ABSTRACT

We investigate applications of machine learning models to directly infer physical properties of brown dwarfs from their photometry and spectra using *The Cannon*. We demonstrate that absolute magnitudes, spectral types, and spectral indices can be determined from low-resolution SpeX prism spectra of L and T dwarfs without trigonometric parallax measurements and with precisions competitive with commonly used methods. For T dwarfs with sufficiently precise spectra and photometry, bolometric luminosities and effective temperatures can be determined at precisions comparable to methods that use polynomial relations as a function of absolute magnitudes. We also provide new and updated polynomial relations for absolute magnitudes as a function of spectral types L0–T8 in 14 bands spanning Pan-STARRS r_{p1} to AllWISE $W3$, using a volume-limited sample of 256 brown dwarfs defined entirely by parallaxes. These include the first relations for brown dwarfs using Pan-STARRS1 photometry and the first for several infrared bands using a volume-limited sample. We find that our novel method with *The Cannon* can infer absolute magnitudes with equal or smaller uncertainties than the polynomial relations that depend on trigonometric parallax measurements.

Key words: brown dwarfs – methods: data analysis – methods: statistical – techniques: spectroscopic – stars: fundamental parameters

1 INTRODUCTION

Brown dwarfs are self-gravitating objects more massive than planets ($\geq 13 M_{\text{Jup}}$; Spiegel et al. 2011) whose central temperatures and densities are not sufficient for hydrogen fusion to occur ($\leq 70 M_{\text{Jup}}$; Dupuy & Liu 2017). These faint, substellar objects cool continuously as they age through L (≈ 2000 K), T (≈ 1000 K), and Y (≈ 300 K) spectral types. Spectroscopic analysis provides a useful tool for classification of brown dwarfs and is crucial for discerning their physical properties such as luminosity, temperature, and surface gravity. However, determining these parameters is complicated by their evolution through cooler temperatures and the challenges associated with characterizing precise atmospheric properties from spectra, limiting the information we can extract from modelling and fitting techniques.

Absolute magnitudes of brown dwarfs are also essential data for constraining and modelling evolution and physical properties, and for flux-calibrating spectra. However, absolute magnitudes require distance measurements that are observationally expensive for the many brown dwarfs that are too faint and red for *Gaia* (Best et al. 2020). A more efficient method to determine absolute magnitudes is to use empirical relationships with spectral types calibrated by objects with existing parallax measurements (e.g., Dupuy & Liu 2012; Faherty et al. 2016; Kirkpatrick et al. 2021). (In this paper, “parallax” refers to trigonometric parallax.) In Section 2 we present updated polynomial relations between spectral type and absolute magnitude based

on a volume-limited sample in 14 bands. These include the first determined for Panoramic Survey Telescope and Rapid Response System (Pan-STARRS1) 3π Survey (hereinafter PS1; Chambers et al. 2021) photometry and the first using a volume-limited sample for the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006) photometric system in J and K bands, Y and K bands for the Mauna Kea Observatories (MKO) photometric system (Simons & Tokunaga 2002; Tokunaga et al. 2002), and the Wide-Field Infrared Survey Explorer (AllWISE; Wright et al. 2010) photometric system. Spectral types, however, are heterogeneously determined and do not capture subtle differences in spectral features between objects, limiting the accuracy of these polynomial relations.

Machine learning has been used in astronomical research as a tool to process, analyse, and extract new information from large amounts of data (Ivezić et al. 2014). For example, machine learning models such as *The Cannon* (Ness et al. 2015; Ho et al. 2017a) have been utilized to infer stellar parameters and abundances from spectroscopic data. These models employ “stellar labels” (i.e. measured quantities) from reference stars to infer unknown labels for a new sample of objects. Previous applications of *The Cannon* have used reliable measurements of physical quantities such as effective temperature, surface gravity, and chemical abundances (Casey et al. 2017; Behrard et al. 2019), but any “known” labels could be used to acquire new information from the spectrum of an object. Proven to work well at low signal-to-noise, *The Cannon* could become an effective means of obtaining new information from the spectra of brown dwarfs. (We note also that Aganze et al. 2021 recently used alternative machine learning methods to identify late-M, L, and T dwarfs in large, low-resolution spectroscopic surveys. Their goal was to clas-

† E-mail: wbest@utexas.edu

sify approximate spectral types, rather than physical parameters, but they demonstrated clear success in distinguishing low-S/N ultracool dwarf spectra from contaminants, e.g., galaxies, using both Random Forests and Neural Networks.) In Section 3 we present the results of our investigation into this novel approach to analysing brown dwarf spectra using data-driven models and discuss the efficacy of *The Cannon* for future applications.

2 SPECTRAL TYPE POLYNOMIALS

2.1 The Volume-Limited Sample

Volume-limited samples are ideal for stellar population studies because they minimize selection biases. Starting with a sample of over 1200 L, T, and Y dwarfs with parallax measurements and PS1, MKO, 2MASS, and/or AllWISE photometry compiled from the literature, we extracted objects with declinations $-30^\circ \leq \delta \leq 60^\circ$ and parallax-determined distances less than 25 pc, replicating the volume-limited sample of Best et al. (2021) but also including brown dwarfs with spectral types T8.5–Y1.

