We describe the major low-energy electron-impact processes involving H_2^+ and HD^+ , relevant for the astrochemistry of the early Universe: Dissociative recombination, elastic, inelastic and superelastic scattering. We report cross sections and Maxwellian rate coefficients of both rotational and vibrational transitions, and outline several important features, like isotopic, rotational and resonant effects.

PACS numbers:

I. INTRODUCTION

The models of the early Universe [1, 2] state that atomic hydrogen, helium and lithium - and their cations - have been the very first species produced by the nucleosynthetic activity which followed the Big Bang. Later on, atoms reacted to form simple molecules, like HeH^+ , H_2 , HD , LiH and their cations. These latter ones face Dissociative Recombination (DR):

Ro-Vibrational Transitions (RVT):

and Dissociative Excitation (DE):

where N_i^+/N_f^+ and v_i^+/v_f^+ are the initial/final rotational and vibrational quantum numbers of the target ion, and ε/ε' the energy of the incident/scattered electron.

The dissociative recombination was first bravely proposed as elementary process in the Earth's ionosphere, as a competitor to the photoionisation providing free electrons [3]. Currently, it is considered a corner-stone reaction in the synthesis of interstellar molecules and plays an important role in the ionized layers of other planets, exoplanets and their satellites. In the modeling of the kinetics of cold dilute gases, the ro-vibrational distribution of molecular species is governed by competition between formation and destruction processes, absorption, fluorescence, radiative cascades, and low-energy collisions involving neutral and ionized atomic and molecular species as well as electrons. Rate coefficients for such elementary reactions are badly needed, in particular for the chemical models of the early Universe, interstellar medium, and planetary atmospheres.

Within a semiclassical scenario, a two-step process characterizes the DR. First, the electron is captured by the molecular cation while exciting an electron, similarly to the dielectronic recombination of atomic cations. A neutral molecule is formed, for many species in a doubly-excited, repulsive electronic state, located above the lowest ionization potential. Second, the molecule dissociates rapidly along the potential energy curve of this dissociative state. The (re-)ejection of an electron may occur - autoionization - with low probability due to rapid dissociation which lowers the electronic energy below the lowest ionization limit. The molecule stabilizes then the electron capture by dissociating.

The spectroscopic information, given by the output of RVT reactions (2), is sensitive to the quantum numbers of the target ion (initial: $\{N_i^+, v_i^+\}$ and final: $\{N_f^+, v_f^+\}$) and consequently it provides the structure of the ionized media. As for the RVT, they are called Elastic Collisions (EC), Inelastic Collisions and Super-Elastic Collisions (SEC) when the final energy of the electron is equal, smaller or larger respectively than the initial one.

This paper aims to illustrate our theoretical approach of the reactive collisions of electrons with H_2^+ and HD^+ cations at low - below 1 eV - energy, from basic ideas to computation of cross sections and rate coefficients, *via* details of the methods we use. The results we show are a part of a huge series of data we are about to produce, relevant for the kinetic modelling of the early Universe. This data generation was initiated by previous publications of our group [5, 11]. In the present study, the accent is put on HD^+ rather than on H_2^+ , since most of the latest experiments - performed in storage rings - focused on this isotopologue, is subject of quick vibrational relaxation and, consequently, more easy to vibrationally resolve than the homonuclear species. We have to notice that, whereas for this latter isotopologue, the rotational transitions involve rotational quantum numbers of

strictly the same parity (even or odd), this rule is not valid for the deuterated variant. However, we have assumed it for HD^+ too, since no data are so far available for the *gerade/ungerade* mixing, and since the transitions between rotational quantum numbers of different parity are much less intense than the others [19].

Our paper is organized as follows: The introduction is followed - Section II - by a brief description of the employed theoretical approach and of the major computational details. In section III we present and discuss our calculated cross sections and rate coefficients. The paper ends with conclusions - Section IV.

II. THEORETICAL APPROACH

We presently use a stepwise version of the Multichannel Quantum Defect Theory (MQDT) to study the electron-induced reactions described in Eqs. (1–3). In the last decade, we made evolve this approach and applied it successfully for computing the dissociative recombination, ro-vibrational and dissociative excitation cross sections of H_2^+ and its isotopologues [4, 5, 11, 18], CH^+ [9], SH^+ [8], BeH^+ and its isotopologues [13–15], etc.

