

# Signal Decomposition Using Masked Proximal Operators

Bennet E. Meyers      Stephen P. Boyd

February 21, 2022

## Abstract

We consider the well-studied problem of decomposing a vector time series signal into components with different characteristics, such as smooth, periodic, nonnegative, or sparse. We propose a simple and general framework in which the components are defined by loss functions (which include constraints), and the signal decomposition is carried out by minimizing the sum of losses of the components (subject to the constraints). When each loss function is the negative log-likelihood of a density for the signal component, our method coincides with maximum a posteriori probability (MAP) estimation; but it also includes many other interesting cases. We give two distributed optimization methods for computing the decomposition, which find the optimal decomposition when the component class loss functions are convex, and are good heuristics when they are not. Both methods require only the masked proximal operator of each of the component loss functions, a generalization of the well-known proximal operator that handles missing entries in its argument. Both methods are distributed, *i.e.*, handle each component separately. We derive tractable methods for evaluating the masked proximal operators of some loss functions that, to our knowledge, have not appeared in the literature.

# 1 Introduction

The decomposition of a signal into components is an age old problem, with many different approaches proposed, including traditional filtering and smoothing, seasonal-trend decomposition, Fourier and other decompositions, PCA and newer variants such as nonnegative matrix factorization, various statistical methods, and many heuristic methods. It is believed that ancient Babylonian mathematicians used harmonic analysis to understand astronomical observations as collections of ‘periodic phenomena’ [Neu69]. (We discuss prior work in detail in §3.)

We formulate the problem of decomposing a signal into components as an optimization problem, where components are described by their loss functions. Once the component class loss functions are chosen, we minimize the total loss subject to replicating the given signal with the components. We give a simple unified algorithm for carrying out this decomposition, which is guaranteed to find the globally optimal decomposition when the loss functions are all convex, and is a good heuristic when they are not. The method accesses the component loss functions only through a modified proximal operator interface, which takes into account that some data in the original signal may be missing. The method is distributed, in that each component class is handled separately, with the algorithm coordinating them.

**Handling of missing data.** Our method is designed to handle missing data in the original signal to be decomposed, a common situation in many practical settings. The signal components in the decomposition, however, do not have any missing data; by summing the components in the decomposition, we obtain a guess or estimate of the missing values in the original signal. This means that signal decomposition can be used as a sophisticated method for guessing or imputing or interpolating missing or unknown entries in a signal. This allows us to carry out a kind of validation or self-consistency check on a decomposition, by pretending that some known entries are missing, and comparing the the imputed values to the known ones.

**Expressivity and interpretability.** By describing a signal component class via its loss function, we can handle more complex components classes than traditional simple ones such as a periodic signal, a trend, a smooth signal, and so on. For example we can define a signal component class that consists of periodic, smooth, and nonnegative signals, or piecewise constant signals that have no more than some specified number of jumps. The resulting decomposition is always interpretable, since we specify the component classes.

**Outline.** We describe our signal decomposition framework in §2, where we pose the signal decomposition problem as an optimization problem, concluding with an illustrative simple example in §2.9. In §3 we cover related and previous work and methods. Our distributed methods for the signal decomposition problem are described in §4. The next three sections concern loss functions for signal component classes: general attributes are described in §5, some example classes in §6, and how to fit component class losses given examples of signals

in the class in §6.3. In the following three sections we present examples with real data: Weekly CO2 measurements at Mauna Loa in §7.1, hourly traffic over a New York bridge in §7.2, and 1-minute power output for a group (fleet) of eight photo-voltaic (PV) installations in §7.3.

**Software.** Our paper is accompanied by an open-source software implementation called OSD, short for ‘Optimization(-based) Signal Decomposition’, available at

<https://github.com/cvxgrp/signal-decomposition>.

## 2 Signal decomposition

### 2.1 Signal decomposition into components

**Vector time series signal with missing entries.** Consider a vector time series or signal, possibly with missing entries,  $y_1, \dots, y_T \in (\mathbf{R} \cup \{?\})^p$ . We denote the  $i$ th entry of  $y_t$  as  $(y_t)_i = y_{t,i}$ . The value ? denotes a missing entry in the signal; we say that entry  $y_{t,i}$  is known if  $y_{t,i} \in \mathbf{R}$ , and unknown if  $y_{t,i} = ?$ . We define  $\mathcal{K}$  as the set of indices corresponding to known values, *i.e.*,  $\mathcal{K} = \{(t, i) \mid y_{t,i} \in \mathbf{R}\}$ . We define  $\mathcal{U}$  as the set of indices corresponding to unknown or missing values, *i.e.*,  $\mathcal{U} = \{(t, i) \mid y_{t,i} = ?\}$ . We represent the signal compactly as a  $T \times p$  matrix  $y \in (\mathbf{R} \cup \{?\})^{T \times p}$ , with rows  $y_1^T, \dots, y_T^T$ .

**The mask operator.** Let  $q = |\mathcal{K}|$  be the total number of known entries in  $y$ , with  $q \leq Tp$ . We introduce the mask operator  $\mathcal{M} : (\mathbf{R} \cup \{?\})^{T \times p} \rightarrow \mathbf{R}^q$ , which simply lists the entries of its argument that are in  $\mathcal{K}$  in a vector, in some known order. We will also use its adjoint  $\mathcal{M}^*$ , which takes a vector in  $\mathbf{R}^q$  and puts them into a  $T \times p$  matrix, in the correct order, with other entries zero. Note that while  $y$  can have missing entries,  $\mathcal{M}y$  does not. We also observe that for any  $z \in \mathbf{R}^{T \times p}$ ,  $\mathcal{M}^* \mathcal{M}z$  is  $z$ , with the entries in  $\mathcal{U}$  replaced with zeros.

**Signal decomposition.** We will model the given signal  $y$  as a sum (or decomposition) of  $K$  components  $x^1, \dots, x^K \in \mathbf{R}^{T \times p}$ ,

$$y_{t,i} = (x^1)_{t,i} + \dots + (x^K)_{t,i}, \quad (t, i) \in \mathcal{K}.$$

We refer to this constraint, that the sum of the components matches the given signal at its known values, as the consistency constraint, which can be expressed as

$$\mathcal{M}y = \mathcal{M}x^1 + \dots + \mathcal{M}x^K. \tag{1}$$

Note that the components  $x^1, \dots, x^K$  do not have missing values. Indeed, we can interpret the values

$$\hat{y}_{t,i} = x_{t,i}^1 + \dots + x_{t,i}^K, \quad (t, i) \in \mathcal{U}, \tag{2}$$

as estimates of the missing values in the original signal  $y$ . (This will be the basis of a validation method described later.)

## 2.2 Component classes

The  $K$  components are characterized by functions  $\phi_k : \mathbf{R}^{T \times p} \rightarrow \mathbf{R} \cup \{\infty\}$ ,  $k = 1, \dots, K$ . We interpret  $\phi_k(x)$  as the loss of or implausibility that  $x^k = x$ . We will see later that in some cases we can interpret the classes statistically, with  $\phi_k(x)$  the negative log-likelihood of  $x$  for signal class  $k$ . Roughly speaking, the smaller  $\phi_k(x)$  is, the more plausible it is. Infinite values of  $\phi_k(x)$  are used to encode constraints on components. We refer to  $x$  as feasible for component class  $k$  if  $\phi_k(x) < \infty$ , and we refer to  $\{x \mid \phi_k(x) < \infty\}$  as the set of feasible signals for component class  $k$ . When a component class takes on the value  $\infty$  for some  $x$ , we say that it contains or encodes constraints; when  $\phi_k$  does not take on the value  $\infty$ , we say the component class has no constraints, or has full domain. We will assume that every component class has at least one feasible point, *i.e.*, a point with finite loss.

We will see many examples of component class losses later, but for now we mention a few simple examples.

**Mean-square small class.** One simple component class has the mean-square loss

$$\phi(x) = \frac{1}{Tp} \sum_{t,i} (x_{t,i})^2 = \frac{1}{Tp} \|x\|_F^2, \quad (3)$$

where  $\|\cdot\|_F$  denotes the Frobenius norm, the squareroot of the sum of squares of the entries. (To lighten the notation, we drop the subscript  $k$  when describing a general component class.) All signals are feasible for this class; roughly speaking, smaller signals are more plausible than larger signals. We call this the component class of mean-square small signals.

We will assume that the first class is always mean-square small, with loss function (3). We interpret  $x^1$  as a residual in the approximation

$$y \approx x^2 + \dots + x^K,$$

and  $\phi_1(x^1)$  as the mean-square error.

**Mean-square smooth class.** The component class of mean-square smooth signals has loss

$$\phi(x) = \frac{1}{(T-1)p} \sum_{t=1}^{T-1} \|x_{t+1} - x_t\|_F^2, \quad (4)$$

the mean-square value of the first difference. Here too all signals are feasible, but smooth ones, *i.e.*, ones with small mean-square first difference, are more plausible.

**Boolean signal class.** As one more simple example, consider the component class with loss function

$$\phi(x) = \begin{cases} 0 & x_{t,i} \in \{0, 1\} \text{ for all } t, i \\ \infty & \text{otherwise.} \end{cases} \quad (5)$$

This component class consists only of constraints, specifically that each entry is either 0 or 1. It has a finite number,  $2^{Tp}$ , of feasible signals, with no difference in plausibility among them. We refer to this class as the Boolean component class.

## 2.3 Signal decomposition problem

We will estimate the components  $x^1, \dots, x^K$  by solving the optimization problem

$$\begin{aligned} & \text{minimize} && \phi_1(x^1) + \dots + \phi_K(x^K) \\ & \text{subject to} && \mathcal{M}y = \mathcal{M}x^1 + \dots + \mathcal{M}x^K, \end{aligned} \tag{6}$$

with variables  $x^1, \dots, x^K$ . We refer to this problem as the *signal decomposition (SD) problem*. Roughly speaking, we decompose the given signal  $y$  into components so as to minimize the total implausibility.

We observe that the entries of the mean-square small component  $x^1$  with indices in  $\mathcal{U}$  do not appear in the constraints, so their optimal value is zero, *i.e.*,  $x^1 = \mathcal{M}^* \mathcal{M}x^1$ . It follows that  $\phi_1(x^1) = \frac{1}{T_p} \|\mathcal{M}x^1\|_2^2$ . We can now eliminate  $x^1$ , and express the SD problem as the unconstrained problem

$$\text{minimize} \quad \frac{1}{T_p} \|\mathcal{M}y - \mathcal{M}x^2 - \dots - \mathcal{M}x^K\|_2^2 + \phi_2(x^2) + \dots + \phi_K(x^K), \tag{7}$$

with variables  $x^2, \dots, x^K$ . From a solution of this problem we can recover an optimal  $x^1$  for (6) from the residual in the first term, as  $x^1 = \mathcal{M}^*(\mathcal{M}y - \mathcal{M}x^2 - \dots - \mathcal{M}x^K)$ .

**Solving the signal decomposition problem.** If the class losses  $\phi_k$  are all convex functions, the SD problem (6) is convex, and can be efficiently solved globally [BV09]. In other cases it can be very hard to find a globally optimal solution, and we settle for an approximate solution. In §4 we will describe two methods that solve the SD problem when it is convex (and has a solution), and approximately solve it when it is not. The first method is based on block coordinate descent (BCD) [BT13, Wri15], and the second is based on ADMM [BPC<sup>+</sup>11], an operator splitting method. Both methods handle each of the component classes separately, using the masked proximal operators of the loss functions (described in §4.1). This gives a very convenient software architecture, and makes it easy to modify or extend it to many component classes.

**Existence and uniqueness of decomposition.** With our assumption that the first component class is mean-square small, and all other component classes contain at least one signal with finite loss, the SD problem is always feasible. But it need not have a solution, or when it does, a unique solution. For example, consider  $K = 2$  with a mean-square small component and a Boolean component. If the  $(t, i)$  entry in  $y$  is unknown, then  $x_{t,i}^2$  can be either 0 or 1, without affecting feasibility or the objective.

## 2.4 Statistical interpretation

We can give our losses a simple statistical interpretation in some cases, which conversely can be used to suggest class losses. Suppose that  $\phi$  is continuous on its domain, with

$$Z = \int \exp -\phi(x) dx < \infty.$$

(The integration is with respect to Lebesgue measure.) We associate with this component class the density

$$p(x) = \frac{1}{Z} \exp -\phi(x).$$

Thus,  $\phi(x)$  is a constant plus the negative log-likelihood of  $x$  under this density, a standard statistical measure of implausibility. Convex loss functions correspond to log-concave densities.

As an example, with the mean-square loss  $\phi(x) = \frac{1}{2Tp} \|x\|_F^2$  (note the additional factor of two in the denominator), the associated density is Gaussian, with the entries of  $x$  IID  $\mathcal{N}(0, 1)$ . As another example, the mean-square smooth component class with loss (4) has  $Z = \infty$ , so we cannot associate it with a density.

When all component classes have  $Z < \infty$ , we can interpret the SD problem statistically. Suppose  $x^1, \dots, x^K$  are independent random variables with densities  $p_1, \dots, p_K$ . Then the SD objective is a constant plus the negative log-likelihood of the decomposition with  $x^1, \dots, x^K$ , and the SD decomposition is the maximum a posteriori probability (MAP) decomposition of the observed signal  $y$ .

## 2.5 Optimality and stationarity conditions

Here we give optimality or stationarity conditions for the SD problem for some special but common cases. In all cases, the conditions include primal feasibility (1), *i.e.*, consistency, and a second condition, dual feasibility, which has a form that depends on the properties of the losses.

**Differentiable losses.** We first suppose that the losses are differentiable. The dual feasibility condition is that there exists a Lagrange multiplier  $\nu \in \mathbf{R}^q$  for which

$$\nabla \phi_k(x^k) = \mathcal{M}^* \nu, \quad k = 1, \dots, K,$$

where  $\nu \in \mathbf{R}^q$  is a dual variable or Lagrange multiplier associated with the consistency constraint (1). In words: the gradients of the losses all agree, and are zero in the unknown entries. If all losses are convex, this condition together with primal feasibility are the necessary and sufficient optimality conditions for the SD problem. If the losses are not all convex, then this condition together with primal feasibility are stationarity conditions; they hold for any optimal decomposition, but there can be non-optimal points that also satisfy them.

Since  $\phi_1(x) = \frac{1}{Tp} \|x\|_F^2$ , we have  $\nabla \phi^1(x) = (2/Tp)x$ . The dual conditions can then be written as

$$x^1 = \mathcal{M}^* \mathcal{M} x^1, \quad \nabla \phi_k(x^k) = \frac{2}{Tp} x^1, \quad k = 2, \dots, K, \quad (8)$$

*i.e.*, the gradients of the component class losses all equal the mean-square residual, scaled by  $2/(Tp)$  in the known entries, and are zero in the unknown entries. These are also the conditions under which the gradients of the objective in the unconstrained SD problem formulation (7) with respect to  $x^2, \dots, x^K$  are all zero.

**Convex losses.** If the losses are convex but not differentiable, we replace the gradients in (8) with subgradients, to obtain

$$x^1 = \mathcal{M}^* \mathcal{M} x^1, \quad g^k = \frac{2}{Tp} x^1, \quad g^k \in \partial \phi_k(x^k), \quad k = 2, \dots, K, \quad (9)$$

where  $\partial \phi_k(x^k)$  is the subdifferential of  $\phi_k$  at  $x^k$ . This condition, together with primal feasibility, are optimality conditions for the SD problem.

**Other cases.** When the losses are neither convex nor differentiable, the stationarity conditions can be very complex, with the gradients in (8) or subgradients in (9) substituted with some appropriate generalized gradients.

## 2.6 Signal class parameters

The component class losses  $\phi_k$  can also have parameters associated with them. When we need to refer to the parameters, we write  $\phi_k(x^k)$  as  $\phi_k(x^k; \theta_k)$ , where  $\theta_k \in \Theta_k$ , the set of allowable parameters. These parameters are fixed whenever we solve the SD problem, but it is common to solve the SD problem for several values of the parameters, and choose one that works well (*e.g.*, using a validation method described later). The role of the parameters  $\theta_k$  will be made clear when we look at examples. For now, though, we mention a few common examples.

**Weight or scaling parameters.** It is very common for a parameter to scale a fixed function, *i.e.*,  $\phi(x; \theta) = \theta \ell(x)$ ,  $\theta \in \Theta = \mathbf{R}_{++}$ , the set of positive numbers. (Of course we can have additional parameters as well.) In this case we interpret the parameters as weights that scale the relative implausibility of the component classes. We will use the more traditional symbol  $\lambda$  to denote scale factors in loss functions, with the understanding that they are part of the parameter  $\theta$ .

**Value and constraint parameters.** Parameters are often used to specify constant values that appear in the loss function. For example we can generalize the Boolean loss function, which constrains the entries of  $x$  to take on values in  $\{0, 1\}$ , to one where the entries of  $x$  take on values in a finite set  $\{\theta_1, \dots, \theta_M\}$ , where  $\theta_i \in \mathbf{R}$ , *i.e.*,

$$\phi(x) = \begin{cases} 0 & x_{t,i} \in \{\theta_1, \dots, \theta_M\} \text{ for all } t, i \\ \infty & \text{otherwise.} \end{cases} \quad (10)$$

In this case, the parameters give the values that the entries of  $x$  are allowed to take on. As another example, consider a loss function that constrains the entries of  $x$  to lie in the interval  $[\theta_1, \theta_2]$  (with  $\theta_1 \leq \theta_2$ ). Here the parameters set the lower and upper limits on the entries of  $x$ .

**Basis.** Another common use of parameters is to specify a basis for the component, as in

$$\phi(x) = \begin{cases} 0 & x = \theta z \text{ for some } z \in \mathbf{R}^{d \times p} \\ \infty & \text{otherwise,} \end{cases} \quad (11)$$

where  $\theta \in \mathbf{R}^{T \times d}$ , and  $z \in \mathbf{R}^{d \times p}$ . This component class requires each column of  $x$ , *i.e.*, the scalar time series associated with an entry of  $x$ , to be a linear combination of the basis (scalar) signals given by the columns of  $\theta$  (sometimes referred to as a dictionary). The entries of  $z$  give the coefficients of the linear combinations; for example, the first column of  $x$  is  $z_{11}\theta_1 + \dots + z_{1d}\theta_d$ , where  $\theta_i$  is the  $i$ th column of  $\theta$ , *i.e.*, the  $i$ th basis signal.

## 2.7 Validation

We can validate, or at least check consistency of, our choice of the component classes and their parameter values. To do this, we select (typically randomly) some entries of  $y$  that are known, denoted  $\mathcal{T} \subset \mathcal{K}$  (for ‘test’), and replace them with the value ?. A typical choice of the number of test entries is a fraction of the known entries, such as 20%. We then carry out the decomposition by solving the SD problem, using the entries  $\mathcal{K} \setminus \mathcal{T}$  of  $y$ . This decomposition gives us estimates or guesses of the entries of  $y$  in  $\mathcal{T}$ , given by (2). Finally, we check these estimates against the true values of  $y$ , for example by evaluating the mean-square test error

$$\frac{1}{|\mathcal{T}|p} \sum_{(t,i) \in \mathcal{T}} (y_{t,i} - \hat{y}_{t,i})^2.$$

A more stable estimate of test error can be found by evaluating the mean-square test error for multiple test sets  $\mathcal{T}^{(1)}, \dots, \mathcal{T}^{(M)}$ , each with the same number of entries, and averaging these to obtain a final mean-square error.