Brown dwarfs with ages ≤ 200 Myr are still undergoing significant contraction and will exhibit inflated radii when compared to older brown dwarfs (Burrows et al. 1997). These young objects will therefore have relatively low surface gravity and photospheric pressure, causing them to differ spectroscopically and photometrically from field dwarfs (e.g., Liu et al. 2016). Older objects with lower metallicities will also differ from field objects, appearing bluer (Kirkpatrick et al. 2008). Therefore, we removed any object classified as young or a subdwarf by Best et al. (2021). Unresolved binaries that blend the spectra of two objects can exhibit unusual spectroscopic features (e.g., Burgasser et al. 2010), so we also excluded known binaries, as well as objects that have not been confirmed as single using high-angular resolution imaging. Objects with spectral types indicating peculiarities or unusually blue or red colours were additionally excluded.

Tables 1, 2, and 3 show the volume-limited sample and photometry we used. The numerical spectral type (SpT) represents the adopted value used for the analysis, with L0 = 10 and Y1 = 31. We used optical spectral types for L dwarfs when available and near-infrared (NIR) otherwise; NIR spectral types were adopted for T and Y dwarfs. The final volume-limited sample contains 256 field objects; not all objects had photometry in all bands we analysed. For each band, we selected objects with parallax uncertainties ≤ 20 per cent and absolute magnitude uncertainties < 0.2 mag. Some bluer bands, primarily r_{P1} and i_{P1} , have limited samples at later spectral types which restricted our analysis in these ranges.

2.2 Analytical Methods

As an initial quality assessment and to identify outliers, we fit polynomials to the photometry as a function of spectral type for each band using weighted total least squares and orthogonal distance regression. Both methods produced visually reasonable fits with no major outliers in all bands. We then used the Monte Carlo approach of Dupuy & Liu (2012), re-sampling normally distributed absolute magnitude errors and uniformly distributed spectral type errors (between their quoted limits) to obtain 10^4 re-sampled points for each object. This approach allows us to account for the uncertainties of both absolute magnitudes and spectral type, the latter assumed to be ± 1 unless indicated otherwise. With each data point randomly sampled about its respective uncertainties, we then performed a least-squares fit to

all of the re-sampled points and obtained a final n th degree polynomial function for each band. We used the same degree for the MKO, 2MASS, and AllWISE polynomials as in Dupuy & Liu (2012): sixth degree polynomials for all MKO bands, J_{2M} and H_{2M} , and fourth degree for K_{2M} and all AllWISE bands. The PS1 bands had not been fit previously; we used sixth degree polynomials for z_{P1} and y_{P1} bands, fourth degree for i_{P1} band, and second degree for r_{P1} band. For all bands, these were the lowest order polynomials that captured the major trends in the data. Higher order functions produced nominal changes in the RMS about fits, and led to over-fitting in some cases.

2.3 Results

2.3.1 Absolute Magnitude vs. Spectral Type Relations for Single Field Objects

We present our polynomial fits in Table 4. For each polynomial, we include an RMS over all valid spectral types as well as RMS for up to four smaller spectral type ranges. In all bands, late-T dwarfs exhibit more scatter in absolute magnitude than earlier spectral types. Figures 1 and 2 show our polynomial fits plotted over our cleaned sample of field objects (Section 2.1). We note the phenomenon recognized as the “*J*-band bump,” in which early-T dwarfs appear brighter than late-L dwarfs (e.g.,Looper et al. 2008a) in *J*-band. This apparent brightening is also seen in the Y_{MKO} band, although less pronounced. In H_{MKO} , H_{2M} , z_{P1} , and y_{P1} bands there is a more gradual decline or plateau in absolute magnitude through the L/T transition. This prominent feature corresponds to the evolution of condensate clouds in the photospheres of late-L dwarfs as they age and cool into T dwarfs, whose photospheres are relatively cloud-free. One explanation for this is the “patchy clouds” model that suggests the disruption of clouds at $T_{\text{eff}} \approx 1200$ K allows for hotter flux from cloud-free regions to dominate the total emitted flux (Ackerman & Marley 2001; Burgasser et al. 2002b). Another hypothesis, the “sudden downpour” model, suggests that the rapid increase in efficiency of sedimentation causes the dusty clouds to condense out around $T_{\text{eff}} \approx 1300$ K (Knapp et al. 2004).

2.3.2 Young Objects, Subdwarfs, and Binaries

As described in Section 2.1, young objects and older subdwarfs differ photometrically from their field-age counterparts. This is demonstrated in Figure 3, where young objects clearly deviate from the polynomial fits to the field objects in some bands. Early-L dwarf absolute magnitudes are comparable to the field sequence, but at mid-to-late L dwarfs, young objects are fainter in the MKO, 2MASS, and PS1 (z_{P1} and y_{P1}) bands (e.g., Faherty et al. 2016; Liu et al. 2016). There are too few young or subdwarf T dwarfs in our sample to assess possible systematic differences in absolute magnitudes. As discussed in Filippazzo et al. (2015), Liu et al. (2016), and Faherty et al. (2016), polynomial relations determined for field objects should not be used for young or suspected young sources. Additionally, known binaries appear overluminous compared with the single field group, as expected for unresolved sources that blend the light of two objects.

Notes. This table contains 256 single L0–Y1 dwarfs with declinations between -30° and $+60^\circ$ and parallaxes greater than 40 mas (i.e., distances less than 25 pc), which we used to determine our spectral type vs. absolute photometry polynomials. The numerical spectral type (SpT) represents the value adopted for the analysis, with L0 = 10 and Y1 = 31. The table is available in its entirety in a machine-readable form in the online journal. A portion is shown here.