The reactive collision between an electron and a diatomic cation target can follow two pathways, a *direct* one when the electron is captured into a (most often doubly-excited) dissociation state of the neutral and an *indirect* one where the electron is captured in a bound mono-excited Rydberg state which in turn is predissociated by the dissociative one. Both pathways involve ionization and dissociation channels, *open* if the total energy of the molecular system is higher than the energy of its fragmentation threshold, and *closed* in the opposite case. The open channels are responsible for the direct mechanism and for the autoionization/predissociation, while the closed ionization channels imply the electron capture into series of Rydberg states [16?]. The quantum interference between the indirect and the direct mechanisms results in the *total* processes.

A detailed description of method has been given in previous articles [9, 11], and here, the main ideas and steps will be recalled.

1. *Building the interaction matrix:* Within a quasidiabatic representation, for a given set of conserved quantum numbers of the neutral system, Λ (projection of the electronic angular momentum on the internuclear axis) and N (total rotational quantum number), the interaction matrix is based on the couplings between ionization channels - associated with the ro-vibrational levels N^+, v^+ of the cation and with the orbital quantum number l of the incident/Rydberg electron - and dissociation channels.
2. *Computation of the reaction matrix:* We adopt the second-order perturbative ‘exact’ solution [12] of the Lippmann-Schwinger integral equation [6, 10].
3. *Diagonalization of the reaction matrix:* We end up in building the *eigenchannel* short-range representation.

FIG. 1: Dissociative Recombination (DR) and Elastic Collisions (EC) of $\text{HD}^+(\text{X}^2\Sigma_g^+)$, effect of the excitation of the target. Black: target in its ground state ($N_i^+ = 0, v_i^+ = 0$). Red: target rotationally excited ($N_i^+ = 1, v_i^+ = 0$). Blue: target vibrationally excited ($N_i^+ = 0, v_i^+ = 1$).

4. *Frame transformation* We switch from the *Born-Oppenheimer* (short-range) representation, characterized by N, v , and Λ to the close-coupling (long-range) representation, characterized by N^+, v^+, Λ^+ for the ion, and l (orbital quantum number) for the incident/Rydberg electron.
5. *Building of the generalized scattering matrix:* Based on the frame-transformation coefficients and on the Cayley transform, we obtain the generalized scattering matrix, organized in blocks associated with energetically open (*o*) and/or closed (*c*) channels:

$$\mathbf{X} = \begin{pmatrix} \mathbf{X}_{oo} & \mathbf{X}_{oc} \\ \mathbf{X}_{co} & \mathbf{X}_{cc} \end{pmatrix}. \quad (4)$$

6. *Building of the physical scattering matrix:* Applying the method of ‘elimination of the closed channels’ [17] we get the scattering matrix:

$$\mathbf{S} = \mathbf{X}_{oo} - \mathbf{X}_{oc} \frac{1}{\mathbf{X}_{cc} - \exp(-i2\pi\nu)} \mathbf{X}_{co}. \quad (5)$$

The diagonal matrix ν in the denominator above contains the effective quantum numbers corresponding to the vibrational thresholds of the closed ionisation channels at the current total energy of the system.

7. *Computation of the cross-sections:* For the target initially in a state characterized by the quantum numbers $N_i^+, v_i^+, \Lambda_i^+$, and for the energy of the incident electron ε , the dissociative recombination and the ro-vibrational transitions global cross-sections

FIG. 2: Ro-Vibrational Excitation (RVE) of $\text{HD}^+(X^2\Sigma_g^+)$, effect of the excitation of the target. Left: target in its ground state ($N_i^+ = 0, v_i^+ = 0$). Middle: target vibrationally excited ($N_i^+ = 0, v_i^+ = 1$). Right: target rotationally excited ($N_i^+ = 1, v_i^+ = 0$).