It is reasonable to prefer a model (*i.e.*, choice of component classes and their parameters) that results in small test error, compared to another model with higher test error. The out-of-sample validation method described above can be used to guide the choice of the component classes and parameters that define an SD model.

**Validating with non-unique decompositions.** We note that the basic validation method fails when the SD problem has multiple solutions, or more precisely, when multiple optimal signal decompositions correspond to different values of  $\hat{y}_{t,i}$  for  $(t,i) \in \mathcal{T}$ . One simple work-around is to regard the multiple solutions as each providing an estimate of the missing entry, and to evaluate the test loss using the best of these estimates. For example, suppose the second component class is Boolean, so  $(x^2)_{t,i}$  can have the value 0 or 1 for  $(t,i) \in \mathcal{T}$ . We judge the error using

$$\frac{1}{|\mathcal{T}|p} \sum_{(t,i) \in \mathcal{T}} \min_{x_{t,i}^2 \in \{0,1\}} (y_{t,i} - \hat{y}_{t,i})^2.$$

**Parameter search.** As is standard in machine learning and data fitting, it is common to carry out multiple decompositions with the same loss functions but different parameters, and validate each of these choices on one or more test sets, as described above. We then choose as our final parameter values ones correspond to the lowest achieved test error. As in machine learning and data fitting, the final decomposition is then fit with all known data, using the parameter values found in the parameter search.

## 2.8 Data pre-processing

As in other data processing problems, pre-processing the raw data is often useful, leading to better results or interpretability.

**Standardization.** The most basic pre-processing is to standardize the entries of  $y$ , with a scale and offset for each component that results in the average value being around zero and the standard deviation around one. In some cases, for example when the entries of  $y$  are all measured in the same physical units, it can be more appropriate to use the same scaling for all components of  $y$ .

**Log transform.** If the data are all positive and vary over a large range of values, a log transform of the raw data can be appropriate. Roughly speaking, this means that we care about relative or fractional deviations, as opposed to absolute errors in the raw data, *e.g.*, we consider the values 10 and 11 to be as close as the values 1000 and 1100. With a log transform, the signal decomposition has an interpretation as a multiplicative decomposition (in the raw data), as opposed to an additive decomposition. If we denote the raw data as  $\tilde{y}$  and the transformed data as  $y = \log \tilde{y}$  (entrywise), and our decomposition is  $y \stackrel{\mathcal{K}}{=} x^1 + \dots + x^K$ , in terms of the raw data we have

$$\tilde{y}_{t,i} = \tilde{x}_{t,i}^1 \cdots \tilde{x}_{t,i}^K, \quad (t, i) \in \mathcal{K},$$

where  $\tilde{x}^i = \exp x^i$  (entrywise),  $i = 1, \dots, K$ . The signals  $\tilde{x}^i$  can be thought of as multiplicative factors.

## 2.9 Simple example

In this section we give a simple synthetic example to illustrate the idea.

**Signal decomposition model.** We construct an SD problem with  $p = 1$  (*i.e.*, a scalar signal),  $T = 500$ , and  $K = 3$  component classes: mean-square small, mean-square second-order smooth, and a scaled Boolean. For mean-square small we use loss function (3), and for mean-square second order smooth we use the loss

$$\phi_2(x) = \frac{\theta_1}{(T-2)p} \sum_{t=2}^{T-1} (x_{t+1} - 2x_t + x_{t-1})^2, \quad (12)$$

where  $\theta_1$  is a positive weight parameter. For the Boolean component class, we require that all entries of  $x$  are in  $\{0, \theta_2\}$ , where  $\theta_2$  is another positive parameter. Our SD problem contains two signal class parameters,  $\theta_1$  and  $\theta_2$ . Since  $\phi_3$  is not convex, the SD problem is not convex. (Nevertheless our method does a good job at approximately solving it.)

**Data generation.** We generate a signal  $y$  of length  $T = 500$  as a sum of three ‘true’ signal components, one that is Gaussian noise, one that is smooth, and one that is Boolean, *i.e.*, takes on only two values. The first signal, denoted  $\tilde{x}^1 \in \mathbf{R}^T$ , has IID entries  $\mathcal{N}(0, 0.1^2)$ . The second true component is the quasiperiodic signal with three frequencies

$$\tilde{x}_t^2 = \sum_{j=1}^3 a_j \cos(\omega_j t + \delta_j), \quad t = 1, \dots, T,$$

where  $a_j > 0$  are the amplitudes,  $\omega_j > 0$  are the frequencies, and  $\delta_j \in [0, 2\pi]$  are the phases, all chosen randomly. The last true component signal  $\tilde{x}^3$  has the form

$$\tilde{x}_t^3 = \begin{cases} \tilde{\theta}_2 & \sum_{j=1}^3 a'_j \cos(\omega'_j t + \delta'_j) \geq 0 \\ 0 & \sum_{j=1}^3 a'_j \cos(\omega'_j t + \delta'_j) < 0, \end{cases}$$

for  $t = 1, \dots, T$ , where  $a'_j$ ,  $\omega'_j$ , and  $\delta'_j$  are a different set of amplitudes, frequencies, and phases, also chosen randomly. We construct our signal as

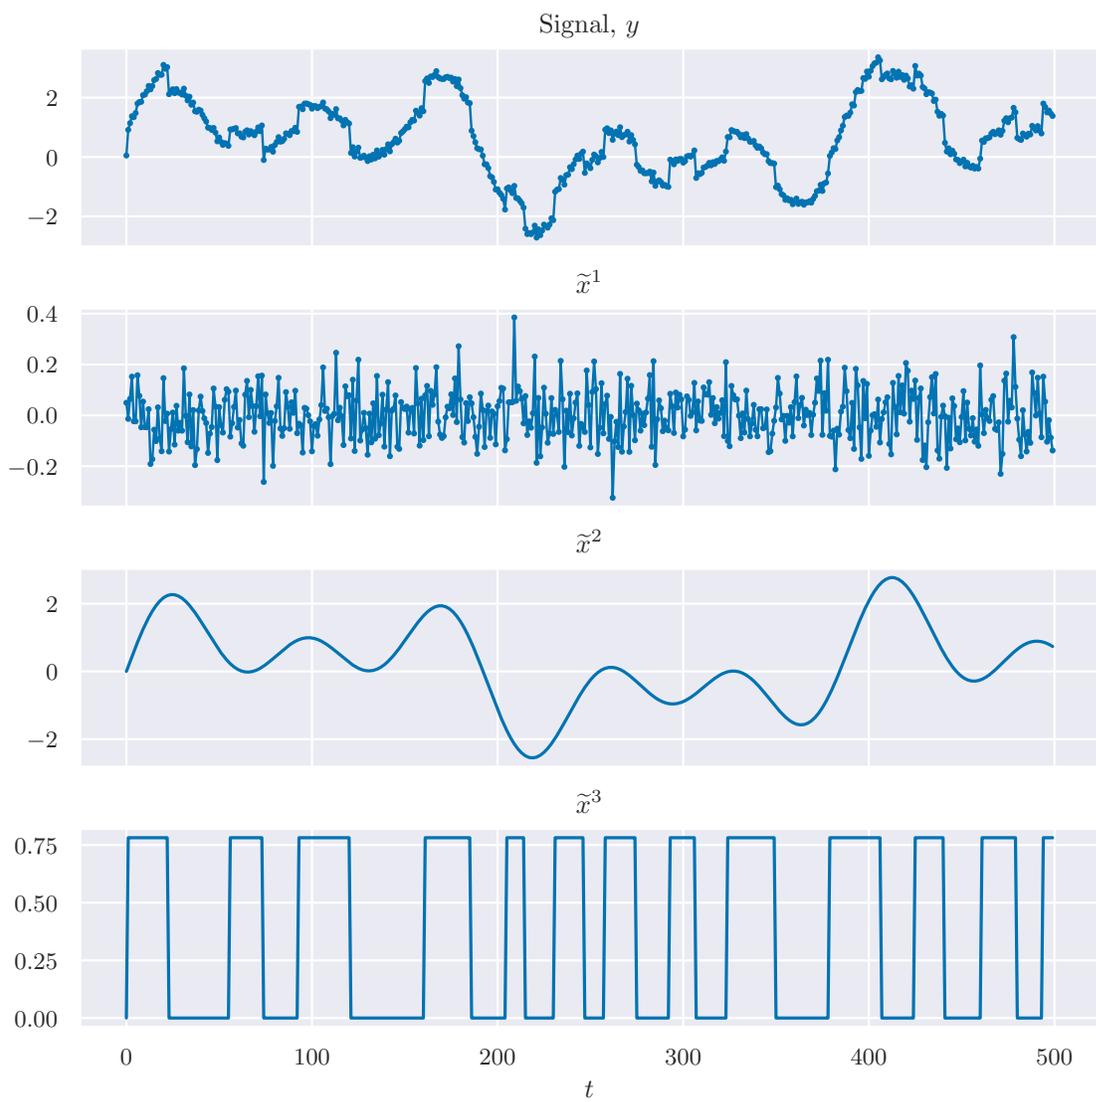

$$y = \tilde{x}^1 + \tilde{x}^2 + \tilde{x}^3,$$

with  $\tilde{\theta}_2$  (the ‘true’ value of  $\theta_2$ ) chosen randomly. The signal  $y$  and the three true components  $\tilde{x}^i$  are shown in figure 1. The data in this example have no missing entries.

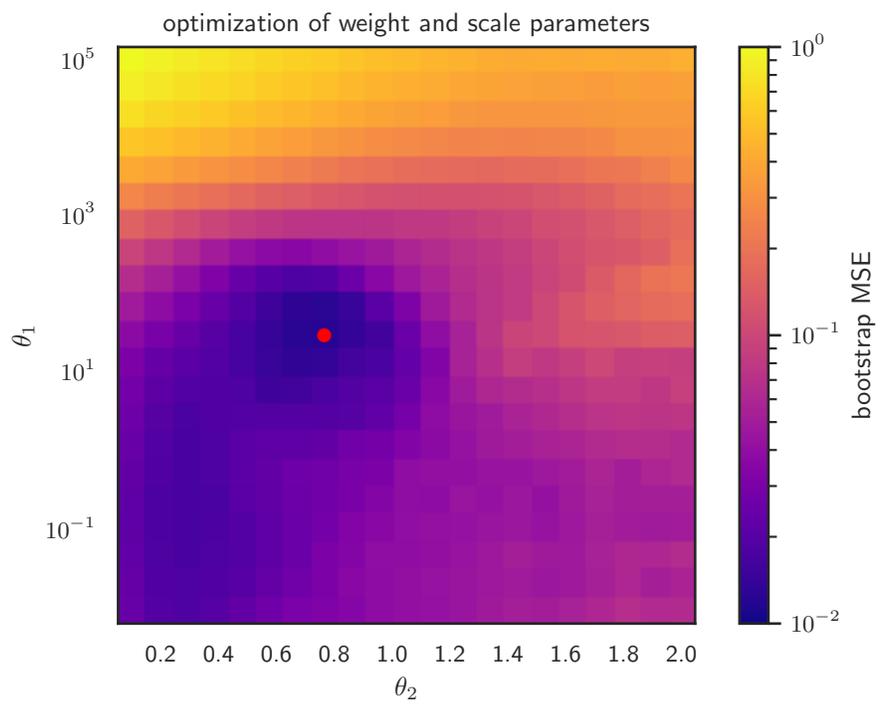

**Parameter search.** We use our method (described in detail later) to approximately solve the SD problem for a grid of 21 values of  $\theta_1$ , logarithmically spaced between  $10^{-1}$  and  $10^6$ , and 21 values of  $\theta_2$ , linearly spaced between 0.1 and 2.0, for a total of 441 different values of the parameters. For each of these, we evaluate the test error using 10 random selections of the test set as described above. Thus all together we solved 4410 instances of the SD problem, which took about 13 minutes on a 2016 MacBook Pro. Each SD problem took about 0.17 seconds to solve. (We solved the problems sequentially, but the computation is embarrassingly parallel and could have been carried out faster using more processors.)

The mean-square test error for the parameter grid search is shown as a heat map in figure 2. We use the final values  $\theta_1 = 320$ ,  $\theta_2 = 0.765$ , which achieved the smallest mean-square test error. Having chosen  $\theta_1$  and  $\theta_2$ , we approximately solve the SD problem one final time, using all the data.

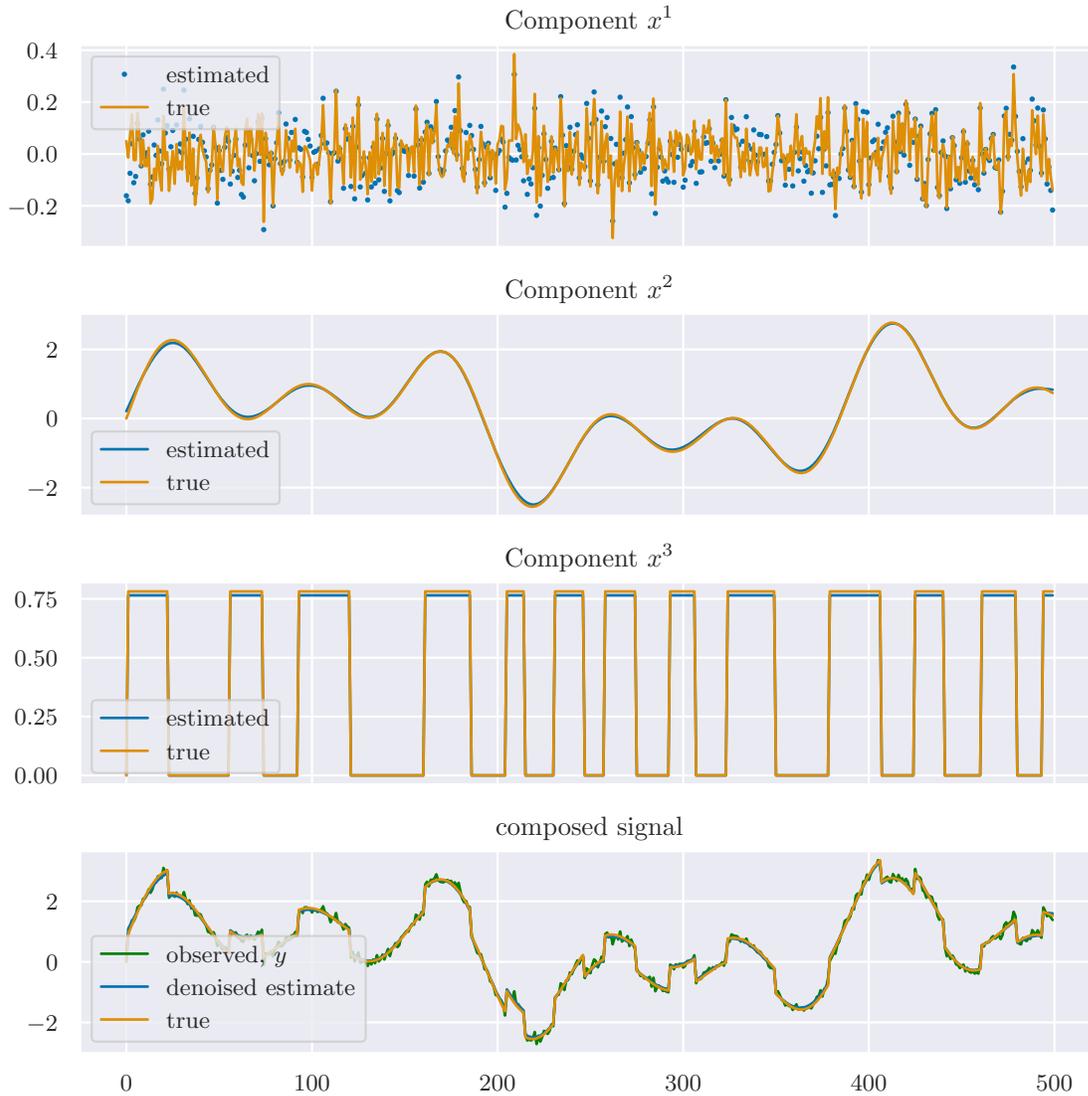

There is some discrepancy between the value we find  $\theta_2 = 0.765$  and the true value used to generate the data,  $\tilde{\theta}_2 = 0.7816$ , due to the discreteness of the grid search. (In a real application, we might do a secondary, refined grid search of values near the best ones found in this crude grid search.)

**Figure 1:** Synthetic data for simple signal decomposition example.

**Figure 2:** Validation mean-square test error as a function of the parameters  $\theta_1$  and  $\theta_2$ .

**Figure 3:** Signal decomposition for simple example. The top three plots show the true component and the estimated component. The bottom plot shows the original signal  $y$  and  $x^2 + x^3$ , *i.e.*, our decomposition without the residual component  $x^1$ .

**Final decomposition.** The final decomposition is shown in figure 3. Evidently the decomposition is quite good. The Boolean component is exactly reconstructed, aside from the slight discrepancy in its amplitude. The smooth component is also well reconstructed, with an RMS (root mean-square) error about 0.04.

### 3 Related work

Here we discuss a wide variety of methods that relate to the SD problem, some of which are quite old. Many methods listed here do not explicitly form an optimization problem, and when they do, it need not be the same as our SD problem.

**Regression.** Least-squares linear regression is a particular instance of the SD problem, with two component classes, a mean-square small component, and a component defined by a basis (11), with the basis components the regressors or features. This SD problem instance admits a well-known, closed form solution [BV18, §12]. The idea of solving an over-determined system of linear equations by minimizing the sum of the squares of the errors was proposed independently by the mathematicians Carl Friedrich Gauss and Adrien-Marie Legendre around the beginning of the 19th century. Statistical justifications for this fitting procedure were subsequently provided by Gauss, Laplace, Cauchy, and Thiele, among others [Far01].

**Robust regression.** Robust regression covers a variety of techniques to reduce model variance in the presence of data ‘outliers,’ which is a term without a precise definition but can be thought of as data points that are not well explained by a linear regression model. Common methods include Huber regression [Hub64, Hub81], Theil-Sen estimation [The50, Sen68], and RANSAC [FB81], which are included in the popular Python package, `scikit-learn` [PVG<sup>+</sup>11]. In the SD framework, the residual component class used in linear regression is substituted with an alternative penalty function that is less sensitive to outliers. The penalty function formulation is discussed in detail in [BV09, §6.1 and §6.4]. Interestingly, the idea of minimizing the sum of absolute errors in an over-determined system of equations actually predates the development of least-squares minimization, having been proposed in the mid-18th century by Roger Joseph Boscovich [FB81]. In the SD framework, robust regression is modeled using two residual classes, one the standard mean-square small, and the other a loss function that grows slowly for large values, like the average absolute loss

$$\phi(x) = \frac{1}{Tp} \|x\|_1 = \frac{1}{Tp} \sum_{t=1}^T \sum_{i=1}^p |x_{t,i}|. \quad (13)$$

(This same loss is used as a convex heuristic for a sparse signal, *i.e.*, one with many entries zero.)