Notes. Absolute AllWISE and PS1 photometry for all objects in the volume-limited sample (Table 1), calculated using the parallaxes in Table 1. The AllWISE photometry reference is Cutri et al. (2014) for all objects except the T3 dwarf 2MASS J02132062+3648506C (Deacon et al. 2017). The PS1 photometry reference is Chambers et al. (2021) for all objects except the T8 dwarf 2MASS J0415195-093506 (Best et al. 2018). This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here.

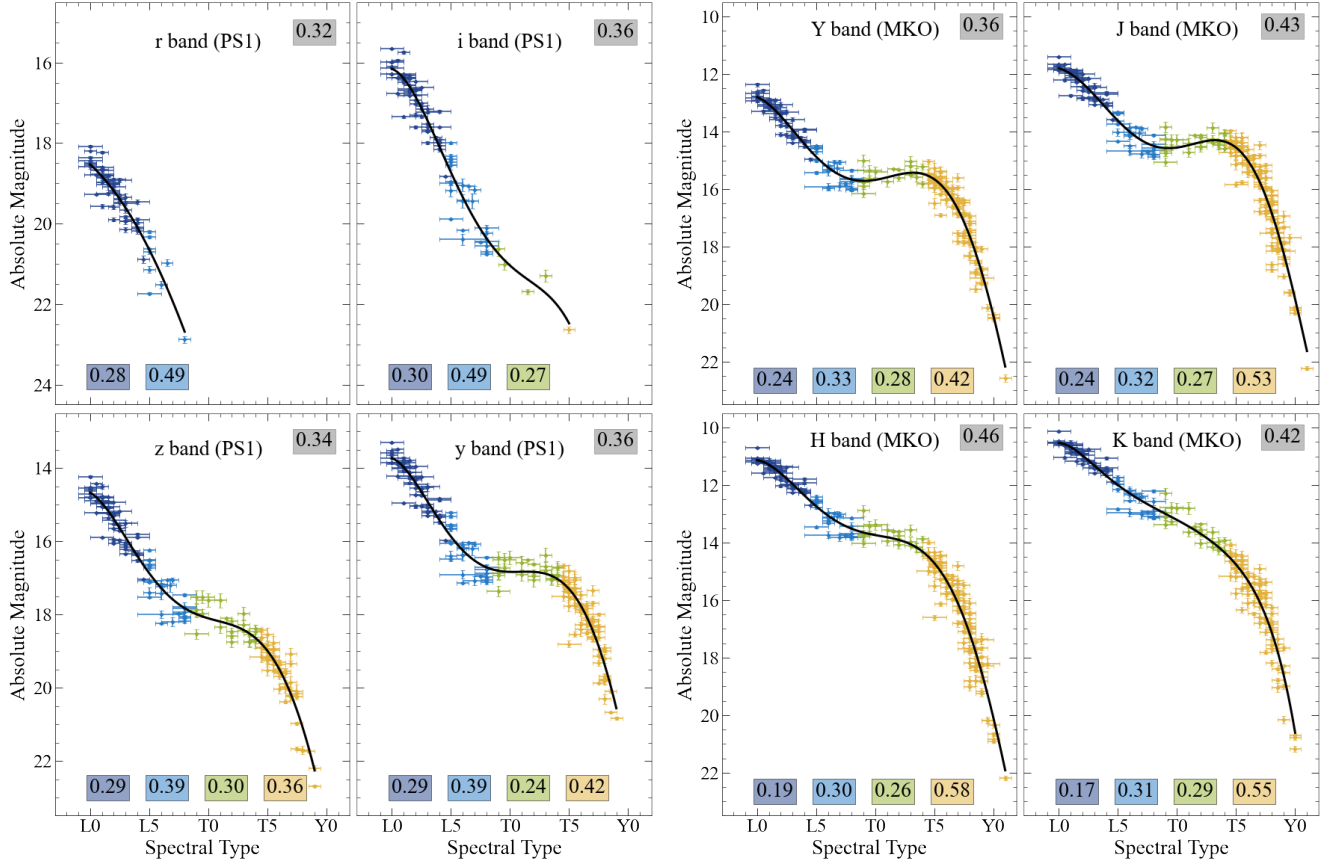

Figure 1. Absolute magnitude as a function of spectral type for single ultracool field dwarfs with parallax measurements for $YJHK_{\text{MKO}}$ and riz_{PS1} photometry. The solid black curves show the polynomial fits for our volume-limited sample (Table 4). Polynomials are limited to the spectral type ranges for which objects were detected in each band. The total RMS about the fit is indicated in the gray box at upper right in each plot. The RMS about four spectral type ranges are given at the bottom: L0–L4.5 (dark blue), L5–L8.5 (light blue), L9–T4 (green), and $\geq T4.5$ (yellow). The polynomial functions display clean trends with no major outliers.