read respectively

$$\sigma_{diss \leftarrow N_i^+ v_i^+} = \sum_{\Lambda, sym} \sigma_{diss \leftarrow N_i^+ v_i^+}^{(sym, \Lambda)}, \quad (6)$$

$$\begin{aligned} \sigma_{diss \leftarrow N_i^+ v_i^+}^{(sym, \Lambda)} &= \frac{\pi}{4\epsilon} \rho^{(sym, \Lambda)} \sum_N \frac{2N+1}{2N_i^++1} \times \\ &\times \sum_{l, j} |S_{d_j, N_i^+ v_i^+ l}^{(sym, \Lambda, N)}|^2, \end{aligned} \quad (7)$$

$$\sigma_{N_f^+ v_f^+ \leftarrow N_i^+ v_i^+} = \sum_{\Lambda, sym} \sigma_{N_f^+ v_f^+ \leftarrow N_i^+ v_i^+}^{(sym, \Lambda)}, \quad (8)$$

$$\begin{aligned} \sigma_{N_f^+ v_f^+ \leftarrow N_i^+ v_i^+}^{(sym, \Lambda)} &= \frac{\pi}{4\epsilon} \rho^{(sym, \Lambda)} \sum_N \frac{2N+1}{2N_i^++1} \times \\ &\times \sum_{l, l'} |S_{N_f^+ v_f^+ l', N_i^+ v_i^+ l}^{(sym, \Lambda, N)} - \delta_{N_i^+ N_f^+} \delta_{v_i^+ v_f^+} \delta_{ll'}|^2, \end{aligned} \quad (9)$$

where *sym* is referring to the inversion symmetry - gerade/ungerade - and to the spin quantum number of the neutral system, N is standing for its total rotational quantum number, and $\rho^{(sym, \Lambda)}$ is the ratio between the multiplicities of the neutral system and of the ion.

III. RESULTS AND DISCUSSIONS

The results presented in this work are the first ones going beyond our previous studies performed on HD^+ [11, 18] and H_2^+ [5] for low collision energies relevant for astrophysical applications. Indeed, not only we extended the range of the incident energy of the electron but, furthermore, we considered for the first time simultaneous rotational and vibrational transitions (excitations and/or de-excitations).

The calculations were performed using the step-wise MQDT method including rotation, briefly outlined in the previous section. We have used the same molecular structure data sets as those from our previous studies [5, 11, 18]. The cross sections have been calculated with the inclusion of both *direct* and *indirect* mechanisms for the Σ^+ , Π and Δ - singlet and triplet, gerade and ungerade - symmetries at the highest (second) order of perturbation theory. The energy range considered here was $10^{-5} - 1.7$ eV, while the energy step was taken as 0.01 meV.

Our results are presented in figures 1-4, where we have chosen three different initial ro-vibrational levels of the ground electronic state of both target systems, namely $(N_i^+, v_i^+) = (0, 0)$, $(1, 0)$ and $(0, 1)$, corresponding to *ground state*, lowest rotationally *excited state* and low-

FIG. 3: De-excitation of the lowest vibrationally-excited level ($N_i^+ = 0, v_i^+ = 1$) of $\text{HD}^+(\text{X}^2\Sigma_g^+)$, dependence on the *final* ro-vibrational state: ($N_i^+ = 0, v_i^+ = 0$) - vibrational de-excitation, black, ($N_i^+ = 2, v_i^+ = 0$) and ($N_i^+ = 4, v_i^+ = 0$) - rotational excitation and vibrational de-excitation, blue and red respectively.

est *vibrationally* excited state respectively.

The calculated cross sections (Figs. 1-3) are restricted to low collision energies - $\varepsilon \leq 0.5$ eV - where the rotational effects are the most relevant, while for calculating the rate coefficients (Fig. 4) we have used the cross sections on the whole energy range.

Figure 1 shows the dissociative recombination (solid lines) and resonant elastic scattering (dashed lines) cross sections of HD^+ for the previously defined three initial target states. The background $\frac{1}{\varepsilon}$ trend is due to the direct mechanism, while the resonant structures correspond to the temporary captures of the incident electron into ro-vibrational levels of Rydberg states - indirect mechanism.