**Regularized regression.** Regularized regression, also known as penalized regression or shrinkage methods, is a family of estimators that introduce an additional penalty term on coefficients of a linear regression problem. Well known examples include ridge regression [Tik63, Phi62, HK70], lasso regression [Tib96], and elastic-net regression [ZH05]. An overview of different regularizer functions for regression is given in [BV09, §6.3], and a review of other regressor selection methods is given in [HTF13, Ch. 3–4]. In the SD framework, regularized regression is modeled by extending the basis class (11) with an additional loss term on the internal variable, as in

$$\phi(x) = \begin{cases} \ell(z) & x = \theta z \text{ for some } z \in \mathbf{R}^{d \times p} \\ \infty & \text{otherwise.} \end{cases}$$

**Sparse dictionary methods.** These methods are concerned with representing signals as superpositions of parameterized waveforms. Unlike in standard least-squares regression, which has an under-complete basis matrix, this approach assumes an over-complete matrix of waveforms, called a dictionary. A popular method for solving this class of problem is called basis pursuit [CD95, CDS01]. As with the regularized regression case, this is a specific instance of the SD problem, with a mean-square small component and a linear-basis component with an  $\ell_1$  penalty on the basis coefficients.

**Isotonic regression.** In isotonic (or monotonic) regression we fit a given signal with a non-decreasing (or non-increasing) signal [BC90, WWM01]. This is a particular instance of the SD problem, with  $p = 1$  and  $K = 2$  component classes: a sum-of-squares small residual and a monotone component, which has a loss function that is zero if its argument is non-decreasing and infinite otherwise. An efficient algorithm, with complexity linear in  $T$ , is included in `scikit-learn` [PVG<sup>+</sup>11]. A detailed discussion of a linear time algorithm and the connection to projection operators is given in [GW84].

**Trend filtering.** Trend filtering, also called signal smoothing, is the process of estimating a slowly varying trend from a scalar time series that includes rapidly varying noise. In many cases this is also a special case of SD, with a mean-square residual component and a component that is slowly varying, for example, with a mean-square second difference loss function. Trend filtering has been employed in a wide variety of applications and settings, including astrophysics [Tit85], geophysics [BC02, Blo92, BN92], social sciences [Lev04], biology [LS94], medicine [GL92], image processing [TK93], macroeconomics [HP97, Sin88], and financial time series analysis [Tsa05, §11]. Many specific trend filtering methods have been proposed, including moving-average filtering [Osb95] and Hodrick-Prescott (HP) filtering [HP97, Les61] being two of the most well known. More recently, Kim et al. have proposed  $\ell_1$  trend filtering [KKBG09], which uses as component loss function the  $\ell_1$  norm of the second difference, which tends to result in piecewise affine signals (see §6.2 for an example). A Bayesian interpretation of trend filtering and signal denoising is presented in [Tit85, TK93, BS93, CP11].

**Seasonal-trend decomposition.** Seasonal-trend decomposition was originally motivated by the analysis of economic data which tend to have strong seasonality; this method is arguably what most people think of when they hear the term “time series decomposition,” having first been proposed in the 1920s as a natural extension of moving average smoothing [And27]. Seasonal-trend decomposition is the only one presented in the chapter on time series decomposition in Hyndman and Athanasopoulos [HA18, §6]. A popular algorithm that implements a specific method for seasonal-trend decomposition is STL [CCMT90], with packages available for Python, R, and Matlab [STLa, STLb, STLc].

STL can be considered a specific case of the SD problem, with a scalar signal  $y$  and  $K = 3$  component classes, *i.e.*, seasonal, trend, and residual. However, STL does not formulate the method as an optimization problem and uses an iterative heuristic to form the estimates of the components.

**Traditional frequency domain filtering.** Traditional EE-style filtering (*e.g.*, [OS10]) can be interpreted as a form of SD. For example, low pass filtering decomposes a signal into a smooth component (the filter output) and a small, rapidly varying component (the residual, or difference of the original signal and the low pass signal). This can often be represented as SD with two components, a residual and a smooth or low-pass component with appropriate time-invariant quadratic loss function. A traditional filter bank can be interpreted as giving a decomposition of a signal into multiple components, each one corresponding to a different region (or sub-band) in the spectrum of the signal.

**Contextually supervised source separation (CSSS).** This is an optimization-based framework for solving signal decomposition problems, in which the signal components are assumed to be roughly correlated with known basis vectors [WK13], and is very similar in many ways to the method presented in this paper. CSSS is extensible, allowing for different loss terms on the linear representations, component estimates, and linear fit coefficients. The SD formulation proposed in this paper is a further generalization of contextually supervised source separation, and the proposed solution method in §4 solves all instances of contextually supervised source separation as a subset of all SD problems.

**Infimal convolution.** The infimal convolution of functions  $f_i : \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i = 1, \dots, K$  denoted  $f_1 \square \dots \square f_K$ , is defined as

$$(f_1 \square \dots \square f_K)(v) = \inf \{ f_1(x^1) + \dots + f_K(x^K) \mid v = x^1 + \dots + x^K \}$$

as described (for convex functions) in [Roc70, §16] and [PB13, §3.1]. The case of nonconvex functions was considered in [PR96]. We see that the SD problem, with no missing data, is the problem of evaluating the infimal convolution of our component loss functions, on the given signal  $y$ .

**Proximal operator.** The proximal operator of a function  $f$  arises often in optimization, and is the basis of our solution methods. The details are given below, but we note there that

evaluating a proximal operator of the function  $f$  is an SD problem (again, with no missing data) with a mean-square loss and the loss  $f$ .

## 4 Solution methods

In this section we describe two related methods for solving the SD problem (when it is convex), and approximately solving it (when it is not convex). Both rely on the masked proximal operators of the component class losses.

### 4.1 Masked proximal operator

Recall that the *proximal operator* [Mor62, PB13] of  $\phi_k$  is defined as

$$\begin{aligned} \mathbf{prox}_{\phi_k}(v) &= \operatorname{argmin}_x \left( \phi_k(x) + \frac{\rho}{2} \|x - v\|_F^2 \right) \\ &= \operatorname{argmin}_x \left( \phi_k(x) + \frac{\rho}{2} \sum_{t,i} (x_{t,i} - v_{t,i})^2 \right), \end{aligned}$$

where  $\rho$  is a positive parameter, and  $v \in \mathbf{R}^{T \times p}$ . When  $\phi_k$  is convex, the function minimized is strictly convex, so there is a unique argmin. When  $\phi_k$  is not convex, there can be multiple argmins; we simply choose one.

The *masked proximal operator* is defined as

$$\begin{aligned} \mathbf{mprox}_{\phi_k}(v) &= \operatorname{argmin}_x \left( \phi_k(x) + \frac{\rho}{2} \|\mathcal{M}(x - v)\|_2^2 \right) \\ &= \operatorname{argmin}_x \left( \phi_k(x) + \frac{\rho}{2} \sum_{(t,i) \in \mathcal{K}} (x_{t,i} - v_{t,i})^2 \right). \end{aligned}$$

Roughly speaking, it is the proximal operator, with the norm term only taken over known entries. (The masked proximal operator depends on  $\mathcal{K}$ , but we suppress this dependency to keep the notation lighter.) The function minimized in the masked proximal operator need not have a unique minimizer, even when  $\phi_k$  is convex. In this case, we simply pick one.

When the function  $\phi_k$  takes on the value  $\infty$  (*i.e.*, encodes constraints), the point  $x = \mathbf{mprox}_{\phi_k}(v)$  is feasible, *i.e.*, satisfies  $\phi_k(x) < \infty$ . We also note that  $\mathbf{mprox}_{\phi_k}(v)$  does not depend on  $v_{t,i}$  for  $(t, i) \in \mathcal{U}$ , so we have

$$\mathbf{mprox}_{\phi_k}(v) = \mathbf{mprox}_{\phi_k}(\mathcal{M}^* \mathcal{M}v). \tag{14}$$

When there are no unknown entries, *i.e.*,  $\mathcal{U} = \emptyset$ , the masked proximal operator reduces to the standard proximal operator. There is another simple connection between the proximal operator and the masked proximal operator. Starting with a loss function  $\phi$ , we define the function

$$\tilde{\phi}(z) = \inf \{ \phi(\mathcal{M}^* \mathcal{M}z + u) \mid \mathcal{M}u = 0 \},$$

which is, roughly speaking, the original loss function where we minimize over the unknown entries in  $y$ . If  $\phi$  is convex, so is  $\tilde{\phi}$ , since it is its partial minimization [BV09, §3.2.5]. The masked proximal operator is then

$$\mathbf{mprox}_{\phi}(v) = \mathbf{prox}_{\tilde{\phi}}(v),$$

the proximal operator of the partially minimized loss function.

For many component loss functions we can work out the masked proximal operator analytically. In many other cases we can compute it with reasonable cost, often linear in  $T$ , the length of the signals. The monographs [PB13, §6] and [BPC+11] discuss the calculation of proximal operators in depth and list many well known results. Many closed form proximal operators are listed in the appendix of [CP11]. Many of these have straightforward extensions to the masked proximal operator.

As a final generalization, we introduce the *weighted* proximal operator, which we define as

$$\mathbf{wprox}_{\phi_k}(v) = \underset{x}{\operatorname{argmin}} \left( \phi_k(x) + \frac{\rho}{2} \sum_{(t,i) \in \mathcal{K}} w_{t,i} (x_{t,i} - v_{t,i})^2 \right),$$

with nonnegative weights  $w_{t,i} \in \mathbf{R}_+$  for all  $(t,i) \in \mathcal{K}$ . The weighted proximal operator arises in the evaluation of certain masked proximal operators, as discussed in §5.3 and §5.4. When all the weights are one, the weighted proximal operator coincides with the masked proximal operator.

**Proximal operator as SD problem.** We note that the proximal operator itself can be seen as a simple instance of an SD problem, with  $v$  playing the role of  $y$ , and components  $x$  and  $v - x$ , with associated loss functions  $\phi_k$  and  $(\rho/2) \|\cdot\|_F^2$ , respectively. The masked proximal operator is the version of this signal decomposition problem with missing entries in  $v$ .

Thus, evaluating the masked proximal operator is the same as solving a simple SD problem with two components, one of which is scaled mean-square small. Our algorithms, described below, solve (or approximately solve) the general SD problem by iteratively solving these simple two component SD problems for each component.

**Surrogate gradient.** When  $\phi$  is convex, the optimality condition for evaluating the masked proximal operator  $x = \mathbf{mprox}_{\phi}(v)$  tells us that

$$g = \rho \mathcal{M}^* \mathcal{M}(v - x) \in \partial\phi(x), \tag{15}$$

where  $\partial\phi(x)$  is the subdifferential (set of all subgradients) of  $\phi$  at  $x$ . So evaluating the masked proximal operator at a point  $v$  automatically gives us a subgradient of the loss at the image point  $x = \mathbf{mprox}_{\phi}(v)$ . When  $\phi$  is not convex, we can interpret  $g$  in (15) as a surrogate gradient.

**Stopping criterion.** In both of our algorithms,  $x^2, \dots, x^K$  are found by evaluating the loss function masked proximal operators, *i.e.*,

$$x^k = \mathbf{mprox}_{\phi_k}(v^k), \quad k = 2, \dots, K,$$

for some  $v^k$ . (The particular  $v^k$  used to find  $x^k$  depend on which algorithm is used, but each of them satisfies  $v^k = \mathcal{M}^* \mathcal{M} v^k$ , *i.e.*, they are zero in the unknown entries of  $y$ .) We define  $x^1 = \mathcal{M}^* \mathcal{M}(y - x^2 - \dots - x^K)$ , so  $x^1, \dots, x^K$  are feasible and  $x^1 = \mathcal{M}^* \mathcal{M} x^1$ .

We combine (9) with (15) and define the optimality residual  $r$  as

$$r = \left( \frac{1}{K-1} \sum_{k=2}^K \left\| \rho \mathcal{M}^* \mathcal{M}(v^k - x^k) - \frac{2}{Tp} x^1 \right\|_F^2 \right)^{1/2}, \quad (16)$$

which can be written as

$$r = \left( \frac{1}{K-1} \sum_{k=2}^K \left\| \mathcal{M} \left( \rho(v^k - x^k) - \frac{2}{Tp} x^1 \right) \right\|_2^2 \right)^{1/2}.$$

When  $r = 0$  and the losses are convex,  $x^1, \dots, x^K$  are optimal.

Both of our algorithms use the standard stopping criterion

$$r \leq \epsilon^{\text{abs}} + \epsilon^{\text{rel}} \left\| \frac{2}{Tp} x^1 \right\|_F = \epsilon^{\text{abs}} + \epsilon^{\text{rel}} \left\| \frac{2}{Tp} \mathcal{M} x^1 \right\|_2, \quad (17)$$

where  $\epsilon^{\text{abs}}$  and  $\epsilon^{\text{rel}}$  are specified positive absolute and relative tolerances.

## 4.2 Block coordinate descent algorithm

The BCD algorithm repeatedly minimizes the objective in (7),

$$\frac{1}{Tp} \left\| \mathcal{M} y - \mathcal{M} x^2 - \dots - \mathcal{M} x^K \right\|_2^2 + \phi_2(x^2) + \dots + \phi_K(x^K),$$

over a single (matrix) variable  $x^k$ , holding the other variables fixed. Minimizing the objective over  $x^k$ , with  $x^i$  fixed for  $i \neq k$ , is the same as evaluating the masked proximal operator of  $\phi_k$ :

$$x^k = \mathbf{mprox}_{\phi_k} \left( y - \sum_{i \neq k} x^i \right)$$

with parameter  $\rho = 2/(Tp)$ . (Note that the masked proximal operator does not depend on the entries of its argument that are unknown in  $y$ .) There are many choices for the sequence in which we minimize over the variables, but we will use the simplest round-robin method, updating  $x^2$ , then  $x^3$ , and on to  $x^K$ , and then back to  $x^2$  again. This gives the SD-BCD algorithm described below, with superscript  $j$  on the variables denoting iteration number, where an iteration consists of one cycle of (successively) minimizing over  $x^2, \dots, x^K$ .

---

**Algorithm 4.1** BLOCK COORDINATE DESCENT ALGORITHM FOR SD PROBLEM (SD-BCD)

*Initialize.* Set  $(x^k)^0$ ,  $k = 2, \dots, K$ , as some initial estimates.

**for** iteration  $j = 0, 1, \dots$

**for** component class  $k = 2, \dots, K$

*Update a component using masked proximal operator.*

$$(x^k)^{j+1} = \mathbf{mprox}_{\phi_k} \left( y - \sum_{i < k} (x^i)^{j+1} - \sum_{j > k} (x^i)^j \right).$$

---

In SD-BCD we use the most recently updated value for the other components, in Gauss-Seidel fashion. Since we fix  $\rho = 2/(Tp)$ , this algorithm contains no parameters to tune. Note that SD-BCD accesses the component class loss functions only through their masked proximal operators; in particular we never evaluate  $\phi^k$  or its derivatives.

**Stopping criterion.** We evaluate the stopping criterion (17) at the end of each iteration, using  $x^1 = \mathcal{M}^* \mathcal{M}(y - x^2 - \dots - x^K)$  and  $v^k$  the argument of the proximal operator in SD-BCD.

**Convergence.** SD-BCD is evidently a descent algorithm, *i.e.*, the objective is nonincreasing in each iteration. (In fact, it is nonincreasing after each update of one of the components.) Well known simple examples show that block coordinate descent need not converge to an optimal point even when the objective is convex. There is a large body of literature on the convergence of block coordinate descent type methods. Some recent review papers include [Wri15, BT13, RT14] and a classic textbook that addresses the topic is [Ber16, §3.7]. These convergence proofs often rely on randomly permutating the block update order, but we have found this has no practical effect on the convergence of SD-BCD. None of cited literature exactly proves the convergence of the algorithm presented here, so we give a simple proof that any fixed point of SD-BCD must be optimal, when the losses are all convex. When one or more loss functions are not convex, the algorithm may (and often does) converge to a non-optimal stationary point.

**Fixed point of SD-BCD.** Here we show that if  $x^2, \dots, x^K$  are a fixed point of SD-BCD, and the losses are all convex, then the decomposition is optimal. If these variables are a fixed point, then for  $k = 2, \dots, K$ ,

$$x^k = \mathbf{mprox}_{\phi_k} \left( y - \sum_{i \geq 2, i \neq k} x^i \right).$$

From these and (15) we find that for  $k = 2, \dots, K$ ,

$$\begin{aligned}
g^k &= \frac{2}{Tp} \mathcal{M}^* \mathcal{M} \left( y - \sum_{i \geq 2, i \neq k} x^i - x^k \right) \\
&= \frac{2}{Tp} \mathcal{M}^* \mathcal{M} \left( y - \sum_{i=2}^K x^i \right) \\
&= \frac{2}{Tp} x^1 \\
&\in \partial \phi_k(x^k),
\end{aligned}$$

where in the third line we use  $x^1 = \mathcal{M}^* \mathcal{M}(y - \sum_{i=2}^K x^i)$ . This is the optimality condition (9).

### 4.3 ADMM algorithm

Here we introduce an operator splitting method for the SD problem. The particular operator splitting method we use is the alternating directions method of multipliers (ADMM) [GM75, GM76, BPC<sup>+</sup>11]. The ADMM algorithm we develop for the SD problem is closely related to the sharing problem [BPC<sup>+</sup>11, §7.3] and the optimal exchange problem [BPC<sup>+</sup>11, §7.3.2], but not the same. The algorithm uses a scaled dual variable  $u \in \mathbf{R}^q$ , and we denote iteration number with the superscript  $j$ .

---

**Algorithm 4.2** ADMM FOR SD PROBLEM (SD-ADMM)

*Initialize.* Set  $u^0 = 0 \in \mathbf{R}^q$ , and  $(x^k)^0 \in \mathbf{R}^{T \times p}$ ,  $k = 1, \dots, K$ , as some initial estimates

**for** iteration  $j = 0, 1, \dots$

1. *Evaluate masked proximal operators of component classes in parallel.*

$$(x^k)^{j+1} = \mathbf{mprox}_{\phi_k}((x^k)^j - 2\mathcal{M}^*u^j), \quad k = 1, \dots, K.$$

2. *Dual update.*

$$u^{j+1} = u^j + \frac{1}{K} \left( \sum_{k=1}^K \mathcal{M}(x^k)^{j+1} - \mathcal{M}y \right).$$

---

A detailed derivation of this algorithm is given in appendix §A. Unlike BCD, SD-ADMM is not a descent method. It is also not a feasible method: the iterates satisfy the consistency constraint  $\mathcal{M}y = \mathcal{M}x^1 + \dots + \mathcal{M}x^K$  only in the limit.