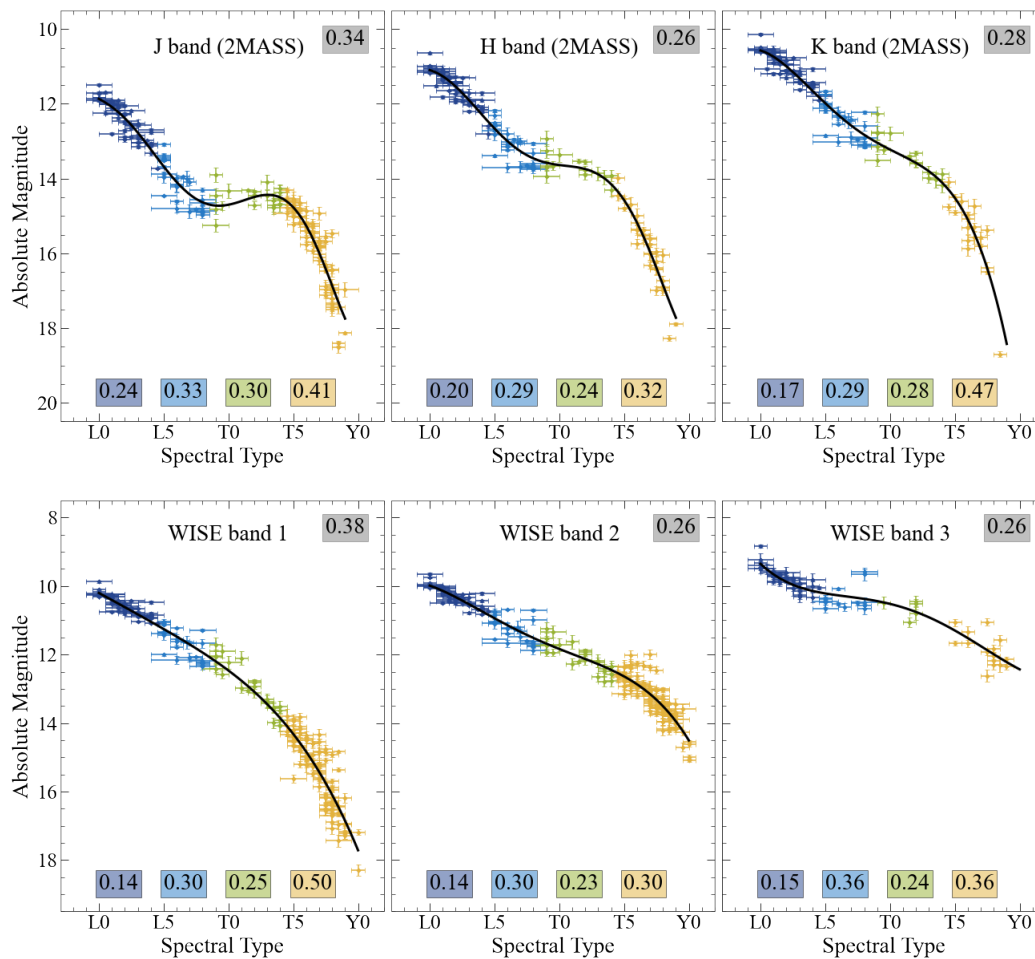

Figure 2. Absolute magnitude as a function of spectral type (same as Figure 1) for 2MASS and AllWISE photometry.

