances of SGL, using GW standard sirens does not obtain competitive precision for the constraints on Ω_k in this lens model. For instance, by using the combination of 137 SGL data and Pantheon SN Ia sample, Zhou & Li (2020) inferred the cosmic curvature parameter as $\Omega_k = 0.483^{+0.239}_{-0.385}$ at 1σ confidence level based on the SIS lens model. With 161 galactic-scale SGL systems and 1048 SN Ia data, Wang et al. (2020b) obtained a value of $\Omega_k = 0.57^{+0.20}_{-0.28}$ at 1σ confidence level in the framework of SIS lens model. Although the constraint error of Ω_k has not been significantly improved by using simulated GW data, with the increase of SGL data observed in the future, the GW standard siren observation covering a wider redshift range could calibrate more SGL systems than SN Ia, which will help reduce the statistical error for the constraint on Ω_k .

For the EPL1 model, we present the constraint results in Figure 2 and Table 1. The fit value at 1σ confidence level of Ω_k is $\Omega_k = -0.052^{+0.194}_{-0.154}$, in excellent agreement with a flat universe. By comparing with the results from the SIS model, we find that the model selection has a strong influence on the constraint on Ω_k , which further confirms the conclusion of previous works as well (Qi et al. 2019c; Wang et al. 2020b). Moreover, for the constraint on Ω_k in the EPL1 model, we obtain a more stringent result by using GWs as the distance indicators with respect to using SN Ia. Zhou & Li (2020) presented a result of $\Omega_k = 0.100^{+0.538}_{-0.114}$, and Wang et al. (2020b) obtained $\Omega_k = 0.25^{+0.23}_{-0.16}$ from the combination of 161 SGL data and 1048 SN Ia data. On the other hand, we stress that the EPL1 model will be reduced to the standard SIS

model if $\gamma_0 = 2$. The constraint result of γ_0 we obtain is $\gamma_0 = 2.106 \pm 0.013$. It is clearly shown that the SIS model has been excluded at 2σ confidence level.

For the EPL2 model, the one-dimensional marginalized posterior distributions and the contours of parameters are shown in Figure 2, and the constraint results are summarized in Table 1. It can be clearly seen that the result $\Omega_k = -0.139^{+0.278}_{-0.172}$ is well consistent with a flat universe. Compared to the results of the EPL1 model, this constraint on Ω_k becomes weaker, possibly due to the addition of a parameter γ_1 . However, this constraint on Ω_k is tighter than that of the SIS model, even though the number of parameters here is one more than the SIS model. All these results indicate that reasonably modeling the mass distribution of lens galaxies is an important factor for constraining Ω_k with this method. For the lens model parameters, we have $\gamma_0 = 2.098 \pm 0.019$, and $\gamma_1 = 0.053^{+0.098}_{-0.108}$, wherein a zero value of γ_1 is included at 1σ confidence level. This suggests that the dependence of the total mass density profile slope γ on the redshift is not significant in this work, which supports the EPL2 lens model being reduced to the EPL1 model at 1σ confidence level.

In our analyses, GW data are used as the distance indicator to calibrate the distances of source and lens in SGL data. For the constraint on Ω_k , which of the two data (SGL or GW) is dominant needs to be clarified. First, for the best-fit values, by comparing with the previous results using SN Ia as distance indicators, we find that the best-fit values of Ω_k in the same lens model are very close, as discussed above. In addition, the simulation of GW to provide the distances is based on the flat $(\Omega_k = 0)$ ACDM model. Therefore, a flat universe under any lens model should be obtained if the GW data dominate the constraint on Ω_k . However, we find that the best-fit values of Ω_k in three lens models are different. These two points indicate that the SGL data are dominant for the constrained best-fit values. Second, we explore which of the two data dominates the constrained uncertainties of Ω_k . Taking the EPL2 model as an example, we perform the same constraint by using the Λ CDM model as same as the fiducial model in the simulation of GW to provide the distances instead of GW data. In the right panel of Figure 2, we find that the result from the ΛCDM model is almost the same as that from GW data, even though the distances provided by the Λ CDM model have no errors. All of these imply that the SGL data dominate the constraints of Ω_k in this approach.

3.2 Results from LSST simulation sample

During the construction and subsequent observations of ET, the upcoming LSST with wide field-of-view is expected to observe 1.2×10^5 galaxy-galaxy strong lensing. Such a large sample of SGL data is bound to produce extensive cosmological applications. Here we also make a forecast for what constraint on Ω_k can be achieved with such a tremendous increase of SGL data. Based on the performance of LSST, Collett (2015) performed a simulation of a realistic population of galaxy-galaxy strong lensing. For our estimations of Ω_k , a fraction of the SGL sub-sample is available, considering the determination of redshift and accurate measurement on velocity dispersion, and so on. Therefore, in this paper, by

Figure 2. One-dimensional and two-dimensional posterior distributions for all parameters from 130 SGL systems. Left: The constraints on spatial curvature Ω_k and the lens profile parameter f_E in the SIS lens model. Middle: The constraints on spatial curvature Ω_k and the lens profile parameter γ_0 in the ELP1 lens model. Right: The constraints on spatial curvature Ω_k and the lens profile parameters γ_0 and γ_1 by using GW and the Λ CDM to provide the distances in the EPL2 lens model.

Table 1. The fit values of all parameters from 130 SGL systems at the 1σ confidence level in the SIS, EPL1, and EPL2 models.