**Interpretations.** From the dual update, we see that  $u^j$  is the running sum of the residual in the consistency constraint, scaled by  $1/K$ ; this term is used in the argument of the masked proximal operator to drive  $x^k$  to optimality.

**Convergence with convex losses.** When  $\phi_k$  are all convex, SD-ADMM converges to a solution, and  $\rho u^j$  converges to an optimal dual variable  $\nu$  [BPC<sup>+</sup>11, §3.2]. In particular, the consistency constraint (1) holds asymptotically.

**Convergence with nonconvex losses.** When any of the loss functions is nonconvex, there are no convergence guarantees at all. The ADMM algorithm need not converge, and if it converges it need not converge to a solution of the SD problem. But it has been observed in practice that ADMM, when applied to nonconvex problems, often converges to a useful value, which in our case is a useful signal decomposition; see, *e.g.*, [BPC<sup>+</sup>11, §9].

**Stopping criterion and final decomposition.** The consistency constraint generally does not hold for the iterates. To obtain a decomposition that satisfies the consistency constraint, we can simply absorb the residual in the consistency constraint into  $x^1$  to obtain a feasible signal decomposition. We can then evaluate the residual in (17), with  $v^k$  the arguments of the proximal operators in step 1 of SD-ADMM.

**Choice of  $\rho$ .** When the problem is convex, SD-ADMM converges to a solution for any positive value of the algorithm parameter  $\rho$ , although the practical convergence speed can be affected the choice of  $\rho$ . The natural value  $\rho = 2/(Tp)$  seems to give good performance in practice. When the problem is not convex, the choice of  $\rho$  is more critical, and can affect whether or not the algorithm converges, and when it converges, the decomposition found. For such problems too, the natural choice  $\rho = 2/(Tp)$  seems to often give good results, although we have found that scaling this value can improve the practical convergence for some nonconvex problems. We take  $\rho = 2\eta/(Tp)$ , with  $\eta$  in the range between 0.5 and 2.

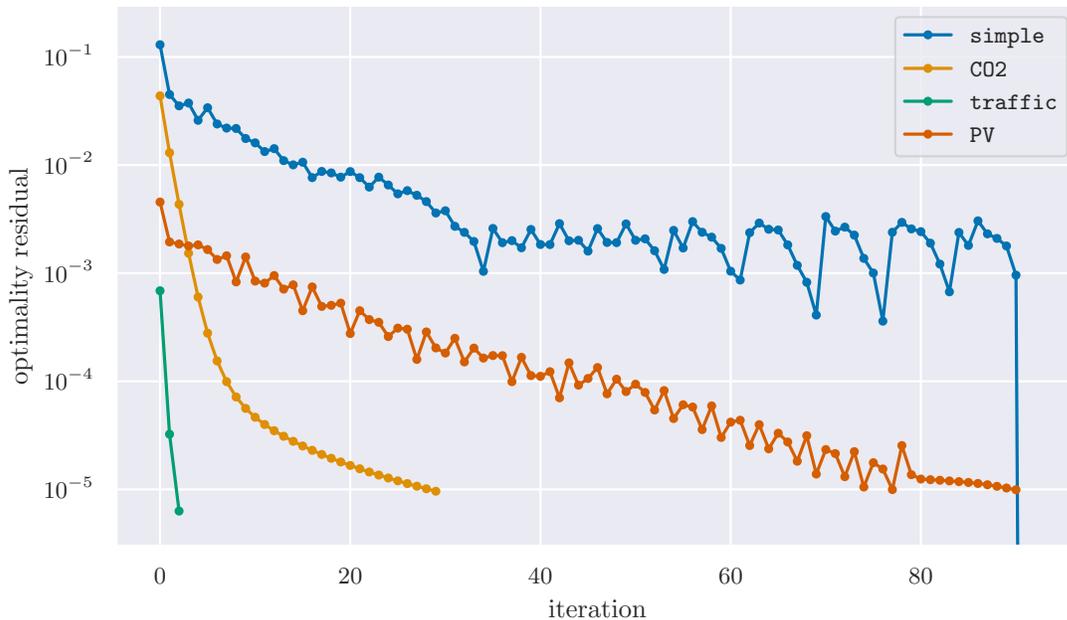

## 4.4 Hybrid algorithms

**Comparison of SD-BCD and SD-ADMM.** For convex SD problems, SD-BCD often outperforms SD-ADMM, but not by much. For nonconvex SD problems, we have found that SD-ADMM often outperforms SD-BCD in the quality of the decomposition found. Specifically, CD-BCD often ends up converging to a poor local minimum, whereas SD-ADMM is able to find a much better (lower objective) decomposition. On the other hand, for nonconvex SD problems, one or two iterations of SD-BCD, starting from the decomposition found by SD-ADMM, can lead to a modest improvement in the objective value found. (These iterations cannot increase the objective, since SD-BCD is a descent method.)

**Hybrid methods.** A reasonable strategy, and the default in our implementation, is to use SD-BCD if the SD problem is convex. If the SD problem is nonconvex, the default uses SD-ADMM (with scale factor  $\eta = 0.7$ ) until convergence, and then follows this with SD-BCD, again run until convergence (quite often, but not always, only a few iterations). This hybrid method seems to work well on a wide variety of SD problems.

**Table 1:** Summary of numerical examples

Name	Section	$K$	$T$	$p$	Size ( $KTp$ )	$q$	Convex
simple	§2.9	3	500	1	1,500	500	no
C02	§7.1	3	2,459	1	7,377	2,441	yes
traffic	§7.2	5	105,552	1	527,760	101,761	yes
PV	§7.3	5	20,212	7	707,420	135,899	no

**Figure 4:** Residual versus iteration number for the 4 numerical examples given in §2.9, §7.1, §7.2, and §7.3 respectively.

**Numerical examples.** In this paper we consider four numerical examples, summarized in table 1. They include convex and nonconvex problems, and range from small to large, with the SD problem in PV having over 700,000 variables. We use these examples to illustrate the convergence of the hybrid algorithm. In figure 4 we plot the residual (16) versus iteration number for these four problems.

We see rapid and monotonic convergence for problems C02 and traffic, which are convex. For simple and PV, which are nonconvex, we can see the switch to SD-BCD at the end, with a sharp reduction in residual in simple in just a few iterations, and a smoother reduction of residual over 12 iterations in PV. None of the examples requires more than 100 iterations to converge.

## 5 Component class attributes

In this section we describe some very basic attributes that component class losses can have.

### 5.1 Separability

A component class loss function can be separable across time, or entries, or both.

**Time-separable losses.** A function  $\phi : \mathbf{R}^{T \times p} \rightarrow \mathbf{R} \cup \{\infty\}$  is separable across time if it has the form

$$\phi(x) = \sum_{t=1}^T \ell_t(x_t)$$

for some functions  $\ell_t : \mathbf{R}^p \rightarrow \mathbf{R} \cup \{\infty\}$ ,  $t = 1, \dots, T$ . It is common for the loss functions to not depend on  $t$ , in which case we say it is time-invariant. A simple example is the mean-square loss (3), with  $\ell_t(x_t) = \frac{1}{T_p} \|x_t\|_2^2$  for all  $t$ .

**Entry-separable losses.** A component class function  $\phi$  is separable across entries if it has the form

$$\phi(x) = \sum_{i=1}^p \ell_i(\check{x}_i)$$

for some functions  $\ell_i : \mathbf{R}^T \rightarrow \mathbf{R} \cup \{\infty\}$ ,  $i = 1, \dots, p$ , where  $\check{x}_i$  is the  $i$ th column of  $x$  (which can be interpreted as a scalar time series), the  $i$ th entry of the vector time series  $\{x_t\}$ . Here too it is common for the loss function to not depend on  $i$ , in which case we say it is symmetric (in the entries of  $x_t$ ). The mean-square loss (3) is symmetric (in addition to being time-separable).

**Separability and proximal operators.** Separability reduces the complexity of evaluating the masked proximal operator. For example if  $\phi$  is separable across time, say,  $\phi(x) = \sum_t \ell_t(x_t)$ , its masked proximal operator is

$$\mathbf{mprox}_\phi(v) = \begin{bmatrix} \mathbf{mprox}_{\ell_1}(v_1)^T \\ \vdots \\ \mathbf{mprox}_{\ell_T}(v_T)^T \end{bmatrix},$$

*i.e.*, we can evaluate the masked proximal operator in parallel for each time  $t = 1, \dots, T$ . (Note the masked proximal operator for  $t$  depends on the missing data for that time period.)

## 5.2 Time-invariance

Time-invariance or shift-invariance is another important attribute. We let  $M < T$  denote the memory of the loss function  $\phi$ . We say  $\phi$  is time-invariant if it has the form

$$\phi(x) = \sum_{t=1}^{T-M+1} \ell(x_{t:t+M-1}),$$

where  $x_{t:t+M-1}$  is the  $M \times p$  slice of  $x$ , that includes rows  $t, \dots, t + M - 1$ , and  $\ell : \mathbf{R}^{M \times p} \rightarrow \mathbf{R} \cup \{\infty\}$  is the slice loss. Thus, a time-invariant component class loss is sum of the slice loss, applied to all  $M$ -long slices of its argument. With this definition, a time-separable time-invariant loss is a special case of time-invariance, with memory  $M = 1$ .

The second-order mean-square smooth loss (12) is a simple example of a time-invariant component class loss, with  $M = 3$ . As another example, consider the class of  $P$ -periodic signals, with loss

$$\phi(x) = \begin{cases} 0 & x_{t+P} = x_t, \quad t = 1, \dots, T - P, \\ \infty & \text{otherwise,} \end{cases} \quad (18)$$

which has memory  $M = P + 1$ .

## 5.3 Convex quadratic

A loss is convex quadratic if it has the form

$$\phi(x) = \begin{cases} (1/2)x^T P x + q^T x + r & Ax = b \\ \infty & \text{otherwise,} \end{cases} \quad (19)$$

where  $x \in \mathbf{R}^{Tp}$  is a vector representation of  $x$  (and  $x^T$  is its transpose),  $P \in \mathbf{R}^{Tp \times Tp}$  is symmetric positive semidefinite,  $q \in \mathbf{R}^{Tp}$ ,  $r \in \mathbf{R}$ ,  $A \in \mathbf{R}^{L \times Tp}$ , and  $b \in \mathbf{R}^L$ . Thus  $\phi$  is convex quadratic, with some equality constraints. We have already encountered a few examples of convex quadratic loss functions, such as mean-square small and mean-square smooth.

As a more interesting example, consider the  $P$ -periodic smooth loss, defined as

$$\phi(x) = \frac{1}{Pp} (\|x_2 - x_1\|_2^2 + \dots + \|x_P - x_{P-1}\|_2^2 + \|x_1 - x_P\|_2^2), \quad (20)$$

provided  $x$  is  $P$ -periodic, *i.e.*,  $x_{t+P} = x_t$  for  $t = 1, \dots, T - P$ , and  $\phi(x) = \infty$ , otherwise. This is the same as the  $P$ -periodic loss (18), with mean-square smoothness, taken circularly.

**Masked proximal operator of convex quadratic loss.** The masked proximal operator of a convex quadratic loss function can be efficiently evaluated; more precisely, after the first evaluation, subsequent evaluations can be carried out more efficiently. Evaluating the masked proximal operator involves minimizing a convex quadratic function subject to equality constraints, which in turn can be done by solving a set of linear equations, the KKT (Karush-Kuhn-Tucker) equations [BV18, §16]. If we cache the factorization used to solve this

set of linear equations (*e.g.*, the  $LDL^T$  factorization of the coefficient matrix), subsequent evaluations require only the so-called back-solve step, and not the factorization. This idea is often exploited in ADMM; see [BPC<sup>+</sup>11, §4.2].

**Weighted proximal operator.** In evaluating the masked proximal operators of certain convex quadratic loss functions, it can be more computationally efficient to evaluate a related weighted proximal operator. This is seen commonly with loss functions that are  $P$ -periodic. In this case, the solution to the masked proximal operator may be found by evaluating a smaller weighted proximal operator. Specifically, the weighted proximal operator is evaluated over a vector  $z \in \mathbf{R}^{P \times p}$ , representing a single period of component. The input to this smaller proximal operator is the original input, averaged across periods, using only the available data, *e.g.*, the entries in  $\mathcal{K}$ . The weights are defined as the number of real entries used in each averaging operation, divided by the total possible number of entries. (Some additional care must be taken here when evaluating signals that are not an even multiple of the period length.)

## 5.4 Common term

Another common attribute of a component class is when it represents a common term across the entries of the signal. The loss has the form

$$\phi(x) = \begin{cases} \tilde{\phi}(z) & x_t = z_t \mathbf{1}, \quad t = 1, \dots, T \\ \infty & \text{otherwise,} \end{cases} \quad (21)$$

where  $\tilde{\phi} : \mathbf{R}^T \rightarrow \mathbf{R} \cup \{\infty\}$  is a loss function for a scalar signal. Roughly speaking, this component class requires that all entries of  $x$  (*i.e.*, its columns) are the same, and uses a scalar-valued signal loss function on the common column. If  $\tilde{\phi}$  is separable, then  $\phi$  is separable across time.

The proximal operator of such a  $\phi$  is readily found in terms of the proximal operator of  $\tilde{\phi}$ . It is

$$\mathbf{prox}_{\phi}(v) = \mathbf{prox}_{\tilde{\phi}}((1/n)v\mathbf{1})\mathbf{1}^T.$$

In words: to evaluate the proximal operator for a common term loss function, we first average the columns of  $v$ , then apply the proximal operator of  $\tilde{\phi}$ , and finally broadcast the result to all columns.

The masked proximal operator is a bit more complex. Each row can have a different number of entries in the known set, so the average across columns must be taken with respect to the number of real entries in the row instead of the number of columns. However, to make use of the scalar formulation  $\tilde{\phi}(z)$ , we must invoke the weighted proximal operator,

$$\begin{aligned} \mathbf{mprox}_{\phi}(v) &= \underset{x}{\operatorname{argmin}} \left( \tilde{\phi}(z) + \frac{\rho}{2} \sum_{t,i \in \mathcal{K}} (x_{t,i} - v_{t,i})^2 \right), \quad \text{s.t. } x_t = z_t \mathbf{1} \\ &= \mathbf{wprox}_{\tilde{\phi}}(\mathbf{ravg}(v))\mathbf{1}^T, \end{aligned}$$

where  $\mathbf{ravg} : (\mathbf{R} \cup \{?\})^{T \times p} \rightarrow (\mathbf{R} \cup \{?\})^T$  is the row-wise average of the matrix  $v$ , over only the known entries. (If a row has no known entries, the function returns ? for that time index.) The weights are the number of known entries used in each averaging operation, divided by the total possible number of entries.

## 6 Component class examples

There is a wide variety of useful component classes; in this section we describe some typical examples. In most cases the proximal operator of the loss is well known, and we do not give it; we refer the reader to other resources, such as [CP11, PB13, BPC<sup>+</sup>11]. When the loss function is convex, but an analytical method to evaluate the proximal operator is not known, we can always fall back on a numerical method, *e.g.*, using CVXPY [DB16, AVDB18]. In a few cases where we believe our method of evaluating the proximal operator is new, we give a short description of the method.

### 6.1 Time-separable classes

Time-separable classes are given by the loss functions  $\ell_t$  on  $\mathbf{R}^p$ . We have already seen the mean-square small class, with loss  $\ell_t(u) = \frac{1}{T_p} \|u\|_2^2$ , and the finite set class, which requires that  $x_t$  be one of a given set of values. We mention a few other examples in this section.

**Value constraint component classes.** As an extension of the finite value class, we require that  $x_t \in \mathcal{S}_t$ , where  $\mathcal{S}_t \subset \mathbf{R}^p$  is some given set. If  $\mathcal{S}_t$  are all convex, we have a convex loss function. Simple convex examples include the nonnegative component class, with  $\mathcal{S} = \mathbf{R}_+^p$ , and the vector interval signal class, with  $\mathcal{S} = \{u \mid x_t^{\min} \leq u \leq x_t^{\max}\}$ , where the inequality is elementwise and  $x_t^{\min}$  and  $x_t^{\max}$  are given lower and upper limits on the entries of the signal (which can be parameters). In addition to the constraint  $x_t \in \mathcal{S}_t$ , we can add a nonzero penalty function of  $x_t$  to the objective.

**Mean-square close entries.** The loss

$$\ell(u) = \frac{1}{p} \sum_{i=1}^p (u_i - \mu)^2, \quad \mu = \frac{1}{p} \sum_{i=1}^p u_i, \quad (22)$$

which is the variance of the entries of the vector  $u$ , defines the mean-square close entries class. If we scale this class by a very large weight, this gives an approximation of the common term class (21) (with  $\tilde{\phi} = 0$ ), in which the entries of the signal must be the same for each  $t$ .

**Robust losses.** We can modify the sum of squares loss so the component class can include signals with occasional outliers, using so-called robust losses, which grow linearly for

large arguments, when they are convex, or sub-linearly when they are not. One well-known example is the Huber loss, defined as

$$\ell(u) = \sum_{i=1}^p H(u_i), \quad H(a) = \begin{cases} a^2 & |a| \leq M \\ 2M(|a| - M) & |a| > M, \end{cases}$$

where  $M > 0$  is a parameter [BV09, §6.1.2]. An example of a nonconvex robust loss is the log Huber loss,

$$\ell(u) = \sum_{i=1}^p \tilde{H}(u_i), \quad \tilde{H}(a) = \begin{cases} a^2 & |a| \leq M \\ M^2(1 + 2 \log(|a|/M)) & |a| > M. \end{cases}$$

**Convex sparsity inducing losses.** The loss function  $\ell(u) = \|u\|_2$  (note that this norm is not squared) leads to vector-sparse (also called block sparse) component signals, *i.e.*, ones for which for many values of  $t$ , we have  $x_t = 0$ . In machine learning this is referred to as group lasso [HTF13, §3.8.4]. With this loss, we typically find that when  $x_t \neq 0$ , all its entries are nonzero. The loss function  $\ell(u) = \|u\|_1$ , sum-absolute small component class, tends to yield signals that are component-wise sparse, *i.e.*, for many values of  $(t, i)$ , we have  $x_{t,i} = 0$ .

**Non-convex sparsity inducing losses.** The most obvious one is the cardinality or number of nonzeros loss, with  $\ell(u)$  being the number of nonzero entries in  $u$  (or, in the vector version, 0 if  $u = 0$  and 1 otherwise). In this case the overall loss  $\phi(x)$  is the number of nonzero values of  $x_{t,i}$ . A variation is to limit the number of nonzeros to some given number, say,  $r$ , which gives the  $r$ -sparse signal component class.