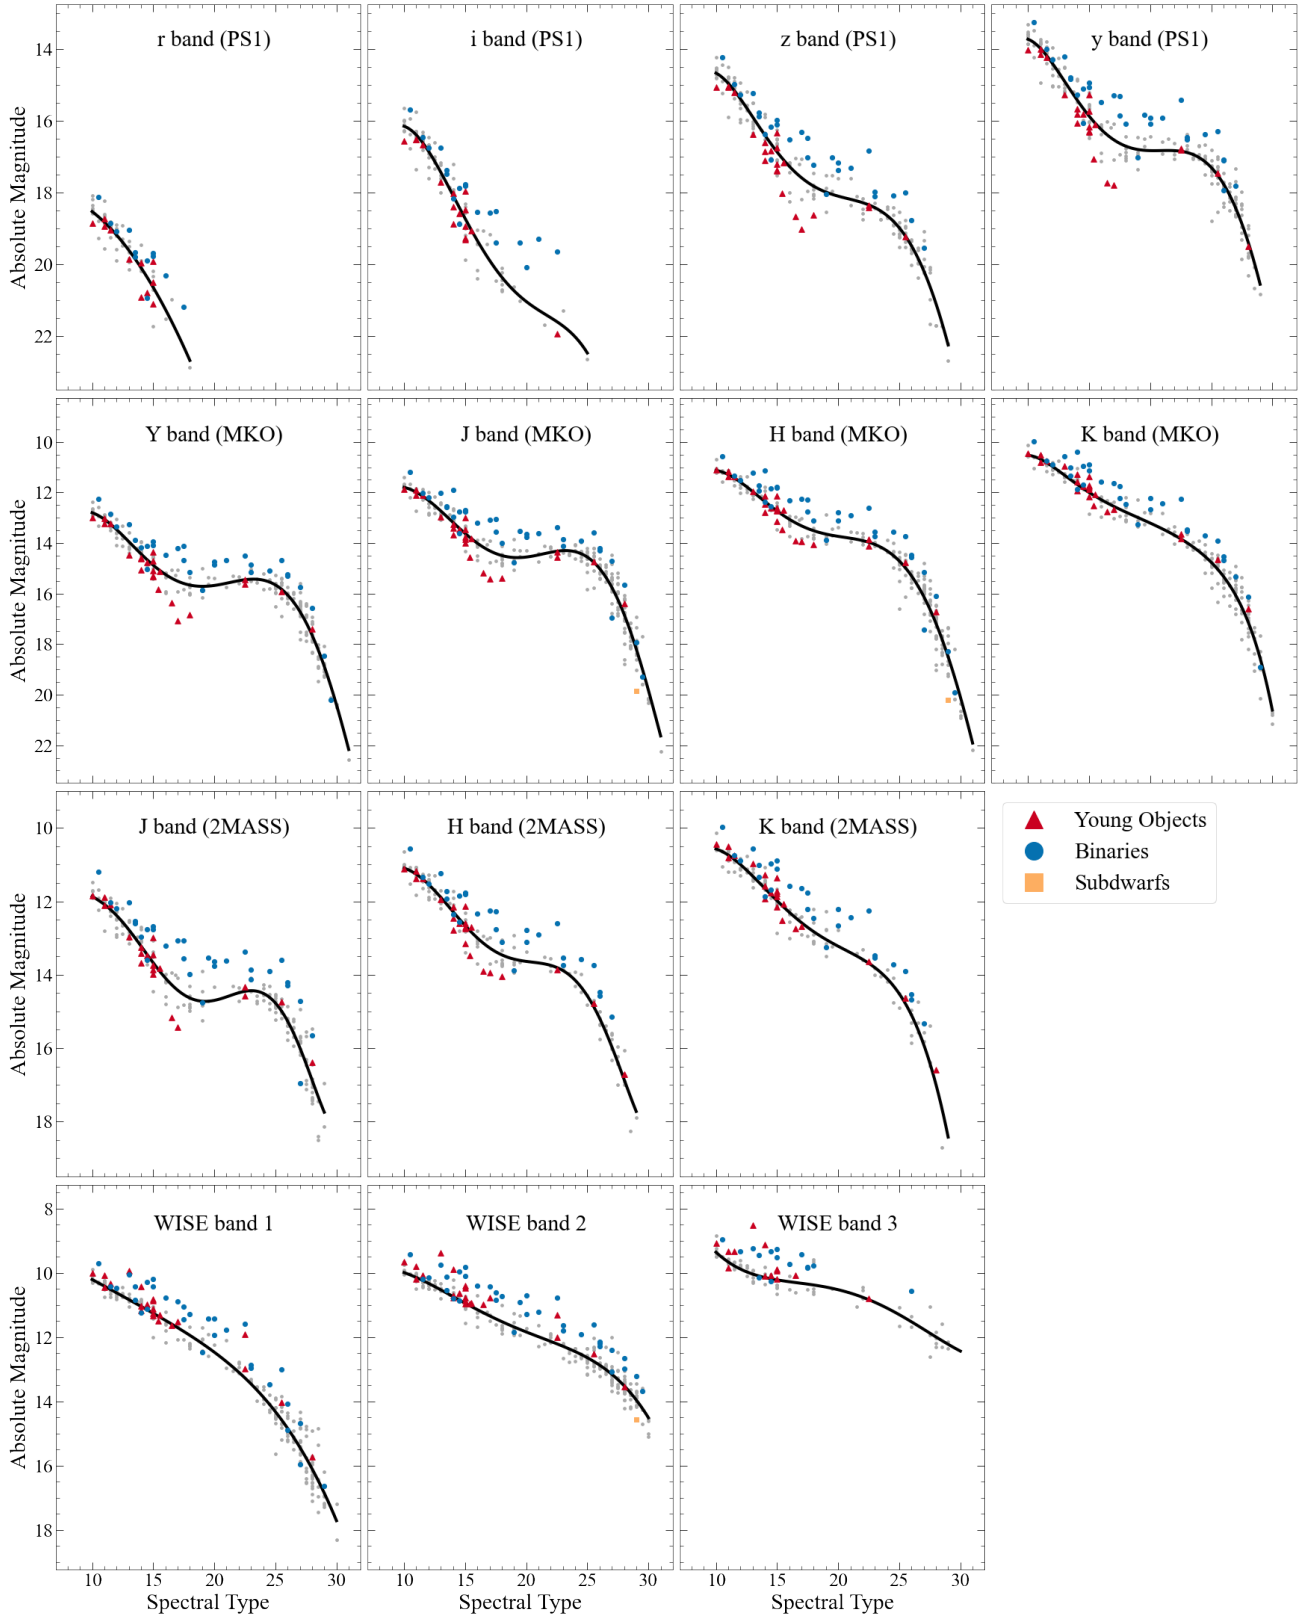

Figure 3. Absolute magnitudes of young brown dwarfs (red triangles), known binaries (blue circles), and subdwarfs (yellow squares) compared to field objects (grey) with the polynomials from Figures 1 and 2 over-plotted. Young objects appear fainter at $\approx L4$ – $L7$ spectral types in 2MASS, MKO and PS1 (z_{P1} and y_{P1}) bands, and binaries appear significantly brighter than single objects.

Table 4. Coefficients for Polynomial Fits of Absolute Magnitude to Spectral Type

y	x	c_0	c_1	c_2	c_3	c_4	c_5	c_6	RMS ^a				Total	Range ^b

The coefficients are defined as $y = \sum_{i=0} c_i x^i$, where y and x are the quantities indicated in the first two columns. The numerical spectral types are defined such that L0 = 10 and Y1 = 31.