Lens model	Ω_k	$f_{\rm E}$	γ_0	γ_1
SIS	$0.550^{+0.313}_{-0.256}$	1.016 ± 0.009	_	-
EPL1	$-0.052^{+0.194}_{-0.154}$	_	2.106 ± 0.013	_
EPL2	$-0.139^{+0.278}_{-0.172}$	_	2.098 ± 0.019	$0.053\substack{+0.098\\-0.108}$

Figure 3. One-dimensional and two-dimensional posterior distributions for the parameters Ω_k and f_E from LSST simulation samples of 2×10^3 (gray solid line), 5×10^3 (red solid line), and 1×10^4 (blue solid line) lenses in the SIS lens model.

Table 2. The best-fit values of the parameters Ω_k and f_E at the 1σ confidence level from 2×10^3 , 5×10^3 , and 1×10^4 LSST simulation SGL systems in the SIS model.

Sample number	Ω_k	$f_{\rm E}$
$2 \times 10^{3} \\ 5 \times 10^{3} \\ 1 \times 10^{4}$	$\begin{array}{c} -0.004 \pm 0.027 \\ -0.005 \pm 0.017 \\ -0.004 \pm 0.012 \end{array}$	$\begin{array}{c} 1.001 \pm 0.004 \\ 1.000 \pm 0.002 \\ 1.000 \pm 0.002 \end{array}$

using a public package LensPop¹, we simulate 2×10^3 , 5×10^3 and 1×10^4 well-measured SGL systems, respectively, to investigate the effect of the increase of data points in SGL sample on improving the constraints on Ω_k . High-quality imaging and spectroscopic data from LSST enable highly precision inferences of Einstein radius and lens velocity dispersion. According to the analysis from Collett & Cunnington (2016), we adopt the fractional uncertainties of observed velocity dispersion and the Einstein radius as 5% and 3%, respectively.

In the framework of the SIS model, the constraint results from combining GWs with 2×10^3 , 5×10^3 , and 1×10^4 mock data from LSST simulation, respectively, are shown in Figure 3 and Table 2. We find that as the number of SGL data increases by an order of magnitude compared to the existing SGL sample, the constraint on Ω_k is improved by an order of magnitude, i.e., $\Omega_k = -0.004 \pm 0.027$, from 2×10^3 simulated SGL systems. This significant improvement is not only contributed by the increase of SGL samples, but also the improvement in the observation precision. However, when the number of SGL data increases by an order of magnitude again, i.e., $\sim 1 \times 10^4$, the constraint on Ω_k is only improved by a factor of ~ 2 , indicating that systematic errors will dominate over statistical errors. Although the constraint on Ω_k here is not as good as the result obtained by the combination of Planck and BAO data (with the error 0.002), it must be emphasized that our constraints are independent of any cosmological model, which will be helpful in solving cosmological tension problem concerning the cosmic curvature in the future.

4 CONCLUSION

With the increasing precision of cosmological observations, tensions in the measurements of some key cosmological parameters has gradually emerged, which is usually viewed to be the measurement inconsistency between the early and late universe. The confusion caused by recent studies concerning cosmic curvature parameter Ω_k suggests that it is necessary to remeasure Ω_k using only the late-universe observations in a cosmological model-independent way. The distance sum rule in SGL provides such a way, provided that the distances in the sum rule can be calibrated by other observations. Usually, SN Ia can be used as a distance indicator to perform the distance calibration in this method. However, SN Ia observation has some drawbacks, such as dependence on distance ladder, narrow redshift range, and so forth. In this work, we propose that GWs can be used to provide the distance calibration in the SGL method, which can avoid the dependence on distance ladder and cover a wider redshift range. We use the simulated GW standard siren observation from the Einstein Telescope as an example to show that this scheme is feasible and advantageous.

Specifically, in the framework of three lens models, namely SIS, EPL1, and EPL2 models, we use 130 current SGL data and 1000 simulated GW standard siren data to estimate Ω_k . We find that the result of the SIS model prefers an open universe at more than 2σ confidence level, while the inferences for Ω_k in EPL1 and EPL2 models are in excellent agreement with a flat universe, which means that the lens-model selection has a strong influence on inferring Ω_k . Moreover, for the constraints on Ω_k in the three lens models, we obtain the most stringent result in the EPL1 model, i.e., $\Omega_k = -0.052^{+0.194}_{-0.154}$, which is slightly tighter than that obtained by using SN Ia as distance indicators. On the whole, we find that these model-independent estimations of Ω_k using only the late-universe observations still somewhat favor a flat universe.

However, it is important to emphasize that although this constraint of Ω_k is independent on cosmological models, it is dependent strongly on lens models in fact. In this paper, the mass distribution of the lens galaxies is assumed to be spherically symmetric, which could characterize well the morphologies of early-type galaxies that are more likely to serve as intervening lenses. Although the sample of SGL we used is obtained with well-defined selection criteria to ensure the validity of the assumption of spherical symmetry, the properties of early-type galaxies as their formation and evolution are still not fully understood. There is still a long way from accurately characterizing the mass distribution of lens galaxies, which is crucial for the unbiased and precise estimation of Ω_k in this way. Fortunately, as future massive surveys observe more and more SGL samples, a more accurate phenomenological model for lens galaxies could be obtained, which will greatly improve the constraint on cosmic curvature.

Then, we further forecast what constraint can be achieved for the spatial curvature in the near future by GW standard sirens from ET and abundant SGL data from the forthcoming LSST survey. We find that about 1×10^4 SGL data combined with 1000 GW standard sirens could achieve a precise constraint of $\Delta\Omega_k \simeq 10^{-2}$. Our results show that the observations of SGL and GWs by the next-generation facilities would improve the late-universe measurement of cosmic curvature by one order of magnitude.