These losses are nonconvex, but have well-known analytic expressions for their proximal operators. For example when the loss is the number of nonzero entries in  $x$ , the proximal operator is so-called hard thresholding [BPC+11, §9.1.1],

$$\mathbf{prox}_{\phi_k}(v)_{t,i} = \begin{cases} 0 & |v_{t,i}| \leq \sqrt{2/\rho} \\ v_{t,i} & |v_{t,i}| > \sqrt{2/\rho}, \end{cases} \quad t = 1, \dots, T, \quad i = 1, \dots, p.$$

**Quantile small.** The quantile loss is a variation on the  $\ell_1$  loss  $\|u\|_1$ , that allows positive and negative values to be treated differently:

$$\ell(u) = \sum_{i=1}^p (|u_i| + (2\tau - 1)u_i), \tag{23}$$

where  $\tau \in (0, 1)$  is a parameter. For  $\tau = 0.5$ , this class simplifies to sum-absolute small. (Its proximal operator is given in [PB13, §6.5.2].)

## 6.2 Time-invariant classes

Any time separable loss for which  $\ell_t$  do not depend on  $t$  is time-invariant. We give a few other examples here.

**Index-dependent offset.** In the common term class (21), the entries of signals are the same. The index-dependent offset class is analogous: Its signals are different for different indexes, but the same over time. It is given by  $\phi(x) = 0$  if for some  $z$ ,  $x_t = z$  for all  $t$ , where  $z \in \mathbf{R}^p$ , and  $\infty$  otherwise. Of course we can add a penalty on  $z$ . This loss is time-invariant, with a memory of one.

**Higher order mean-square smooth component classes.** We have already mentioned the mean-square smooth class which uses the first-order difference (4), and its extension to the second-order difference (12). Higher order mean-square smooth classes use higher order differences.

**Mean-absolute smooth.** Replacing the mean-square penalty in mean-square first-order smooth classes with a average-absolute penalty yields a components whose signal entries are typically piecewise constant. With the second-order difference,

$$\phi(x) = \frac{1}{(T-2)^p} \sum_{t=1}^{T-2} \|x_t - 2x_{t+1} + x_{t+2}\|_1, \quad (24)$$

we obtain a class who entries are typically piecewise linear. (This is discussed under the name  $\ell_1$ -trend filtering in §3.)

**Periodic.** The component class of signals with period  $P$  has loss function

$$\phi(x) = \begin{cases} 0 & x_{t+P} = x_t, \quad t = 1, \dots, T - P, \\ \infty & \text{otherwise.} \end{cases} \quad (25)$$

We can also express this using a basis.

To this constraint we can add a loss function such as mean-square signal or mean-square smooth, to obtain, for example, the component class of  $P$ -periodic mean-square smooth signals. (In this case the differences are computed in a circular fashion.)

**Quasi-periodic.** A variation on the periodic signal class does not require strict periodicity, but allows some variation period to period, with a penalty for variation. The simplest version uses the quadratic loss function

$$\phi(x) = \sum_{t=1}^{T-P} \|x_{t+P} - x_t\|_2^2, \quad (26)$$

the sum of squares of the differences in signal values that are  $P$  period apart. Variations include adding a smoothness term, or replacing the sum of squares with a sum of norms, which tends to give intervals of time where the signal is exactly periodic.

**Composite classes.** Components may be combined to generate more complex loss functions. An example that we will use later has time entries that are smooth (12) and periodic (25) and entries that are mean-square close (22),

$$\phi(x; \lambda_1, \lambda_2) = \begin{cases} \lambda_1 \ell_1(x) + \lambda_2 \ell_2(x) & x_{t+P} = x_t, \quad t = 1, \dots, T - P, \\ \infty & \text{otherwise.} \end{cases} \quad (27)$$

where

$$\begin{aligned} \ell_1(x) &= \frac{1}{(T-2)p} \sum_{t=1}^{T-2} \|x_t - 2x_{t+1} + x_{t+2}\|_2^2, \\ \ell_2(x) &= \frac{1}{p} \sum_{t=1}^T \sum_{i=1}^p (x_{t,i} - \mu_t)^2, \quad \mu_t = \frac{1}{p} \sum_{i=1}^p x_{t,i}. \end{aligned}$$

This composite example is convex quadratic (§5.3).

**Monotone non-decreasing.** The monotone nondecreasing loss is

$$\phi(x) = \begin{cases} 1 & x_{t+1,i} \geq x_{t,i} \quad t = 1, \dots, T - 1, \quad i = 1, \dots, p \\ 0 & \text{otherwise.} \end{cases}$$

It is used in monotone or isotonic regression, typically to represent something like cumulative wear, that does not decrease over time. This loss is a constraint, but we can add an additional term such as mean-square smoothness.

**Markov.** The Markov class is, roughly speaking, an extension of the finite set class (10) that includes costs for the different values, as well as transitions between them. It is specified by some distinct values  $\theta_1, \dots, \theta_M \in \mathbf{R}^p$ , a transition cost matrix  $C \in \mathbf{R}_+^{M \times M}$ , and state cost vector  $c \in \mathbf{R}_+^M$ . Like the finite set component class, the loss is  $\infty$  unless for each  $t$ , we have  $x_t \in \{\theta_1, \dots, \theta_M\}$ . We write this as  $x_t = \theta_{s_t}$ , where we interpret  $s_t \in \{1, \dots, M\}$  as the state at time  $t$ . When this holds, we define

$$\phi(x) = \sum_{t=1}^T c_{s_t} + \sum_{t=2}^T C_{s_t, s_{t-1}}.$$

The first term is the state cost, and the second is the cost of the state transitions.

This component class gets its name from a statistical interpretation in terms of a Markov chain. If the state  $s_t$  is a Markov chain with states  $\{1, \dots, M\}$ , with transition probabilities  $\pi_{ij} = \mathbf{Prob}(s_t = i \mid s_{t-1} = j)$ . Then with  $c = 0$  and  $C_{i,j} = \log \pi_{ij}$ , the loss is the negative log-likelihood, up to a constant.

The proximal operator of this component loss function can be efficiently evaluated using standard dynamic programming. We create a graph with  $MT$  nodes, with each node corresponding to one state at one time. All nodes at time  $t$  are connected to all nodes at time  $t-1$

and  $t + 1$ , so there are  $(T - 1)M^2$  edges. Let  $v$  be the signal for which we wish to evaluate the proximal operator. At each node we attach the cost  $(\rho/2)\|v_t - c_s\|_2^2$ , and on each edge from state  $s$  at time  $t - 1$  to state  $s'$  at  $t$  we attach the cost  $C_{s,s'}$ . Then  $\phi(x) + (\rho/2)\|v - x\|_F^2$  is exactly the path cost through this graph. We can minimize this over  $s_1, \dots, s_T$  using dynamic programming to find the shortest path. The cost is  $O(TM^3)$  flops, which is linear in the signal length  $T$ .

**Single jump.** As a variation on the Markov component class we describe the single jump component class. We describe it for a scalar signal *i.e.*,  $p = 1$ ; it is extended to vector signals with a loss that is separable across entries. The loss function is

$$\phi(x) = \begin{cases} 1 & x = (0_\tau, a\mathbf{1}_{T-\tau}) \\ 0 & x = 0 \\ \infty & \text{otherwise,} \end{cases} \quad (28)$$

for some (jump magnitude)  $a \neq 0$  and some (jump time)  $\tau \in \{1, \dots, T\}$ . Roughly speaking, feasible signals start at zero and either stay zero, or jump once, at a time  $\tau$ , to the value  $a$ . The cost is zero if  $x$  is zero, and one if it does jump. This loss function is evidently nonconvex.

Its proximal operator is readily evaluated directly, by evaluating

$$(\rho/2)\|x - v\|_2^2 + \phi(x)$$

for all feasible  $x$ . For  $x = 0$  we have the value  $(\rho/2)\|v\|_2^2$ . For a jump at time  $\tau$ , the value of  $a$  that minimizes the cost above is simply the average of  $x_t$  over  $t = \tau, \dots, T$ . This value and the cost is readily computed recursively, so the proximal operator can be evaluated in time linear in  $T$ . This method extends readily to the masked proximal operator.

### 6.3 Fitting component class losses

In the discussion above we specify component classes directly in terms of the loss function. We mention here that it is also possible to fit a component class loss from examples of signals in that class, assuming they are available.

One simple method is based on the statistical interpretation given in §2.4. Given a collection of example signals, we fit a statistical model, for example a Gaussian distribution  $\mathcal{N}(\mu, \Sigma)$  with an appropriate mean  $\mu \in \mathbf{R}^{Tp}$  and covariance  $\Sigma \in \mathbf{R}^{Tp \times Tp}$ . We use as loss for this component class the convex quadratic  $\phi(x) = (x - \mu)^T \Sigma^{-1} (x - \mu)$ , which is the negative log-likelihood, up to a scale factor and constant. If we fit a statistical model for each component of the signals we obtain an entry-separable loss; if we fit a common model for the entries of the signal, we obtain an entry-separable symmetric loss. We can fit a time-invariant loss by creating a common statistical model of all  $M$ -long slices of our signal examples, and using the negative log-likelihood as the slice loss.

Another elementary method for fitting a loss to example signals uses the singular value decomposition (SVD) or generalized low-rank model [UHQB16] to find a set of archetype

signals  $a^1, \dots, a^r \in \mathbf{R}^{T \times p}$ , for which each of our examples is close to a linear combination of them. We then use the basis loss function

$$\phi(x) = \begin{cases} 0 & x = z_1 a^1 + \dots + z_r a^r \text{ for some } z \in \mathbf{R}^r \\ \infty & \text{otherwise.} \end{cases} \quad (29)$$

(As a variation on this, we can find a set of (scalar) archetypes in  $\mathbf{R}^T$  for which each component of our examples is close to a linear combination of them, as in (11).) A soft version of the basis loss is the loss function

$$\phi(x) = \min_z \|x - z_1 a^1 - \dots - z_r a^r\|_F^2, \quad (30)$$

which has full domain. (It can also be thought of as a combination of two classes: the basis class, and the a mean-square small residual class.)

The soft basis model can be used to fit a time-invariant loss. We use SVD to find a set of archetypes or basis for which each  $M$ -long slice of each example is close to a linear combination, and then use the soft basis loss (30) as our slice loss.

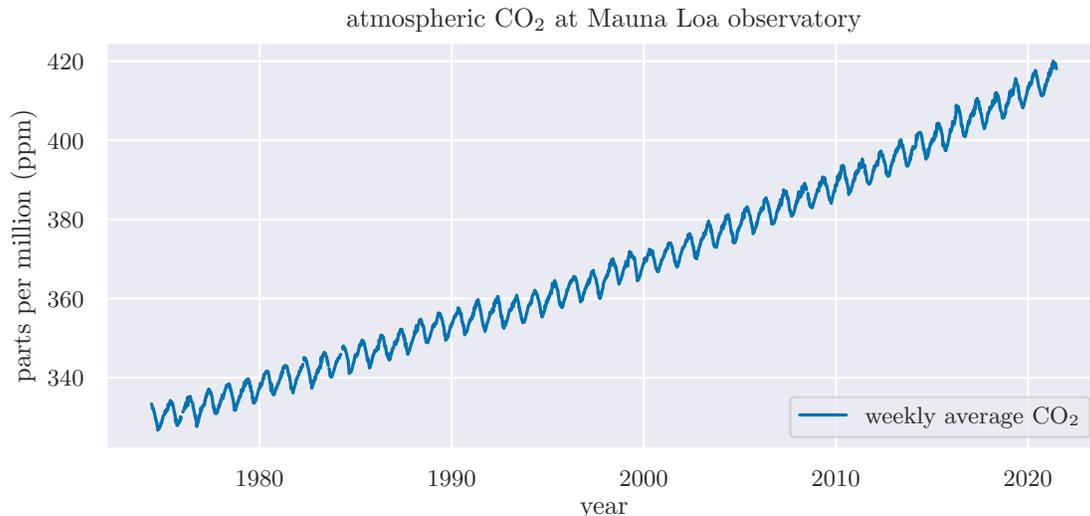

## 7 Examples

### 7.1 Mauna Loa CO<sub>2</sub> measurements

An example often used to demonstrate seasonal-trend decomposition is atmospheric carbon dioxide (CO<sub>2</sub>), which has both a strong seasonal component and a underlying trend. These data were utilized in the original STL paper [CCMT90] as well as the documentation for various implementations of STL [STLa]. In this section we compare the Python implementation of STL in the `statsmodels` package to an SD formulation of the problem of decomposing measurements of atmospheric CO<sub>2</sub> into seasonal, trend, and residual components.

**Data set.** The weekly average CO<sub>2</sub> measured at Mauna Loa, HI from May 1974 through June 2021, available online from the National Oceanic and Atmospheric Administration Global Monitoring Laboratory [TK], is shown in figure 5. The data set is a scalar signal of length 2459 with 18 missing entries. In our notation,  $y_1, \dots, y_T \in \mathbf{R} \cup \{?\}$ , with  $T = 2459$ , and  $|\mathcal{U}| = 18$ .

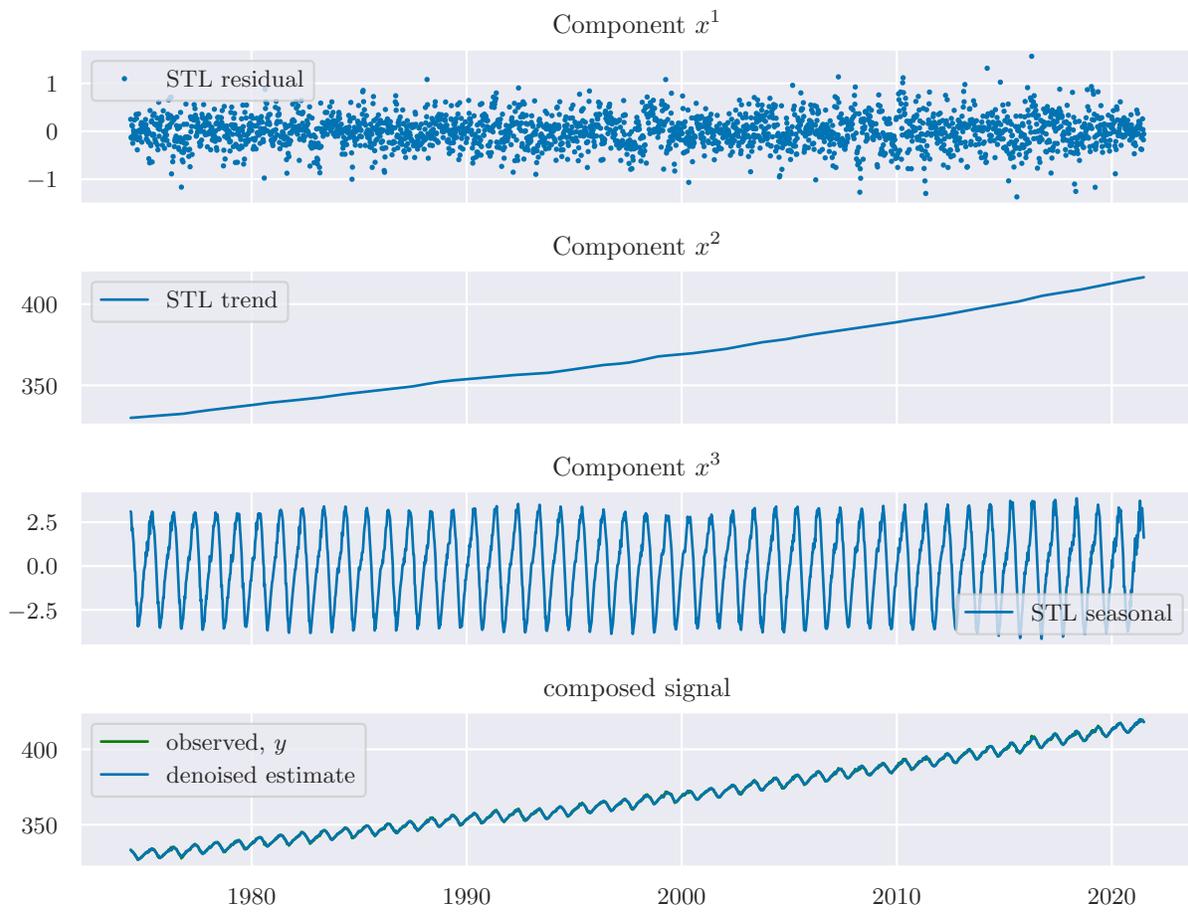

**Decomposition using STL.** We use the implementation in `statsmodels` (v0.12.2) with default settings and `period=52`. We note that while the original STL paper describes how to handle missing data, this particular software implementation cannot handle missing values, so we used simple linear interpolation to fill the missing values before running the algorithm. The resulting decomposition is shown in figure 6, using the conventional names for the components. Interestingly, the “seasonal” component in this estimation is not periodic; it almost repeats each year but with some variation.

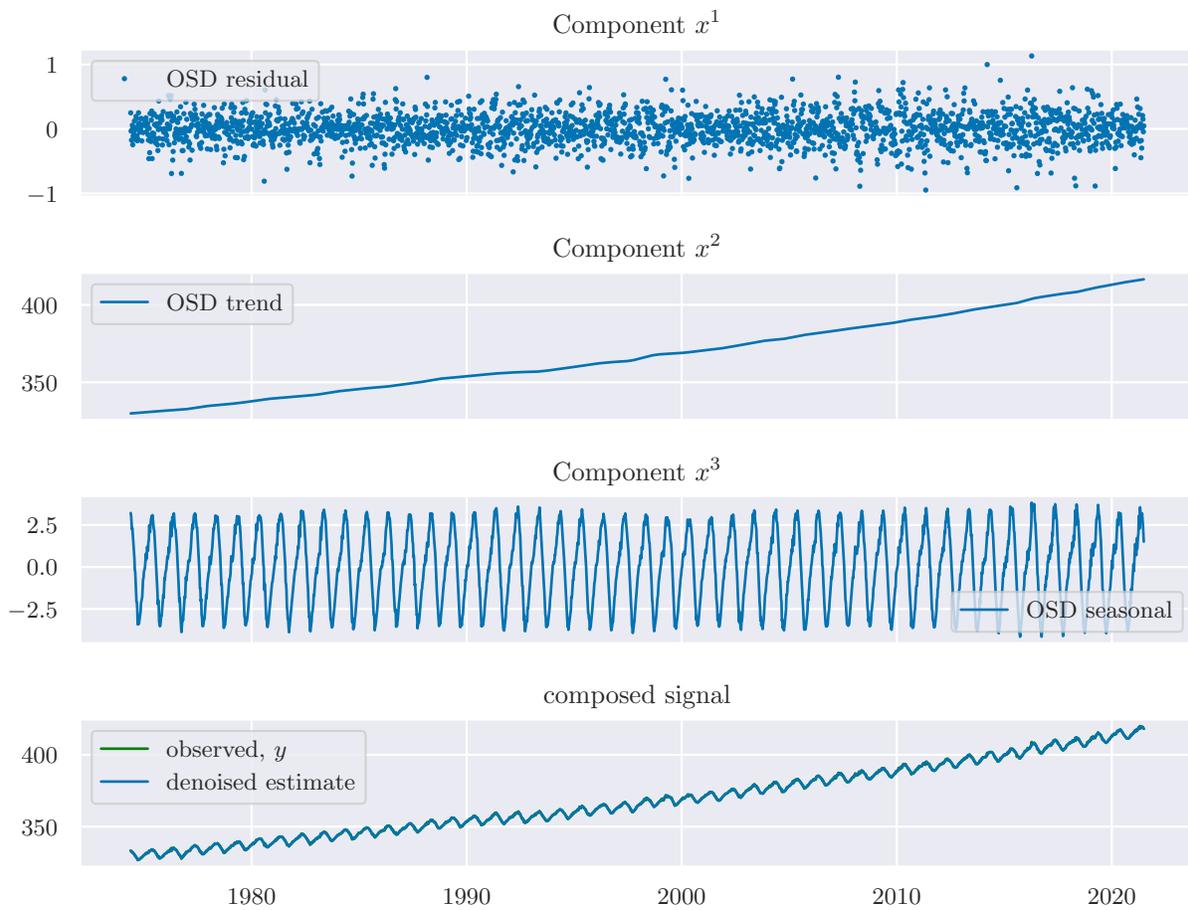

**Figure 5:** Atmospheric CO<sub>2</sub> data obtained from NOAA, which shows clear seasonal and trend components.

**Decomposition using SD.** We form an SD problem with  $p = 1$ ,  $T = 2459$ , and  $K = 3$ , with component classes mean-square small (3), second-order-difference small (12), and a quasi-periodic signal with period 52 (26). All the component classes are convex, so this SD problem is convex. This problem has two parameters  $\lambda_2$  and  $\lambda_3$ , associated with the weights on the second and third loss functions respectively. We found that  $\lambda_2 = 10^4$  and  $\lambda_3 = 1$  give good results, although better parameter values could be found using a validation procedure. The resulting decomposition is shown in figure 7.