^a These columns give the RMS about the fit for four spectral types ranges: L0–L4 (r_1), L4.5–L8 (r_2), L8.5–T4 (r_3), \geq T4.5 (r_4); and for the total RMS about the fit over all spectral types. The r_{P1} and i_{P1} bands do not have RMS values for all ranges due to the lack of detected objects at later spectral types.

^b The spectral type ranges for which the fits are applicable. All ranges are inclusive.

Notes. This table lists the scatter (σ) and bias (Δ) of the inferred labels compared with the reference labels for each *Cannon* model described in Section 3.2. The labels include numerical spectral type (SpT), effective temperature (T_{eff}), bolometric luminosity ($\log L$), MKO photometry (JHK_{MKO}), 2MASS photometry (JHK_{2M}), and SpT -dependent spectral indices (H_2O_{JH} and CH_4K). In general, including photometry measurements and spectral indices as labels, as well as separating L and T dwarfs in the reference sets used to train *The Cannon* models, provided the best results. The scatter (σ) for JHK_{MKO} and JHK_{2M} photometry for these models (M_3 , M_{3L} , M_{3T} , M_{4L} , and M_{4T}) are smaller than the total RMS of our polynomial relations presented in Table 4.

M_1 (Sec. 3.2.1) - Three-label model that includes T_{eff} , numerical SpT , and $\log L$ with L0–T8.5 dwarfs included in the reference set.

M_2 (Sec. 3.2.2) - Nine-label model that includes T_{eff} , numerical SpT , $\log L$, JHK_{MKO} and JHK_{2M} photometry with L0–T8.5 dwarfs included in the reference set.

M_3 (Sec. 3.2.3) - Eleven-label model that includes T_{eff} , $\log L$, JHK_{MKO} photometry, JHK_{2M} photometry, and three SpT -dependent spectral indices with L0–T8.5 dwarfs included in the reference set. M_{3L} includes only L0–L8 dwarfs in the survey set. M_{3T} includes only L8–T8.5 dwarfs in the survey set.

M_{4L} (Sec. 3.2.4) - Eleven-label model that includes T_{eff} , $\log L$, JHK_{MKO} photometry, JHK_{2M} photometry, and three SpT -dependent spectral indices with L0–L8 dwarfs included in the reference set.

M_{4T} (Sec. 3.2.4) - Eight-label model that includes T_{eff} , $\log L$, JHK_{MKO} photometry, and three SpT -dependent spectral indices with L8–T8.5 dwarfs included in the reference set.

