One of the key issues in the physics of topological insulators is whether the topologically non-trivial properties survive at finite temperatures and, if yes, whether they disappear only at the temperature of topological gap closing. Here we study this problem, using quantum fidelity as a measure, by means of *ab-initio* methods supplemented by an effective dissipative theory built on the top of the *ab-initio* electron and phonon band structures. We reveal the presence of a characteristic temperature that can be associated with a change of curvature of the conduction band. The transition is not present in a purely electronic system but it appears once we invoke coupling with a dissipative bosonic bath. Features in the dependence with temperature of the fidelity susceptibility can be related to changes in the band curvature, but signatures of a topological phase transition appear in the fidelity only though the non-adiabatic coupling with soft phonons. Our argument is valid in valley topological insulators, but in principle can be generalized to the broader class of topological insulators which host any symmetry-breaking boson.

Introduction The theoretical description [1] and subsequent observation [2] of topological states in the early 2000s dramatically changed the landscape of research in condensed matter physics. Thousands of theoretical papers have been published on this subject, with an overwhelming majority dedicated to properties of zero-temperature model systems [3]. The question of finite temperature effects is a very difficult one and has been put in the spotlight only a few years ago [4, 5]. A difficulty arises because the standard Ginzburg-Landau theory of phase transitions is inapplicable here – one cannot define a local order parameter, instead one must work with invariants defined along entire trajectories in parameter space [6]. The issue of the theoretical treatment of thermal effects on topological insulators is a pressing one since all the experiments are carried out at finite temperature.

There have been so far several theoretical attempts to tackle this problem. From the single particle density functional theory (DFT) perspective, attempts to assess the topological critical temperature are generally based on the closing of the gap at some finite temperature [7–9]. The conjecture made in these papers is that topological invariants stay unaltered up to this point and the entire physics is determined by the single-particle gap inversion. Since the topological invariants results from the collective behaviour of the entire electronic liquid, this assumption needs to be taken with care. The picture provided by many-body methods is in fact strikingly different. First attempts used the concept of Uhlmann parallel transport which generalized the concept of finite-temperature Chern number and aimed to compute its temperature dependence [4]. These studies were initially limited to quantum 1D systems [4, 10] and later gener-

alized to 2D [5]. This kind of analysis, applied to model systems, revealed that the critical temperature can be up to 70% lower than the mean-field critical temperature [4]. There have also been attempts to apply the Hill's thermodynamics (small quantum systems thermodynamics) to capture the influence of the thermodynamic potential of the boundary terms [6, 11]. These numerical studies confirmed the results of the Uhlmann conjecture in model 2D systems and extended the observations to a 3D case. Recently, the use of fidelity was proposed [12, 13], as an equally good tool to probe the quantum phase transitions even in systems with non-local order parameters. An analysis based on this magnitude suggests that in a topological model the fidelity only shows signs of a phase transition at zero temperature [12, 13]. This result would imply that topological states are a characteristic of zero-temperature states and disappear in a cross-over manner as the temperature increases revealing a lack of protection against thermal fluctuations of the topological state of matter. However in Ref. [12] only Hamiltonians with temperature-independent parameters were considered.

Here we address this issue by computing the fidelity on a realistic system with a temperature-dependent electronic structure. We consider a topological insulator protected by the valley (mirror) symmetry of the underlying crystal lattice as we expect that in this case the contributions from thermal fluctuations of the lattice will manifest particularly strongly. We study SnTe which is perhaps the simplest compound of this kind. Being material-specific allows us to perform a joint study that builds an extension of *ab-initio* results by an exact analytic calculation of drag effect.

Band structure as provided by DFT . Our starting point is the band structure computed using density

functional theory (DFT) [14]. The explicit changes of the electronic structure due to thermal expansion are taken into account by performing calculations at the temperature-dependent lattice parameter, obtained from the linear thermal expansion coefficient as calculated in Ref. [9]. The electronic dispersion curves near the band edges at L are displayed in Fig. 1 as a function of temperature. At low temperatures the bottom of the conduction is shifted with respect to the L point, showing a “Mexican-hat”-like feature that reflects the topological character that results from the inversion of bands of opposite parity close to the L-point [15]. As the temperature increases, and the material expands, the gap tends to close. In the process, the “Mexican-hat”-like minimum disappears and the dispersion becomes linear near the crossover. Neglecting the effect of electron-phonon coupling, according to the DFT simulations the closing of the gap would occur at a temperature of around 1700 K due to lattice expansion exclusively, a temperature larger than the melting temperature of the material (1063 K).

FIG. 1. Evolution of the band structure of SnTe with temperature, as calculated with DFT. The temperature, T varies from 100 K to 1900 K in 200 K steps. (inset) Group velocities of electrons in the CB as a function of temperature.