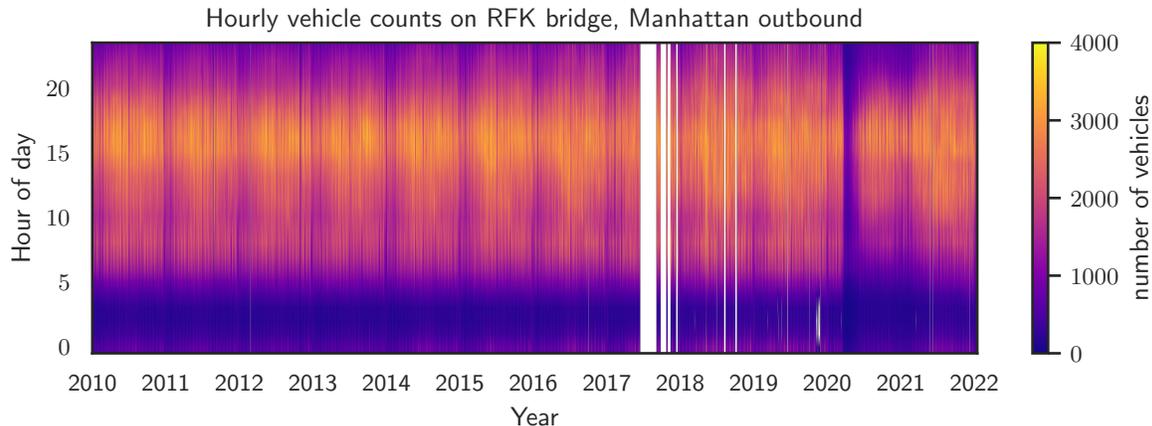

**Comparison.** The decompositions found using STL and SD, shown in figures 6 and 7, and nearly identical. The RMS deviation between trend estimates is  $7.52 \times 10^{-2}$ , about 0.02% of the average measured value. The RMS deviation between seasonal estimates is  $8.79 \times 10^{-2}$ . While STL is based on a heuristic algorithm, SD is based on solving a convex optimization problem (for our particular choice of loss functions).

**Figure 6:** Decomposition of the CO<sub>2</sub> data into residual, trend, and seasonal components, using STL.

**Figure 7:** Decomposition of the CO<sub>2</sub> data into residual, trend, and seasonal components, using SD. It is nearly identical to the decomposition found by STL, shown in figure 6.

**Figure 8:** Hourly vehicle counts for the outbound Manhattan toll plaza of the Robert F. Kennedy bridge, with hour of day on the y-axis and days on the x-axis. White pixels represent missing values.

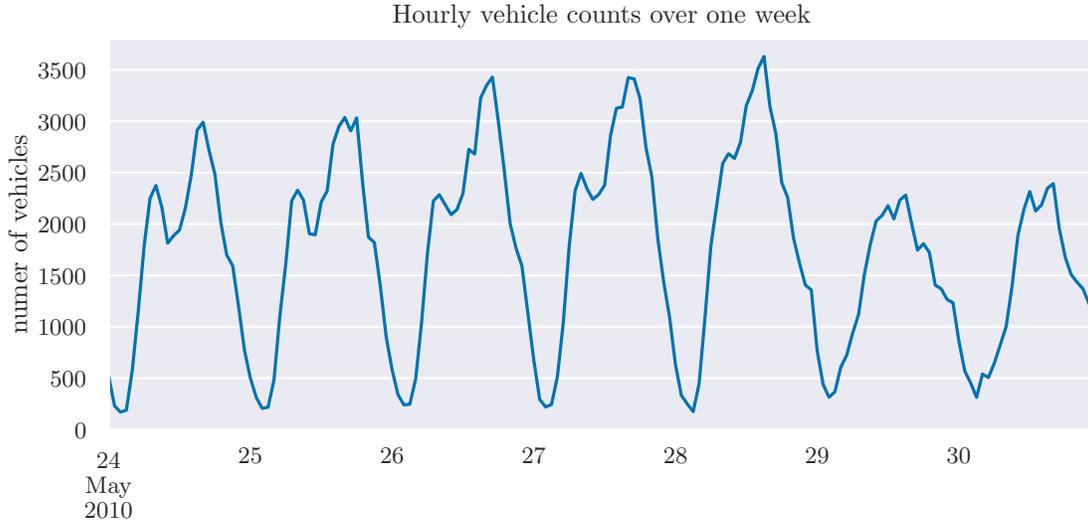

## 7.2 RFK bridge traffic

This example illustrates how the concept of seasonal-trend decomposition can be extended in the SD framework to handle more complex analyses with additional components. Traffic volume is measured with sensors embedded in the roadways that count the number of cars that pass in each hour; from these data, summary statistics such as “Annual Average Daily Traffic” and “Peak Hour Volume” are derived [Sah].

**Data set.** The hourly outbound vehicle count for the Manhattan toll plaza on the Robert F. Kennedy Bridge in New York City from January 1, 2010 through August 28, 2021 is shown in figure 8 as a heat map, with the hour of day shown vertically and the day shown horizontally, and missing entries shown in white. Daily and seasonal variations can be seen, along with the effects of COVID-19. A single week of data is shown in figure 9, where daily variation, and the weekend effect, are evident. The data set is made available online by the New York Metropolitan Transportation Authority (MTA) [MTA].

The data  $y$  is scalar (*i.e.*,  $p = 1$ ), with  $T = 102192$  (24 hours per day, 4258 days). We take the natural logarithm of the data, using the convention  $\log 0 = ?$ . With these unknown entries, plus those that are unknown in the original data set, we have  $|\mathcal{U}| = 3767$ . Thus our decomposition is multiplicative; the components are multiplied to obtain our decomposition.

**SD problem formulation.** We form an SD problem with  $K = 5$  components. The residual component is mean-square small (3), as in previous examples. The second component is the weekly baseline, which is the smooth-periodic cost given in (20) with  $P = 168$  and a weight parameter  $\lambda_2$ . The third component is the yearly seasonal correction, which is also smooth-periodic (20) with  $P = 8760$  and weight parameter  $\lambda_3$ , and the additional constraint

**Figure 9:** One week of hourly vehicle counts in May 2010.

that the sum over each period must be equal to zero. The fourth component is the long-term trend, modeled as piecewise linear with the  $\ell_1$  second difference loss (24), with weight parameter  $\lambda_4$  and the additional constraint that the first value of  $x^4$  must be equal to zero. The fifth and final component is a sparse daily outlier, defined as

$$\phi_5(x) = \begin{cases} \lambda_5 \|x\|_1 & x \in \mathcal{D} \\ \infty & \text{otherwise,} \end{cases} \quad (31)$$

where  $\mathcal{D}$  is the set of signals that are constant over each day. All the component class losses are convex, so this SD problem is convex with parameters  $\lambda_2$ ,  $\lambda_3$ ,  $\lambda_4$ , and  $\lambda_5$ .

**Results.** We solve the SD problem using parameter values

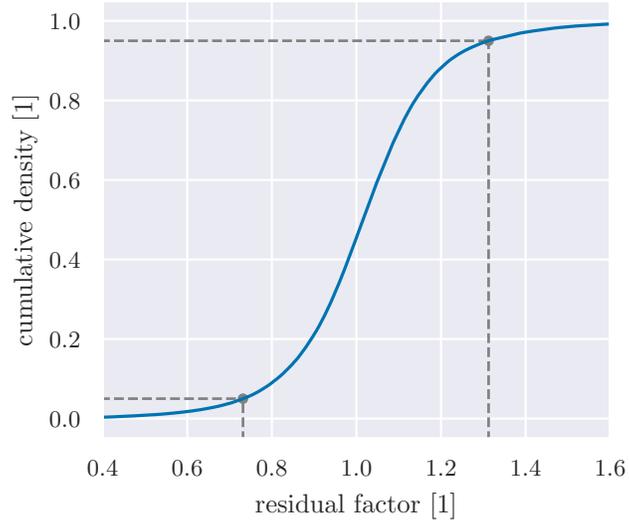

$$\lambda_2 = 10^{-1}, \quad \lambda_3 = 5 \times 10^5, \quad \lambda_4 = 2 \times 10^5, \quad \lambda_5 = 1,$$

selected by hand to provide good results. The decomposition yields components that have vastly different timescales.

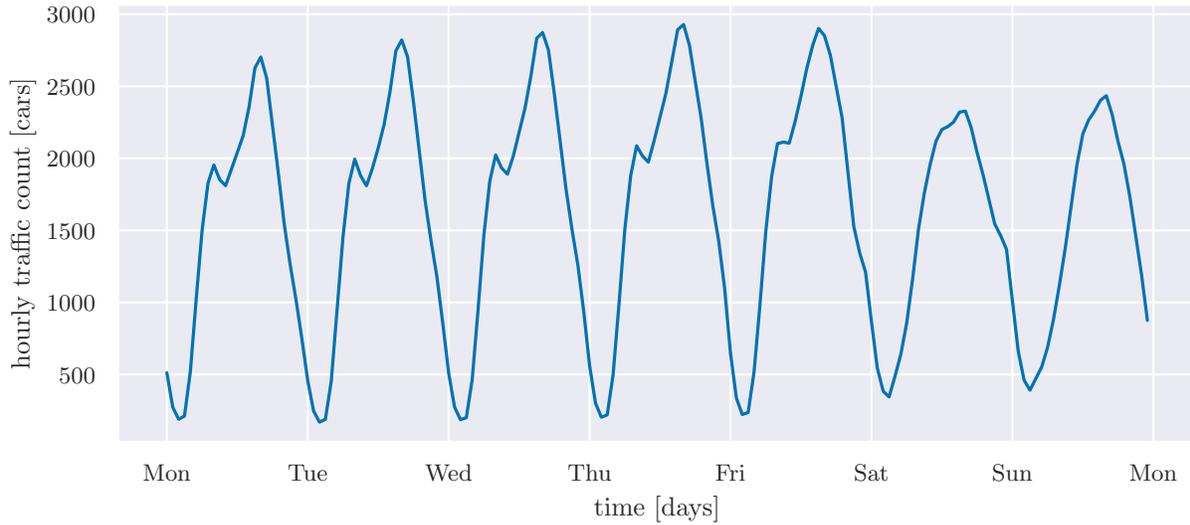

By exponentiating our component estimates,  $\tilde{x}^k = \exp(x^k)$ , we recover a multiplicative model of the traffic count data. The residual component  $\tilde{x}^1$  is centered around 1, with 90% of the residuals in the interval  $[0.74, 1.30]$ , shown in figure 10. This means that in any given hour, our decomposition predicts traffic typically within around  $\pm 30\%$ .

Figure 11 shows one week of the (periodic) weekly baseline. We see many of the phenomena present in figure 9, such as reduced traffic over the weekend, daily variation, and a small increase from Monday to Friday, and a commute rush hour on weekdays.

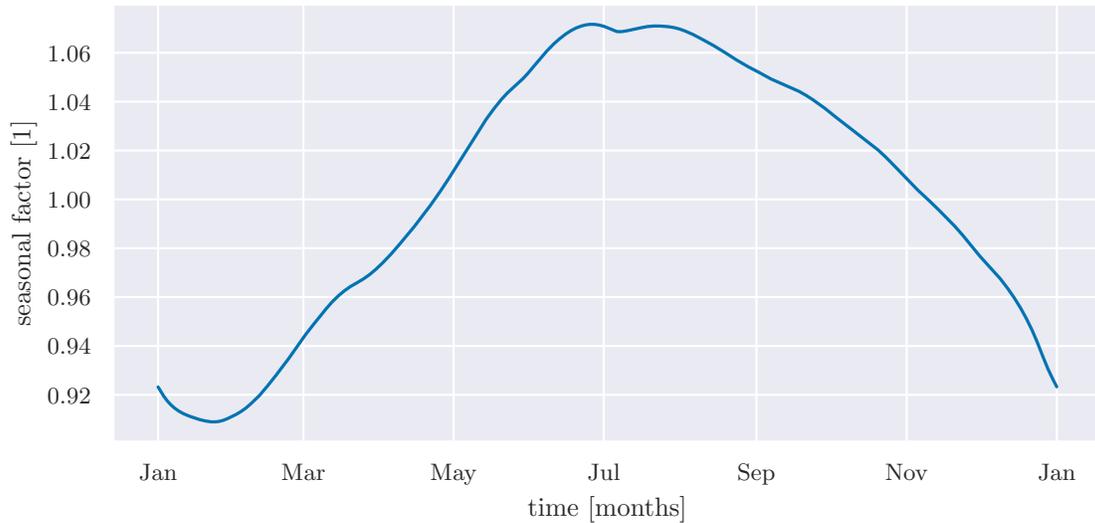

Figure 12 shows component  $\tilde{x}^3$ , the seasonal correction factor, which varies from around  $-9\%$  to  $+7\%$ , with the peak in summer and the low point in late January and early February.

**Figure 10:** Cumulative distribution function of the multiplicative residual  $\tilde{x}_{t,i}^1$  for  $(t, i) \in \mathcal{K}$ . The gray dashed lines indicate the 5th and 95th percentiles. 90% of the residuals are between 0.74 and 1.30.

**Figure 11:** Weekly baseline signal  $\tilde{x}^2$ , shown for a single week (168 values).

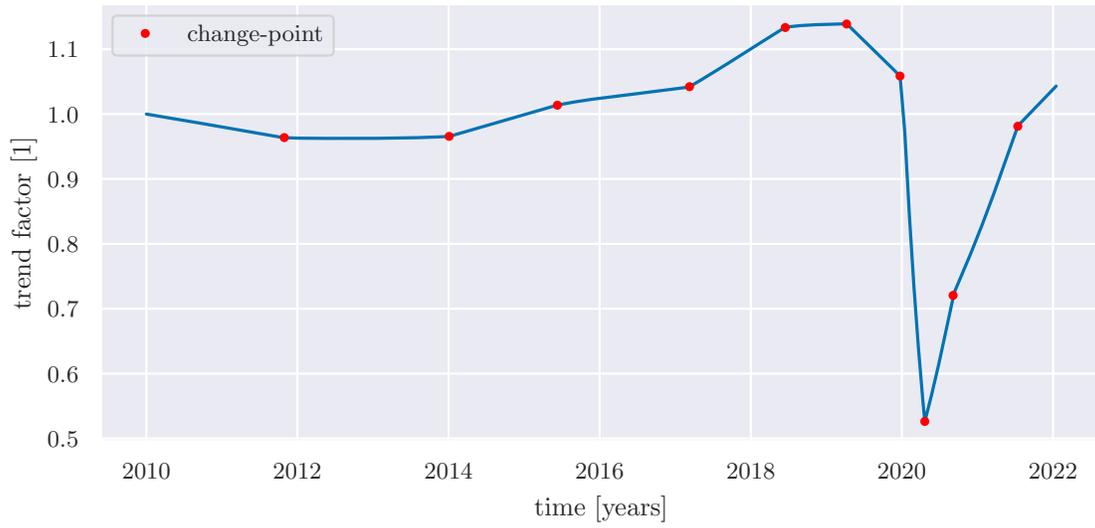

**Figure 12:** Seasonal adjustment  $\tilde{x}^3$ , shown for a single year (8760 values).

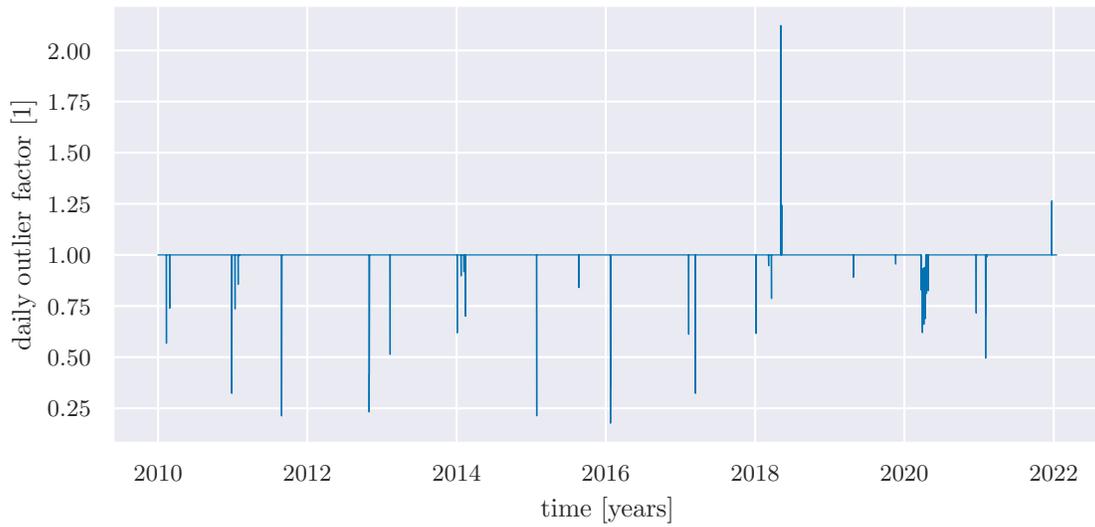

Figure 13 shows the long term  $\tilde{x}^4$ . The component  $x^4$  is piecewise-linear with a small number of breakpoints, so  $\tilde{x}^4$  is piecewise exponential, with a small number of breakpoints, shown as red dots in the plot. We can see a slight increase in traffic over the first 10 years followed by a precipitous drop in traffic due to COVID-19 in early 2020, coinciding with the mandatory lockdown implemented by the New York state government on March 22, 2020 [Cuo].