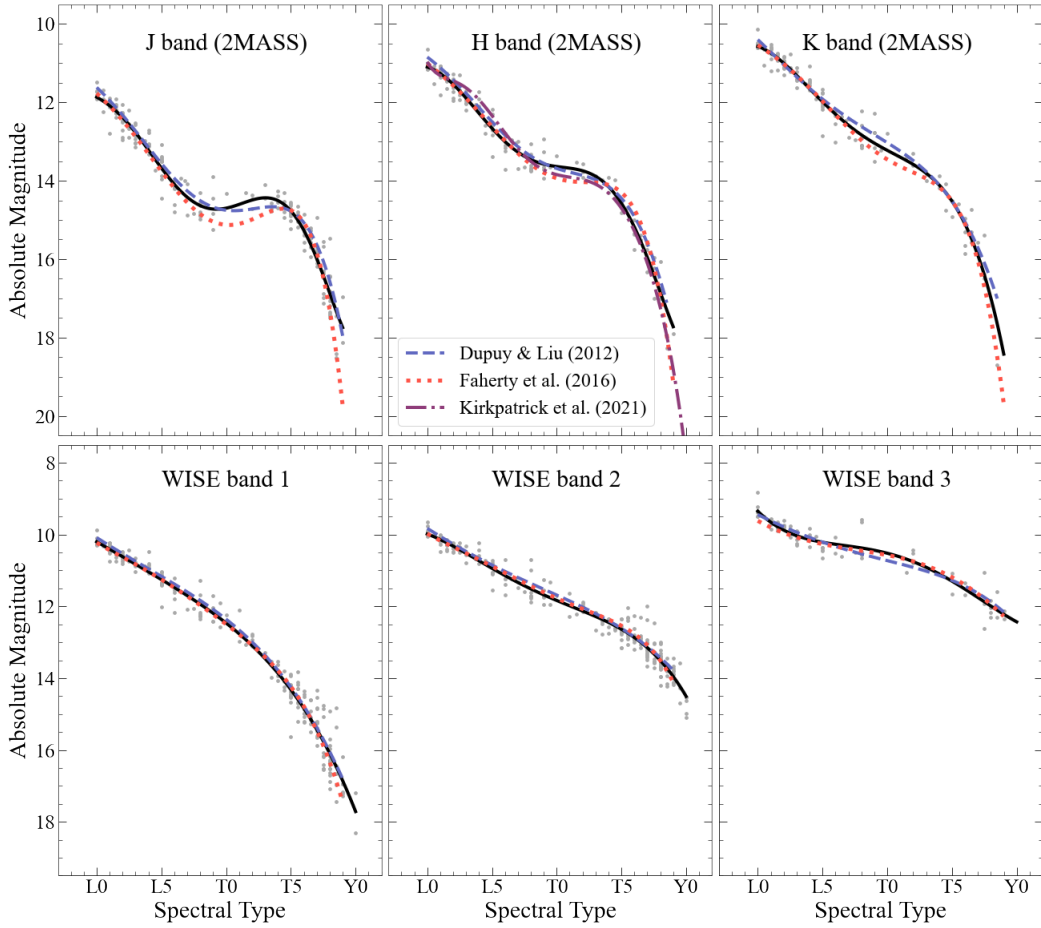

Figure 4. Comparison of our polynomial fits to previous work for 2MASS and AllWISE bands. The solid black curves show our fits (Table 4). Our polynomials are consistent with those of Dupuy & Liu (2012, blue dashed lines) and Faherty et al. (2016, orange dotted lines) for H_{2M} , K_{2M} and the AllWISE bands, and at early-L and late-T dwarfs for J_{2M} . For spectral types L8–T4, our J_{2M} fit has a sharper increase in flux, ≈ 0.5 mag brighter and occurring ≈ 1 –2 spectral subtypes earlier than previous works. The H -band polynomial of Kirkpatrick et al. (2021, combining 2MASS and MKO photometry; purple dot-dashed line) is consistent with ours but deviates by ≤ 0.2 mag except for mid-T dwarfs.

2.3.3 Comparison to Previous Works

Our new polynomials, based on our volume-limited sample, should accurately represent the nearby brown dwarf population for spectral types L0–T8.5. Figures 4 and 5 compare our polynomial relations to previously relations from Dupuy & Liu (2012), Faherty et al. (2016), and Kirkpatrick et al. (2021) for the MKO, 2MASS, and AllWISE bands. Since the fits of Dupuy & Liu (2012) and Faherty et al. (2016) do not use a volume-limited sample, our updated relations now provide a more robust standard for brown dwarf absolute magnitudes as a function of spectral type. The recent polynomials of Kirkpatrick et al. (2021) utilize a different volume-limited sample within 20 parsecs, but only for J_{MKO} and H bands and mid-infrared *Spitzer*/IRAC bands. Kirkpatrick et al. (2021) furthermore take H band to be invariant across the MKO and 2MASS systems and combines them into a single polynomial, whereas we have determined independent fits for MKO and 2MASS H -band photometry.

For MKO bands, our fits are consistent with the relations of Dupuy & Liu (2012) and Kirkpatrick et al. (2021). We find no significant difference at the L/T transition, and any variation at L and late-T spectral types are within 0.3 mag of Dupuy & Liu (2012). The Kirkpatrick et al. (2021) J_{MKO} and H relations appear ≈ 0.5 mag brighter than ours for spectral types L2–L8, possibly due to their inclusion

of brighter mid-L outliers. Differences at late-T and early-Y spectral types for these bands may be accounted for by the presence of additional Y dwarfs in the all-sky volume-limited sample of Kirkpatrick et al. (2021). In general, detection of late-T dwarfs and early-Y dwarfs is limited to ≤ 20 pc so our deeper, narrower sample contains fewer of these very faint objects. For 2MASS bands, we find our fits are consistent with previous work for early to mid-L (L0–L7) and mid to late-T dwarfs (T5–T8). We note some differences at the L/T transition, especially in J -band. For spectral types L8–T4, our fit has a sharper increase in the J -band flux than Dupuy & Liu (2012), appears ≈ 0.5 mag brighter than Faherty et al. (2016), and occurs ≈ 1 –2 spectral subtypes earlier than both. For AllWISE bands, our updated fits based on a volume-limited sample are very consistent with the polynomial relations of Dupuy & Liu (2012) and Faherty et al. (2016).

3 MACHINE LEARNING MODELS WITH *The Cannon*

The Cannon is a data-driven approach designed to determine physical parameters, referred to as “stellar labels”, of stars from spectroscopic data (Ness et al. 2015; Ho et al. 2017a). Using known labels (i.e., any measured quantity such as effective temperature, surface gravity, or

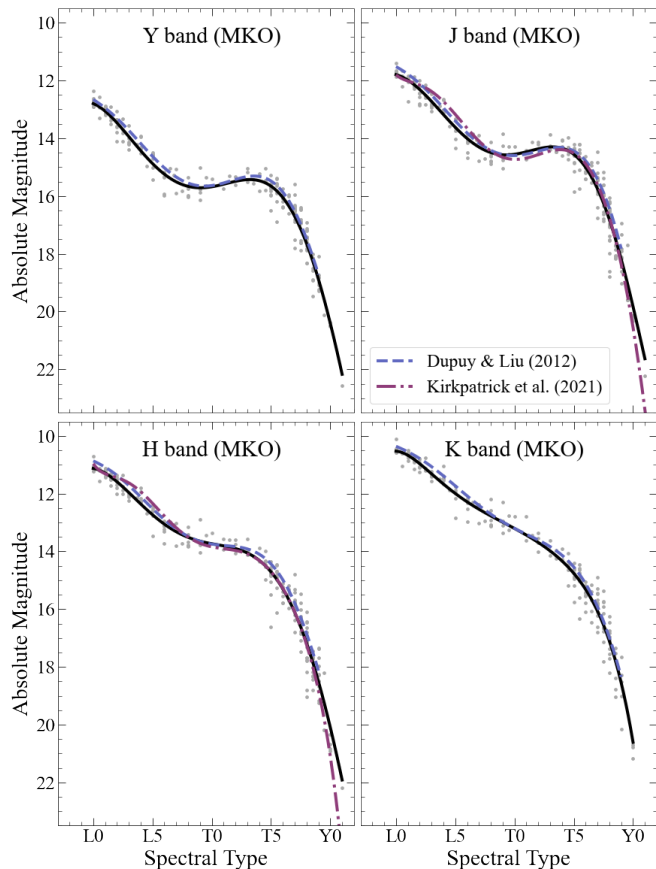

Figure 5. Same as Figure 4 for MKO bands. Our polynomial fits are consistent with those of Dupuy & Liu (2012); we note minor differences with those of Kirkpatrick et al. (2021, *J* and *H* bands) for spectral types \approx L0–L8.