Computing fidelity . We follow the method introduced in Ref. [12] to track the topological phase transition and use the fidelity, defined as

$$\mathcal{F}(\rho^A, \rho^B) = \text{Tr} \left[\sqrt{\sqrt{\rho^A} \rho^B \sqrt{\rho^A}} \right], \quad (1)$$

where ρ^I are the corresponding density matrices. We first compute the single-particle fidelity as a function of temperature using the density matrices obtained from DFT calculations. The single-particle density matrix is readily available in many DFT codes, where it is commonly expressed in the basis of the basis functions used to expand the Kohn-Sham states. In this basis the density matrix

takes the form

$$\rho = \sum_{\nu, \mu} \rho_{\nu, \mu} |\nu\rangle \langle \mu|, \quad (2)$$

with

$$\rho_{\nu, \mu} = \sum_{n\mathbf{k}} f_{n\mathbf{k}} c_{\nu, n\mathbf{k}} c_{\mu, n\mathbf{k}}^*, \quad (3)$$

where $\{|\nu\rangle, |\mu\rangle\}$ are basis orbitals, $n\mathbf{k}$ denotes a Kohn-Sham state, and $f_{n\mathbf{k}}$ is its occupation function.

In the analysis of the topological character based on the *ab initio* electronic structure and zero-temperature invariants, temperature effects are usually limited to lattice expansion and band renormalization due to electron-phonon effects [7–9]. Instead, the analysis based on the quantum fidelity (density matrices) also accounts for changes in the topological character due to the partial occupation of eigenvalues of opposite parity. Remarkably, despite the notable changes in the band dispersion of the material in this temperature range, the single-particle fidelity is not able to detect any sign of the transition, even at the cross-over temperature (~ 1700 K).

FIG. 2. Fidelity as a function of temperature computed from the single-particle, DFT density matrix. (Inset) Derivative of the fidelity as a function of temperature.

Dissipative environment . In SnTe the crystal lattice determines the mirror symmetry by which the topological invariant is defined. At low temperature the material undergoes a ferroelectric phase transition, the electron-phonon coupling must be substantial, so it is necessary to introduce the lattice dynamics explicitly into our considerations. The motion of atoms associated with a soft transverse optical (TO) mode at Γ violates the mirror lattice symmetry with respect to which the topological invariant is defined. If dissipation is brought in by a dynamic electron-phonon coupling then, while the electronic density is in an incoherent fluctuating state, the topological state is undefined. Here we develop a model for an electron gas with a realistic dispersion given by the DFT bands in Fig. 1 interacting non-adiabatically with

the phonon bath. Such dissipative systems are known to host a phase transition [16, 17]. The hamiltonian for electron plus phonon system is

$$H = H_{DFT}[c_k^\dagger c_k] + \sum_{k,q} g(q) c_k^\dagger c_{k-q} (a_q^\dagger + a_{-q}) + \sum_q \omega_q a_q^\dagger a_q, \quad (4)$$

where $\omega_q = c_{ph}q + \omega_0$ is the TO phonon dispersion (a linear dispersion is a valid approximation over a relatively wide range of q around Γ for the TO mode in SnTe [18]), and $g(q)$ is the electron-phonon coupling. We take $g(q) \sim q^\alpha$, a generalization of a displacement potential. In SnTe, for the TO phonon mode $\alpha < 1$ as evidenced by a DFT study [19]. The ladder vertex correction can further renormalize [20] the value of α .

A solution of Eq. 4 at a given temperature T_0 would be a specific state $|\rho_{tot}\rangle = |\rho_{el}, n_{ph}\rangle$. Since the TO phonons are coupled with other branches (which in turn also interact with lattice dislocations, interfaces etc.), this is a dissipative system. We refrain from solving this non-trivial [21] problem, as we are interested only in the *change* of the incoherent part of electronic density as the temperature changes [16, 22]. The form of this Hamiltonian will hold as long as there is no structural phase transition, which for SnTe above 100K is justified.

The time derivative of a density matrix is [23],

$$\frac{d\hat{\rho}_{el}}{dt} = i[\hat{H}, \hat{\rho}_{el}] + \mathcal{R}[\hat{\rho}_{el}] \quad (5)$$

a general form that encapsulates the Lindbladian super-operator [24] for a specific choice of a relaxation functional $\mathcal{R}[\hat{\rho}]$. It has been shown [25] that, in general, for any steady state the norm of L.H.S. (e.g. $|\dots| = Tr \hat{\rho}_{el}$) is minimized, which implies that minimal currents are flowing in the steady state. Even without a detailed knowledge about $\hat{\rho}_{el}$, this condition suffices to state that the variation around the steady state, $\delta\rho_{el}$, of L.H.S must be equal to zero. By noting that only the second term in the Hamiltonian Eq. 4 does not commute with $\hat{\rho}_{el}$ and dividing the relaxation into unitary adiabatic time evolution and dissipative non-adiabatic components we can write the following phenomenological master equation for the *variation* of the density when the temperature changes:

$$\langle \delta(\hat{F}_{abs} - \hat{F}_{emit}) \rangle_{k,q} - q(V_F(k) - c_{ph})\delta\rho_{inc}(k, q; T) - \mathbb{1}q\delta\rho_{coh}(k, q; T) = 0, \quad (6)$$

where we assumed that the q^{th} phonon has been involved in the process, through absorption/emission operators $\hat{F}_{abs,emit}$, V_F is the Fermi velocity and ρ_{coh} and ρ_{inc} are the coherent and incoherent part of the density matrix. We have assumed a stationary condition $d\rho/dt = 0$ and the two terms in the second line of Eq. 6 compensate the modified thermal “drag” force. This equation can be interpreted as an action of the Lindbladian super-operator on the density matrix $\hat{L}\{\delta\rho\} = 0$. The first term in

the Lindbladian is the scattering a term $\hat{F}_i \sim [H, \rho_{tot}]$ and, according to Eq. 4, the electron liquid can constantly absorb and emit phonons [26]. We first consider a case with a *single* phononic event when the emission-absorption drag “force” \hat{F} is given by an analogue of the Fermi Golden rule:

$$\langle \hat{F}_{abs} - \hat{F}_{emit} \rangle_{k,q} = g_{el-ph}(q) N_q (f_{k-q}(1-f_k) - f_k(1-f_{k-q})), \quad (7)$$

where we took mean-field averages, i.e. N_q and f_k are the Bose-Einstein and Fermi-Dirac distribution functions, respectively. Increasing the temperature by dT changes the balance between absorption and emission by an amount proportional to a derivative of the Bose-Einstein distribution.

In the second term of the Lindbladian we have distinguished adiabatic (coherent, $\delta\rho_{coh}$) and non-adiabatic (incoherent $\delta\rho_{inc}$) relaxation channels of fermionic density, with the non-adiabatic one depending on a difference between electron and phonon velocities. We make the conjecture that since the change (due to phonon environment) of diagonal elements of density matrix (a trace of which is proportional to fidelity) is by definition caused by dissipation, only non-adiabatic processes will cause $\delta\mathcal{F}(T) \neq 0$: if in Eq. 1 one takes $\rho^B = \rho^A + \delta\rho_{inc}$ and then Taylor expand, one finds that the fidelity susceptibility $\chi_{\mathcal{F}}(T) = d \log[\mathcal{F}(T)]/dT \sim d\rho_{inc}/dT$.

Since, in Eq. 1, we are interested only in the electronic part of the density matrix, ρ_{el} , we integrate out Eq. 7 over all possible q (all possible single-phonon emission/absorption events) i.e. $\frac{d\rho_{inc}^{(1)}}{dT} = \sum_q \frac{d\rho_{inc}}{dn_q} \frac{dn_q}{dT}$ which can be performed analytically:

$$\begin{aligned} \frac{d\rho_{inc}^{(1)}(\vec{k}, T; E_{DFT}(T))}{dT} = & \frac{v_F(\vec{k}, T)}{v_F(\vec{k}, T) - c_{ph}(T)} \bar{g}_{el-ph} f\left(\frac{E_{DFT}(\vec{k}, T)}{k_B T}\right) \\ & (\Phi[\exp(-E_{DFT}(\vec{k}, T) - \omega_0)/k_B T], \alpha, 1 - 2c_{ph}/v_F(\vec{k}, T)] - \\ & \Phi[\exp(-E_{DFT}(\vec{k}, T) + \omega_0)/k_B T], \alpha, 1 + 2c_{ph}/v_F(\vec{k}, T)]). \end{aligned} \quad (8)$$

We require $\alpha > 0$ as then the generalized Fermi-integral over q evaluates to an analytic expression involving the Lerch transcendent function, $\Phi(\cdot, \cdot)$, which results from integrating out $(1 - f_{k-q})$ times Boltzman distribution times the power law q^α over a Hankel contour. This formula generalizes past results for Fermi integrals that were expressed as a poly-logarithms. The advantage of Eq. 8 is that it does not constrain any of c_{ph}/V or g_{el-ph}/V to a small parameter range (non-adiabatic regime) neither does it make any assumptions on thermal distributions (hence it is valid in the intermediate temperature regime where $f(E)$ is certainly not a step function). Furthermore the accuracy of this semi-analytic approach is not

critically dependent on a density of a reciprocal space sampling, as it would have been in a purely numerical approach.