The final component  $x^5$  is sparse, which means that  $\tilde{x}^5$ , shown in figure 14, mostly takes on the value one. This component identifies 42 days (out of 4258) as outliers, with multiplicative corrections ranging from around 0.2 (*i.e.*, one fifth the normal traffic on that day) to around twice the normal traffic on that (one) day. All but two of the outlier days represent a decrease in traffic on that day. Many of the detected outlier days are weather related, with some notable examples being various blizzards including February 10, 2010 [Blia], December 27, 2010 [Blib], January 27, 2015 [Blic], and February 1, 2021 [Blid]. About 9 outlier days are associated with reduced traffic during the COVID-19 lockdown event in early 2020. Figure 15 highlights the detection of Hurricane Irene in August of 2011 [AC13], with  $\tilde{x}^5 < 1$  during the hurricane.

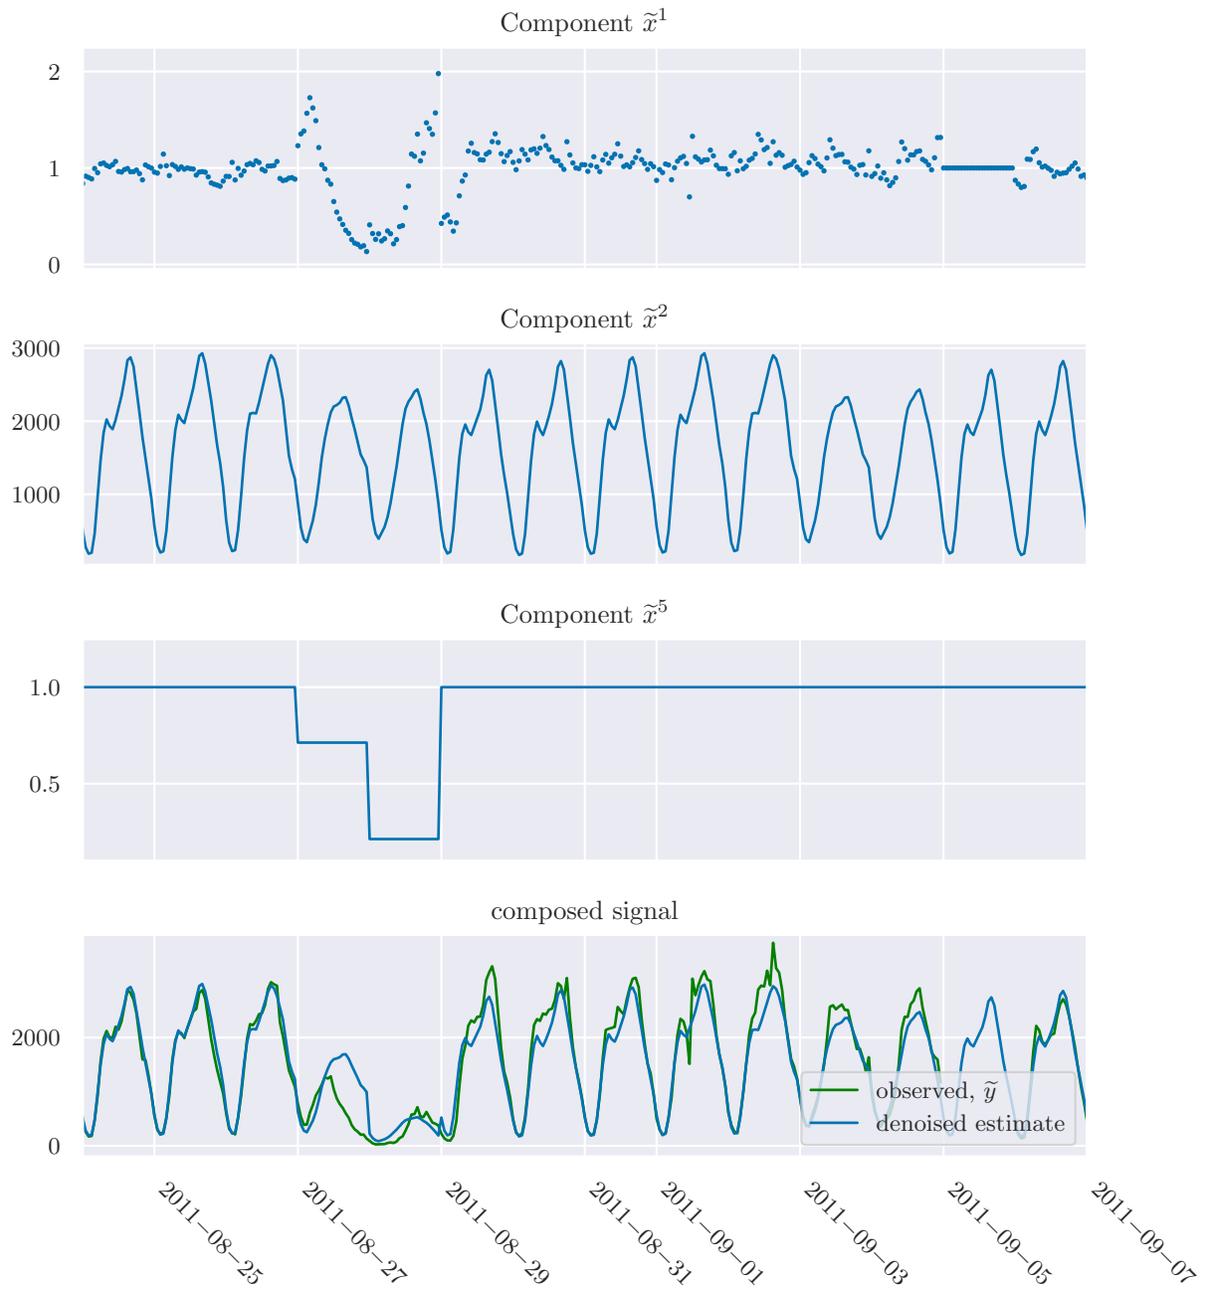

The two positive outlier days occur on May 6 and 10, 2018. The authors could find no explanation for the very high measured traffic on those days in the archives of the New York Times and the New York Post. It is possible that sensors were simply malfunctioning on those two days.

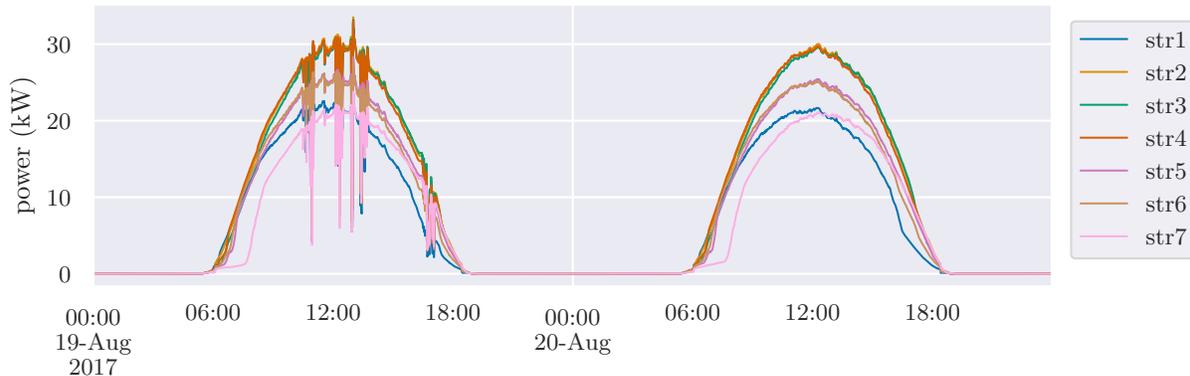

**Figure 13:** Long-term trend multiplicative factor  $\tilde{x}^4$ . This trend is piecewise exponential, with breakpoints shown as red dots.

**Figure 14:** Daily outlier component  $\tilde{x}^5$ .

**Figure 15:** Decomposition components for two weeks in August 2011 (336 values). Hurricane Irene hit New York city on August 27 and 28, greatly reducing traffic on those days, clearly seen as outliers in  $\tilde{x}^5$ .

**Figure 16:** Raw PV combiner box data, shown for two days in August 2017.

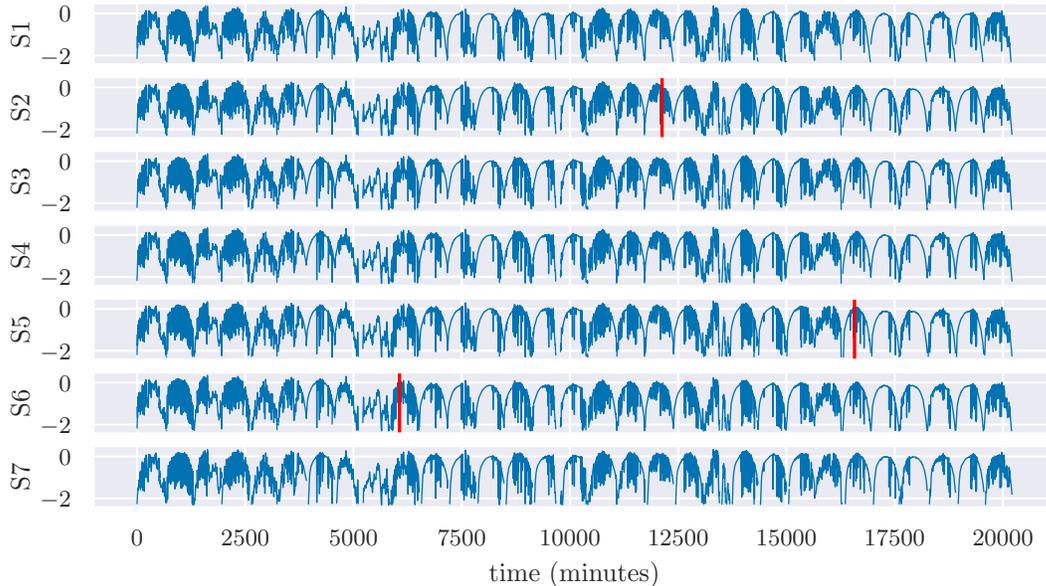

### 7.3 Outage detection in a photovoltaic combiner box

**Data set.** We consider a set of 7 measurements of real power from inside a photovoltaic (PV) combiner box [Fra18], corresponding to 7 strings of series-connected PV modules that are joined in parallel. These data are from PV strings forming the canopy at the NIST campus in Maryland [BCD17]. Detailed documentation of the PV systems at this site, including system designs, meteorological station information, and site layout, are also available [Boy15]. The canopy has multiple roof orientations, so the constituent strings have similar but different power curves, depending on the specific geometry of each string.

The raw data consist of the power output of each of the 7 PV strings, measured each minute over a month (August 2016), organized into a matrix with each column corresponding to a single string and each row a particular minute. This raw data contains some missing data. The power output of each string depends on available sunlight, weather conditions, soiling accumulation, string geometry, and local shade patterns. Two days of string power output are shown in figure 16.

**Data pre-processing.** We first eliminate all data points corresponding to night time and early morning and evening, when string powers are zero or very small. We removed data between 5:40pm and 6:49am. (These times were found as the times when the whole system was producing less than 10% of system capacity.) Thus each day consists of 652 one minute measurements. Next we scale each of the 7 string powers (columns) so that the 95th percentile is one. This gives each column an approximate range of about 0.1 to 1.3.

Finally we take the log of each power output value, resulting in columns with a range of about -2.3 to 0.25. Carrying out signal decomposition on this log signal gives us a multiplicative decomposition, which makes sense for this application. (For example, a cloud passing between the sun and the string gives a percentage reduction in power.) The final data is a signal  $y$  with  $T = 20212$ ,  $p = 7$ , and  $|\mathcal{U}| = 6402$ .

**Figure 17:** PV combiner box data after pre-processing, with simulated outages. The onset times of the simulated outages are shown as vertical red lines.

**Outage simulation.** We modify this real data to include some simulated faults or outages, where some part of each PV string no longer generates power. This is modeled as a (multiplicative) reduction in power output, from the time of failure to the end of the data. We simulated these fault for strings 2, 5, and 6, with onset times

$$T_2 = 12132, \quad T_5 = 16573, \quad T_6 = 6063,$$

and power reduction factors

$$f_2 = -7\%, \quad f_5 = -10\%, \quad f_6 = -12.5\%,$$

chosen randomly. (These are realistic values.) The modified data is shown in figure 17, with vertical red lines indicating the onset of the outages in spower trings 2, 5, and 6. These power reductions can be seen in the plot, but would likely be hard to spot by eye.

**SD problem formulation.** We form an SD problem with  $K = 5$  components. Our signal decomposition models string output as the product of a mean-square small residual (3), a clear sky signal, a common daily correction term, a common cloud/weather term, and a failure term. The clear sky component is modeled as the composite class that is smooth and periodic in time and close in entries (27) (with a small modification to remove the smoothness penalty across day boundaries). This component has two parameters, one for the smoothness term and one for the variance across entries,  $\lambda_{2a}$  and  $\lambda_{2b}$ , respectively. The third component

is a daily scale adjustment that is constant across columns, and constant over each day, meant to capture day-to-day macro-scale changes in atmospheric conditions that effect all strings, such as precipitable water and aerosol optical depth [Ime08]. The fourth component is also constant across the columns and has a quantile loss function (23). This models a common cloud-loss term between the strings, assumed to be equal because the strings are so close to each other and are experiencing the same local weather. The fourth component has two parameters, the quantile term,  $\tau$ , which we set to be 0.65, and a weight,  $\lambda_4$ . The third and fourth components make use of the common term formulation (21). The fifth component is our failure detector. This component uses the single jump class (28), constrained to only have negative jumps, with each column treated independently. The fifth component also has a weight parameter,  $\lambda_5$ . Since our failures are simulated, we know exactly when the onsets are, and what the values are, which we can compare to our estimated failure component.

**Results.** We solve the SD problem with hand-selected weights,

$$\lambda_{2a} = 5 \times 10^4 / (Tp), \quad \lambda_{2b} = 5 \times 10^{-5} / (Tp), \quad \lambda_4 = 2 / (Tp), \quad \lambda_5 = 10 / (Tp),$$

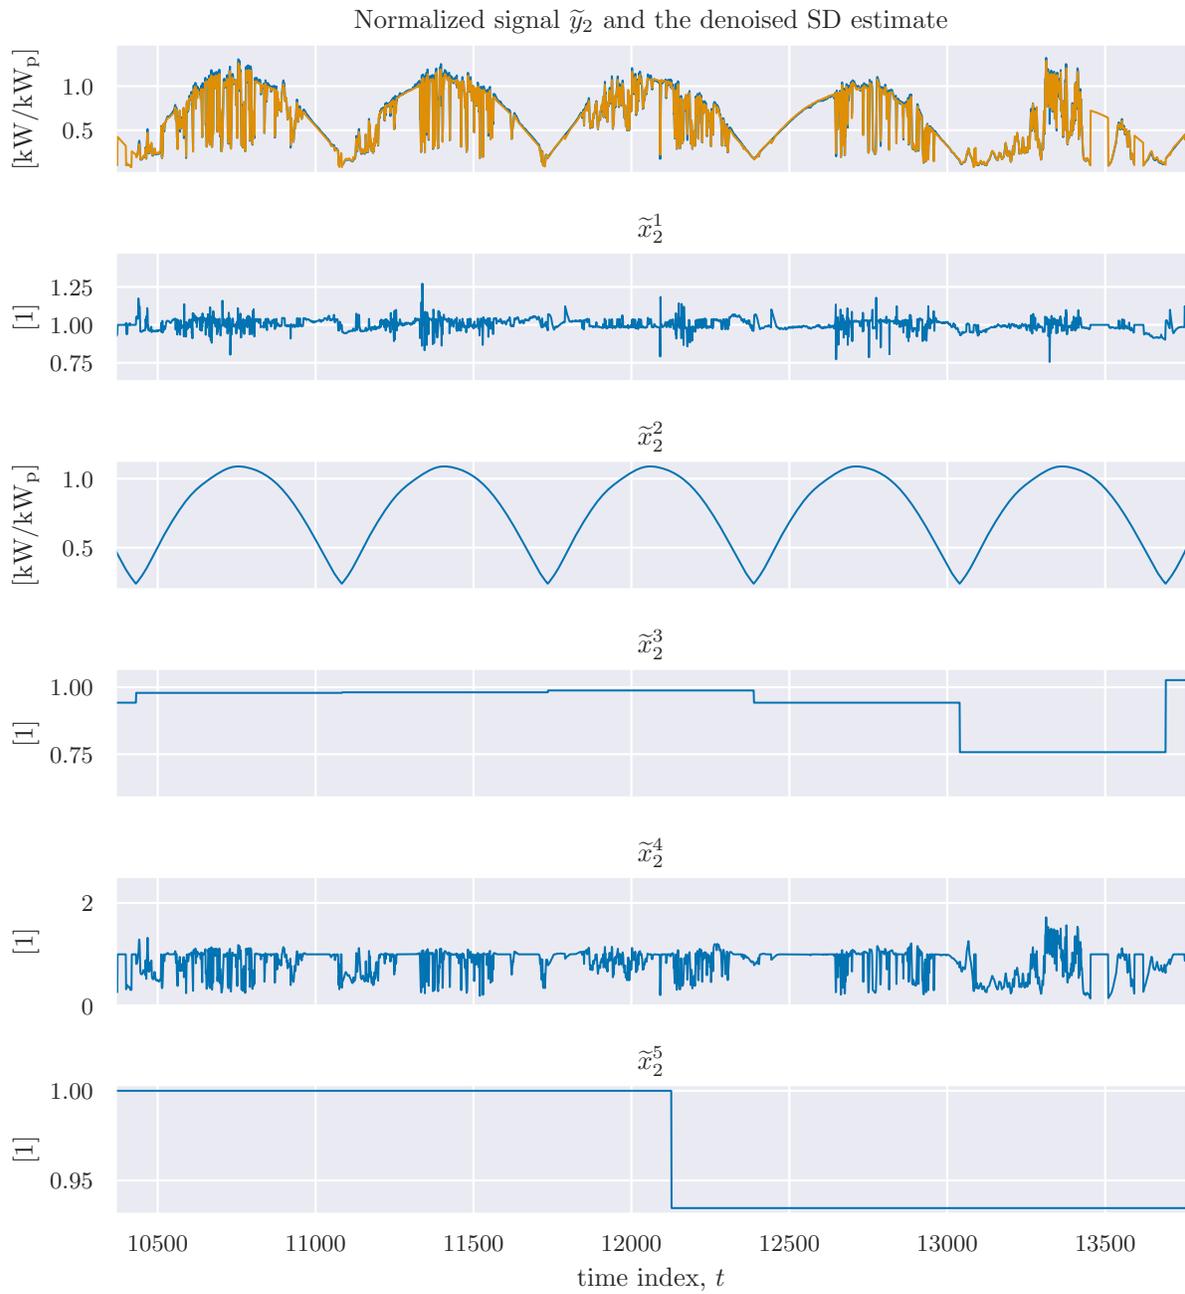

giving us estimates of  $x^1, \dots, x^5$ . Our estimates of the components are  $\tilde{x}^k = \exp x^k$ . We interpret  $\tilde{x}^1, \tilde{x}^2, \tilde{x}^4, \tilde{x}^5$  as multiplicative components, and we interpret  $\tilde{x}^2$  as the baseline clear sky values, normalized. It takes approximately 15 seconds to run the SD-ADMM algorithm to convergence on a 2016 MacBook Pro, with no parallelization of the proximal operator evaluations. A segment of the decomposition is shown in figure 18, highlighting 5 days of data for string 2, including the time of an estimated failure.