The cross section of EC exceeds the DR by at least two orders of magnitudes, and we found that the importance of resonances and of the target-excitation effects are much less pronounced than in the case of the DR, both on order of magnitude and on position and number density of resonances.

Figure 2 illustrates the dependence of the ro-vibrational excitation - $\Delta N^+ = 0, 2, 4$ and $\Delta v^+ = 0, 1$ - cross section on the excitation of the target. While the most prominent $\Delta N^+ = 2, \Delta v^+ = 0$ transition shows very little dependence, those involving more change in the ro-vibrational state are more sensitive to the target state. The largest sensitivity corresponds to the $\Delta N^+ = 4$ transition, where a unity change in either and/or both rotational and vibrational quanta increases the cross section with more than one order of magnitude. The cross sections display threshold effects and, imilarly to DR, prominent resonances. On the other hand, concerning the intensity of the transitions, the $\Delta N^+ = 2, \Delta v^+ = 0$ one is followed by the $\Delta v^+ = 1$ purely vibrational (blue curves) and by either the $\Delta N^+ = 4$ purely rotational (red curves) or $\Delta N^+ = 2, \Delta v^+ = 1$ (green

FIG. 4: Electron-impact dissociative recombination and ro-vibrational transitions of HD^+ and H_2^+ in their ground state: Maxwell rate coefficients.

curves) 'mixed' ro-vibrational excitations. The smallest cross sections characterize the $\Delta N^+ = 4, \Delta v^+ = 1$ excitations.

Figure 3 is an illustration of the dependence of the de-excitation cross section on the *final* ro-vibrational state of the target ion. We have chosen as example the case of $\text{HD}^+(\text{X}^2\Sigma_g^+)$ initially on its ($N_i^+ = 0, v_i^+ = 1$) level. The black, blue and red curves correspond to the ($\Delta v^+ = -1, \Delta N^+ = 0$), ($\Delta v^+ = -1, \Delta N^+ = 2$), and ($\Delta v^+ = -1, \Delta N^+ = 4$) transitions respectively. While bellow 10 meV of collision energy the three cross sections have roughly the same shape and magnitude, above 10 meV the $\Delta N^+ = 4$ transition shows quite different resonance patterns and becomes almost one order of magnitude smaller than the other two transitions.

And finally, in order to obtain the thermal rate coefficients, we have convoluted our cross sections with the isotropic Maxwell distribution function for the kinetic energy of the incident electrons:

$$\alpha(T) = \frac{8\pi}{(2\pi kT)^{3/2}} \int_0^{+\infty} \sigma(\varepsilon) \varepsilon \exp(-\varepsilon/kT) d\varepsilon, \quad (10)$$

where σ is one of the cross sections calculated according the eqs. (6) and (9) and k is the Boltzmann constant.

The DR and RVT Maxwell rate coefficients for electron temperatures between 10 and 3000 K are given in Fig. 4 for HD^+ and H_2^+ targets initially in their ground ro-vibrational state (N_i^+, v_i^+) = (0,0). The resonant EC rates are overall constantly the highest. Among the others proceses the DR ones predominates at very low temperatures, and is surpassed by the lowest rotational excitation above 50 K. The higher excitations become notable above 2000 K only. Figure 4 also illustrates the isotopic effects: it is important for $\Delta N^+ = 2$ and 4 rotational excitations and for DR below 100 K electron temperature.

IV. CONCLUSIONS

The multichannel quantum defect theory results in the detailed modeling of the reactive collisions of electrons with H_2^+ and HD^+ . The account of the interfering mechanisms - direct and indirect - as well as of the major interactions - Rydberg/valence, ro-vibronic and rotational - result in accurate state-to-state theoretical cross sections and rate coefficients.

The results of the present paper are a first step in the extension of our previous studies on reactive collision of HD^+ and H_2^+ with electrons to a wider range of incident collision energy and to mixed - i.e. simultaneous rotational and vibrational - transitions. The results concerning higher ro-vibrational levels are the subject of an ongoing work. We do expect a strong dependence of the cross sections and Maxwell rate coefficients on the target state. The provided collisional data are available on demand to be used in the kinetics modeling in astrochemistry - early Universe, interstellar molecular space - and cold plasma physics.