The above calculation gives a probability of electron density shifting into incoherent part due to interaction with a *single* phonon. Beyond the weak coupling regime [27] we are interested in a recursive process, where electronic density shifted by the n^{th} interaction is consecutively distorted by the $(n + 1)^{\text{th}}$ interaction. We then need to solve such a recursion problem, i.e., the stationary condition expressed in Eq. 6, couples the $|n_{ph}\rangle$ state with $|n_{ph} \pm 1\rangle$ states, hence to find the overall stationary state $\hat{L}\{\delta\rho^{(\infty)}\} = 0$ we need to find the kernel of such a tri-diagonal matrix. The solution $\delta\rho_{inc}^{\infty}(k, q; T)$ is a continued fraction. The result from Eq. 8, $d\rho_{inc}^{(1)}(\vec{k}, T; E_{DFT}(T))/dT$, can be simply incorporated into the continuous fraction solution for the derivative:

$$\frac{d\rho_{inc}^{(n+1)}(\vec{k}, T; E_{DFT}(T))}{dT} = \mathcal{K}_{m=1}^n \frac{\bar{g}_{el-ph}^m \frac{d\rho_{inc}^{(1)}(\vec{k}, T; E_{DFT}(T))}{dT}}{1 + \bar{g}_{el-ph}^m \frac{d\rho_{inc}^{(1)}(\vec{k} \pm \vec{q}_0, T; E_{DFT}(\vec{k} \pm \vec{q}_0) \pm m\omega_0)}{dT}}, \quad (9)$$

where $\mathcal{K}_{m=1}^n$ is a Gauss continued fraction symbol. χ_F , is then calculated by entering the DFT electronic band structure and phonon velocity in Eq. 8 and recursively applying Eq. 9 until convergence is achieved. The fidelity susceptibility plotted in Fig. 3 peaks between 500 K and 700 K, indicating a phase transition of the electron gas, driven by a loss of coherence through the coupling with the TO phonons. The reason for this is that in the regions with extremely low Fermi velocity the drag effect is the strongest and capable of *non-adiabatically* pulling some carriers away from a coherent single particle manifold into states strongly coupled with phonons which do not have a well defined symmetry property anymore. This mechanism is confirmed by the momentum-resolved $\chi_F(T)$, shown in Fig. 4, where we observe close connection between $\chi_F(T)$ and the shape of the conduction band: the manifolds of largest drag are either located close to the minimum(s) or at a large bone-shaped zone at the temperature for which the band curvature changes.

Discussion and Conclusions . Our results show that, using quantum fidelity as a measure, a finite-temperature thermal topological phase transition exists. The position of the peak in the fidelity susceptibility is robust and remains unaffected by small to moderate changes of all renormalizable parameters such as g_{el-ph} , c_{ph} , the exponent α or gap $\Delta(T)$ which implies that it is a generic, stable feature of the system that exist in the regime of intermediate electron-phonon coupling. Furthermore, the effect on the gap size $\Delta(T)$ of electron-phonon coupling and electronic correlations tend to cancel each other, as shown in Ref. [9], at least in the independent-particle framework.

FIG. 3. An overall T dependence of quantum fidelity derivative (with a minus sign) obtained by truncating the interactions at $n = 10^{\text{th}}$ order and integrating over the entire Brillouin zone (BZ) to find $d\rho_{inc}^{(n)}(T)/dT \sim \chi_F(T)$. We see a peak indicating the phase transition.

FIG. 4. Momentum-resolved fidelity susceptibility $\chi_{\mathcal{F}}(T)$ shown in a region of the BZ around the L point. In the main panel we show isosurfaces corresponding to $\chi_{\mathcal{F}}(T) = 0.02$ for $T = 300$ K (blue), 500 K (pink) and 900 K (green). In the first two cases there are two minima and for 500 K the isosurface is the largest. The inset shows three isosurfaces $\chi_{\mathcal{F}}(T) = 0.3$, $\chi_{\mathcal{F}}(T) = 0.03$, $\chi_{\mathcal{F}}(T) = 0.01$ for $T = 500$ K showing that the largest values of drag are indeed concentrated close to the minima.

Our formalism can be generalized to any boson that couples with electrons and violates the symmetry prop-

erty defining the topological class. This may be low energy inter-band plasmons for systems defined by parity symmetry, or para-magnons for systems with strong Rashba interactions. The only conditions that the boson must fulfil is the $g_{el-ph} \sim q^\alpha$ with $\alpha > 0$ and its dispersive character $\omega(q) = c_{ph}q$ for a range of q . While these are typical for acoustic phonons, they are also obeyed by symmetry breaking TO phonons in some incipient ferroelectric. While the position of the phase transition is determined by the change of band's curvature, amplitude of the associated peak is related to TO phonon's c_{ph} and g_{el-ph} . Overall, the topological thermal phase transition should apply to much broader class of materials than only the topological crystal insulators studied here.