The residual term  $\tilde{x}^1$  is shown as a histogram in figure 19. The residual is centered at 1 and has a standard deviation of 0.082. 95% of the entries in the known set have residuals in the range of [0.85, 1.15], *i.e.*,  $\pm 15\%$ .

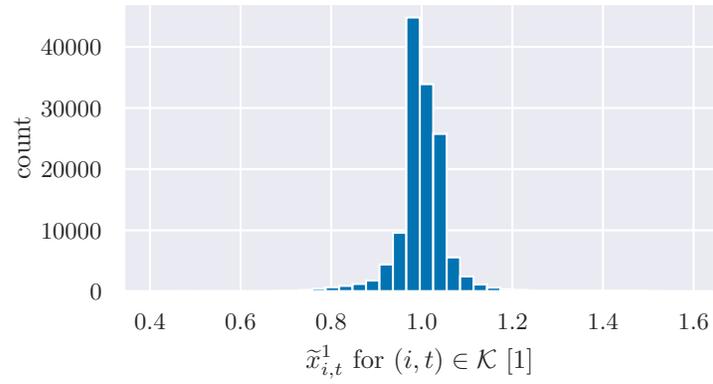

The clear sky component  $\tilde{x}^2$  is shown in figure 20. We plot two days of this periodic component to illustrate the discontinuities in values between adjacent days. We see that the clear sky estimates for the strings are smooth in time, and vary a bit between strings.

The common daily scale factor  $\tilde{x}^3$ , shown in figure 21(a), is constant across days and across columns. This can be thought of how much the clear sky signals need to be scaled to recreate any given day, and the all strings must agree on the factor. Days with significant cloud cover tend to have much smaller scale factors, while clearer days tend to vary by about 10–15%.

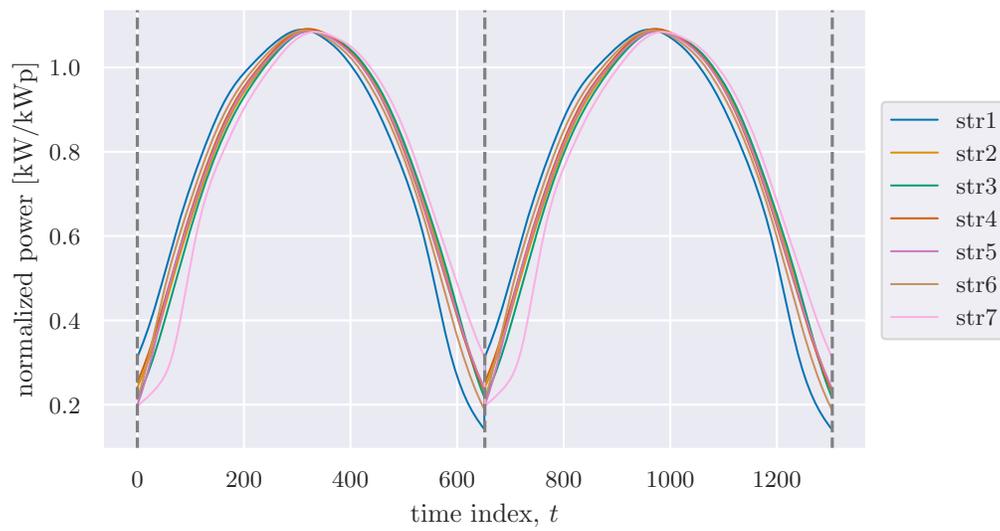

The common weather term  $\tilde{x}^4$ , shown in figure 21(b), is also constant across columns, and it captures the effects of local weather, particularly attenuation by clouds. This term is typically a loss, that is  $\tilde{x}^4 < 1$ . We chose the value of the quantile parameter  $\tau = 0.65$  through hand-tuning and selecting a value that gave good agreement between the clear sky component and the measured data on periods without significant cloud impacts. While having a weather correction term that is larger than about 1.5 does not make much physical sense (see, for example, [ICC16]), we observe that this factor is applied to the combination of components 2 and 3, the clear sky component and the daily scale factor. In fact, we see

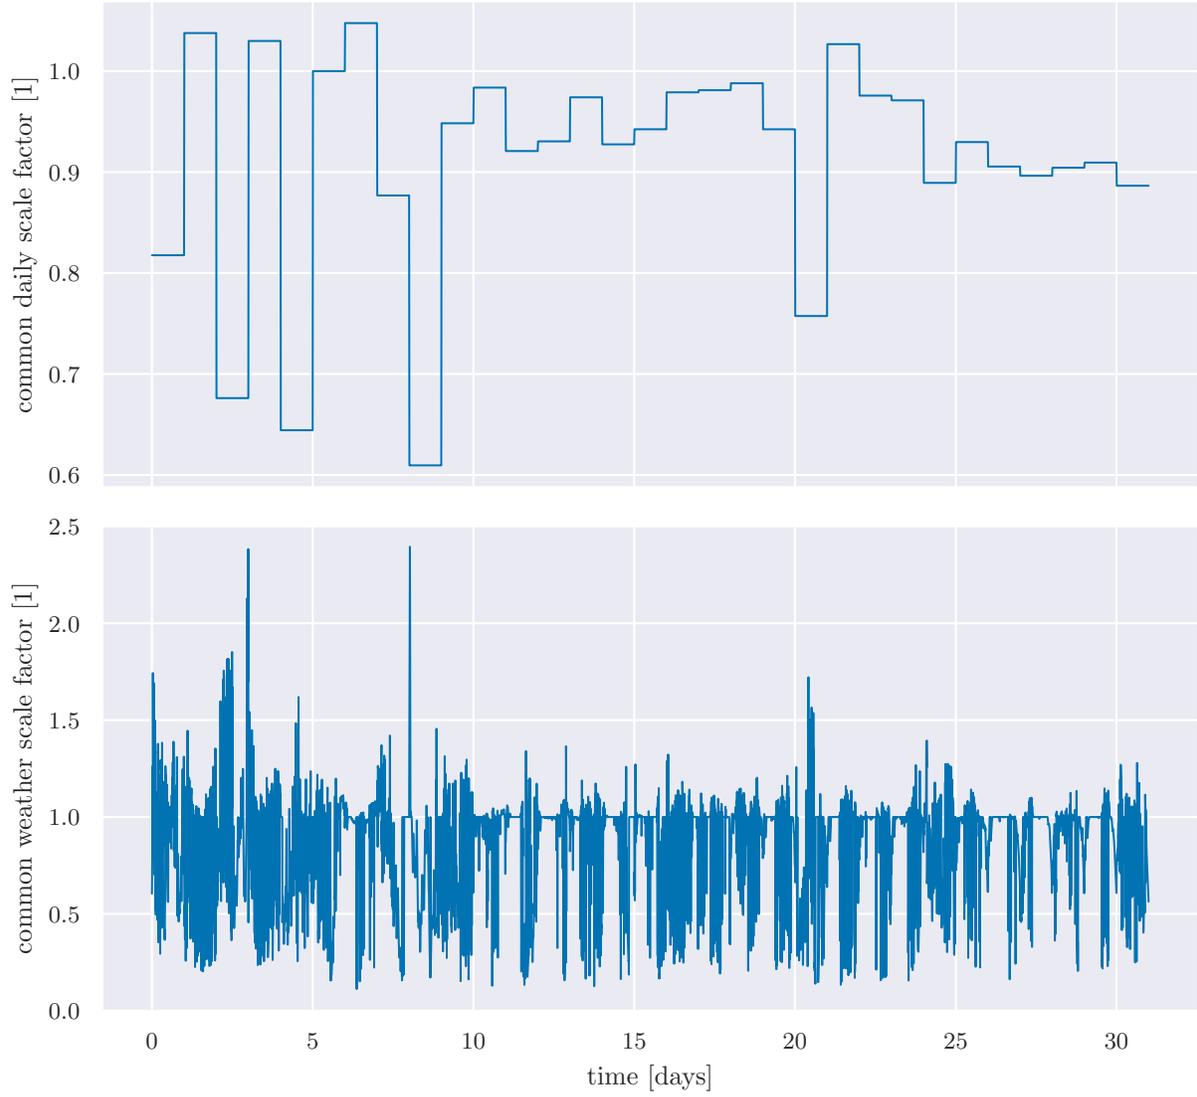

**Figure 18:** Components  $\tilde{x}^k$  for string 2 over 5 days.

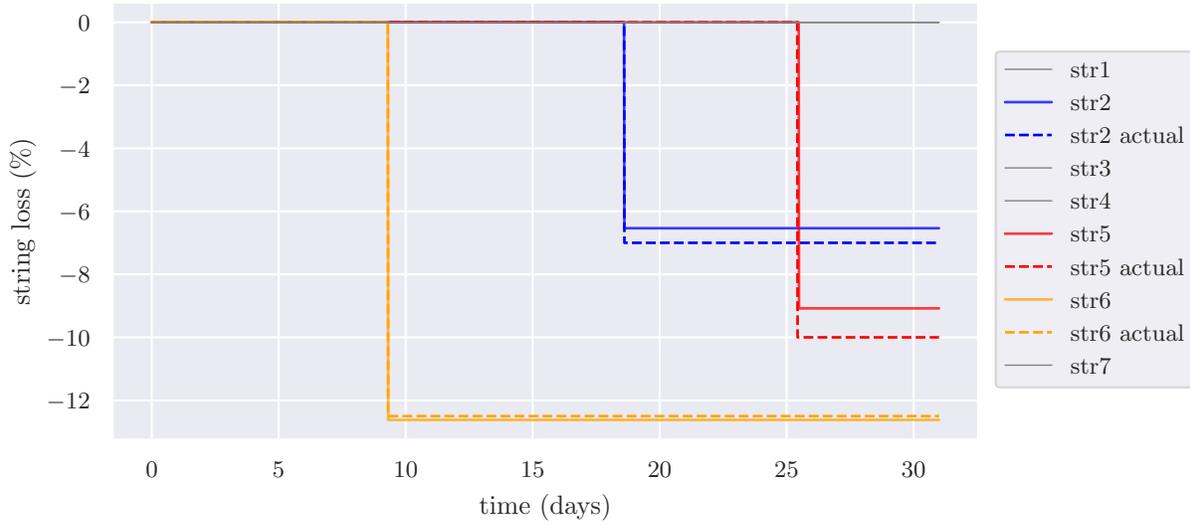

**Figure 19:** Histogram of the residual term  $\tilde{x}^1$  for all entries of the known set  $\mathcal{K}$ .

**Figure 20:** The clear sky component  $\tilde{x}^2$ , with two days shown.

**Figure 21:** (a) Top, the common daily scale factor  $\tilde{x}^3$ . (b) Bottom, the common weather component  $\tilde{x}^4$ . Only one column of each component is plotted as all columns are equal to each other.

**Figure 22:** Failure component, shown as the percentage  $100 \times (1 - \tilde{x}^5)\%$ . The dashed lines show the actual simulated failures.

**Table 2:** Outage detection results

string	metric	actual	predicted
2	amount (%)	-7	-6.24
2	time (days)	18.60	18.61
5	amount (%)	-10	-9.10
5	time (days)	25.42	25.60
6	amount (%)	-12.5	-12.44
6	time (days)	9.30	9.30

the larger values in  $\tilde{x}^4$  exactly on the days that are highly cloudy and use very small daily scale factors.

The failure component  $\tilde{x}^5$  correctly identifies the failures correctly as appearing in only strings 2, 5, and 6, as depicted in figure 22, which shows the predicted and real failure onset times and amounts. The estimated failure time is 5 minutes late for string 2, about 2 hours late for string 5, and exactly correct for string 6; for all three strings, the loss was detected within the same day that the failure occurred. We can also see that the estimated failure amounts are quite good.

## A SD-ADMM algorithm derivation

To derive an ADMM algorithm for SD, we introduce new variables  $z^1, \dots, z^K \in \mathbf{R}^q$  and reformulate the SD problem (7) as

$$\begin{aligned} & \text{minimize} && \phi_1(x^1) + \dots + \phi_K(x^K) \\ & \text{subject to} && \mathcal{M}x^k - z^k = 0, \quad k = 1, \dots, K \\ & && \mathcal{M}y = z^1 + \dots + z^K. \end{aligned}$$

We let  $g$  denote the indicator function of the last constraint,

$$g(z^1, \dots, z^K) = \begin{cases} 0 & \mathcal{M}y = z^1 + \dots + z^K \\ \infty & \text{otherwise,} \end{cases}$$

so the SD problem can be expressed as

$$\begin{aligned} & \text{minimize} && \phi_1(x^1) + \dots + \phi_K(x^K) + g(z^1, \dots, z^K) \\ & \text{subject to} && \mathcal{M}x^k - z^k = 0, \quad k = 1, \dots, K. \end{aligned} \tag{32}$$

We write this in compact form as

$$\begin{aligned} & \text{minimize} && \phi(x) + g(z) \\ & \text{subject to} && \mathcal{M}x^k - z^k = 0, \quad k = 1, \dots, K, \end{aligned} \tag{33}$$

where  $x = (x^1, \dots, x^K)$ ,  $z = (z^1, \dots, z^K)$ , and  $\phi(x) = \phi_1(x^1) + \dots + \phi_K(x^K)$ . We are now ready to derive the ADMM algorithm.

We form the augmented Lagrangian, with parameter  $\rho > 0$ ,

$$\begin{aligned} L_\rho(x, z, \lambda) &= \phi(x) + g(z) + \sum_{k=1}^K \left( \lambda^{kT} (\mathcal{M}x^k - z^k) + (\rho/2) \|\mathcal{M}x^k - z^k\|_2^2 \right) \\ &= \phi(x) + g(z) + (\rho/2) \sum_{k=1}^K \left( \|r^k + u^k\|_2^2 - \|u^k\|_2^2 \right), \end{aligned}$$

where  $r^k = \mathcal{M}x^k - z^k$  are the residuals,  $\lambda^k$  are the dual variables, and  $u^k = (1/\rho)\lambda^k$  are the so-called scaled dual variables [BPC<sup>+</sup>11, §3.1.1].

Iteration  $j$  of ADMM consists of three steps:

$$\begin{aligned} x^{j+1} &= \underset{x}{\operatorname{argmin}} L_\rho(x^j, z^j, u^j) \\ z^{j+1} &= \underset{z}{\operatorname{argmin}} L_\rho(x^{j+1}, z^j, u^j) \\ (u^k)^{j+1} &= (u^k)^j + \mathcal{M}(x^k)^{j+1} - (z^k)^{j+1}, \quad k = 1, \dots, K, \end{aligned}$$

which we refer to as the  $x$ -update,  $z$ -update, and  $u$ -update, respectively.

We now work out and simplify these steps. Since  $L_\rho$  is separable in  $x^k$ , we can minimize over  $x^k$  separately in the  $x$ -update to obtain

$$(x^k)^{j+1} = \operatorname{argmin}_{x^k} (\phi_k(x^k) + (\rho/2)\|\mathcal{M}x^k - (z^k)^j + (u^k)^j\|_2^2), \quad k = 1, \dots, K. \quad (34)$$

The  $z$ -update can be written as

$$z^{j+1} = \Pi(\mathcal{M}(x^1)^{j+1} + (u^1)^j, \dots, \mathcal{M}(x^K)^{j+1} + (u^K)^j),$$

where  $\Pi$  is the projection onto the domain of  $g$ , *i.e.*, the constraints  $\mathcal{M}y = z^1 + \dots + z^K$ . To simplify notation, let  $a^k = \mathcal{M}(x^k)^{j+1} + (u^k)^j$ . The  $z$ -update can be written as

$$\begin{aligned} (z^k)^{j+1} &= a^k + (1/K)(\mathcal{M}y - a^1 - \dots - a^K) \\ &= \mathcal{M}(x^k)^{j+1} + (u^k)^j + (1/K)(\mathcal{M}y - a^1 - \dots - a^K). \end{aligned}$$

Now consider the  $u$ -update. Plugging in the new  $z$ -update above, we get

$$(u^k)^{j+1} = -(1/K)(\mathcal{M}y - a^1 - \dots - a^K).$$

The righthand side does not depend on  $k$ , which means that all  $(u^k)^{j+1}$  are the same and can be denoted as  $u^{j+1}$ . (This simplification is not unexpected since the original problem has only one dual variable, which is a vector in  $\mathbf{R}^q$ .) With this simplification, the  $u$ -update (now for just one scaled dual variable  $u \in \mathbf{R}^q$ ) becomes

$$u^{j+1} = u^j + \frac{1}{K} \left( \sum_{k=1}^K \mathcal{M}(x^k)^{j+1} - \mathcal{M}y \right).$$

Substituting  $u^j$  for  $(u^k)^j$  in the  $z$ -update, we get

$$(z^k)^{j+1} = \mathcal{M}(x^k)^{j+1} - u^{j+1}.$$

Substituting  $(z^k)^j = \mathcal{M}(x^k)^j - u^j$  into the original  $x$ -update (34) above, we obtain

$$\begin{aligned} (x^k)^{j+1} &= \operatorname{argmin}_{x^k} (\phi_k(x^k) + (\rho/2)\|\mathcal{M}x^k - \mathcal{M}(x^k)^j + 2u^j\|_2^2) \\ &= \operatorname{argmin}_{x^k} (\phi_k(x^k) + (\rho/2)\|\mathcal{M}(x^k - (x^k)^j + 2\mathcal{M}^*u^j)\|_2^2) \\ &= \mathbf{mprox}_{\phi_k}((x^k)^j - 2\mathcal{M}^*u^j), \end{aligned}$$

for  $k = 1, \dots, K$ . (We use (14) in the second line.)

We now see that the variables  $z^k$  have dropped out, and we arrive at the final set of ADMM iterations

$$\begin{aligned} (x^k)^{j+1} &= \mathbf{mprox}_{\phi_k}((x^k)^j - 2\mathcal{M}^*u^j), \quad k = 1, \dots, K \\ u^{j+1} &= u^j + \frac{1}{K} \left( \sum_{k=1}^K \mathcal{M}(x^k)^{j+1} - \mathcal{M}y \right). \end{aligned}$$