elemental abundances) from a training set of stars, *The Cannon* develops a generative “spectral model” from their continuum-normalized spectra. The model assumes that stars with identical labels have similar spectra and the spectrum of each object is a smooth function of the labels that describe the object (Ho et al. 2017a). Models generated by *The Cannon* do not rely on physical models of the spectra, nor do they require accurate spectral types, which are heterogeneously determined and do not convey subtle differences in the spectral features that are unique to certain objects (e.g., peculiar objects). Furthermore, *The Cannon* can infer information directly from the spectra.

Previous applications of *The Cannon* have derived stellar labels from spectra in the context of large, high-resolution spectroscopic surveys like APOGEE and LAMOST (Ness et al. 2015, 2016; Hogg et al. 2016; Ho et al. 2017a,b). It also has been shown to work efficiently and effectively on objects at lower signal-to-noise ($20 \lesssim S/N \lesssim 50$) with comparable accuracy to other physics-based approaches (Ness et al. 2015). Proven to work well with *stellar* surveys, *The Cannon* has not been evaluated for *substellar* objects like brown dwarfs. There are significant differences between the spectra of brown dwarfs and the stars used in previous applications of *The Cannon*; in particular, the prevalence of broad molecular absorption bands and (in most cases) the much lower resolution in brown dwarf spectra. Here we present our investigation into *The Cannon*’s potential to infer physical properties of brown dwarfs, its limitations, and future possibilities for its use. We explore the application of *The Cannon* and verify its methodology with low-resolution brown dwarf spectra, beginning with a simple model and successively adding to

its complexity. Our main goal in this paper is to provide a proof of concept, demonstrating that physical properties can be inferred by *The Cannon* from low-resolution spectra containing broad molecular absorption bands. We do not examine all possible models or determine the most optimal model, but our results suggest how *The Cannon* might most successfully be implemented.

3.1 Methodology

The Cannon’s procedures and requirements are described in detail in Ness et al. (2015). Briefly, given a training set of spectra (hereinafter the *reference set* with associated *reference labels*), *The Cannon* performs a training step that generates the spectral model g described by

$$f_{n\lambda} = g(\ell_n | \theta_\lambda) + \text{noise} \quad (1)$$

where θ_λ is a coefficient vector, ℓ_n is a label vector, and $f_{n\lambda}$ is the flux at each flux element. The noise takes into account the intrinsic scatter of the model and the uncertainty associated with the flux at each wavelength. In this training step, *The Cannon* utilizes the labels of the reference set to predict the flux at each wavelength and determine optimal coefficients for the spectral model. That model is then used to infer labels (known as *survey labels*) from a set of survey objects (called the *survey set*) in what is known as the test step. In this test step, *The Cannon* uses the spectral model, with coefficients θ_λ determined in the training step, to optimize the labels of the survey set. In practice, the reference objects and survey objects will be different. For our investigation, the reference and survey sets were the same, allowing us to evaluate the effectiveness of *The Cannon* in analyzing the spectra of brown dwarfs. Additionally, the reference set used to train *The Cannon* should ideally be higher in S/N than the survey set, and it has been demonstrated that *The Cannon* can adequately transfer labels from high S/N reference objects to lower S/N survey objects (Ness et al. 2015).

To use *The Cannon*, the spectra need to meet the requirements outlined by Ness et al. (2015). All spectra must come from the same telescope and reduction pipeline, and their labels must come from consistent sources. Any labels (i.e. any physical quantity of the object) can be included so long as they meet this condition. The spectra (for both reference and survey sets) must be normalized in a consistent manner that is independent of S/N, be radial velocity aligned, be sampled onto a common rest-frame wavelength grid, and have the same line-spread function. Finally, each flux value must have an associated error (or inverse variance).

3.1.1 Preparing the Spectra

The SpeX Prism Library (SPL; Burgasser 2014) is a collection of over 2000 low-resolution ($\lambda/\Delta\lambda \approx 75\text{--}150$) near-infrared spectra primarily of ultracool dwarfs acquired by the facility 0.8–5.5 μm SpeX spectrograph located on the 3.0 m NASA Infrared Telescope Facility (IRTF) (Rayner et al. 2003). As the largest library of L and T dwarf spectra currently available, the SPL has provided an organized and convenient resource for studying brown dwarfs.

We obtained over 1100 spectra of L and T dwarfs (L0–T9) from the SPL. We linearly interpolated each spectrum onto the same wavelength grid, for which we arbitrarily chose the wavelength grid of the $R\text{--}75$ spectrum of the L2 dwarf 2MASS J00550564+0134365 (Faherty et al. 2016). We restricted the wavelength range for our grid to 0.8–2.4 μm to exclude noisy regions at the extrema of the spectra. The wavelength grid contains 440 elements in a non-uniform spacing. *The Cannon* generally requires continuum-normalized spectra,

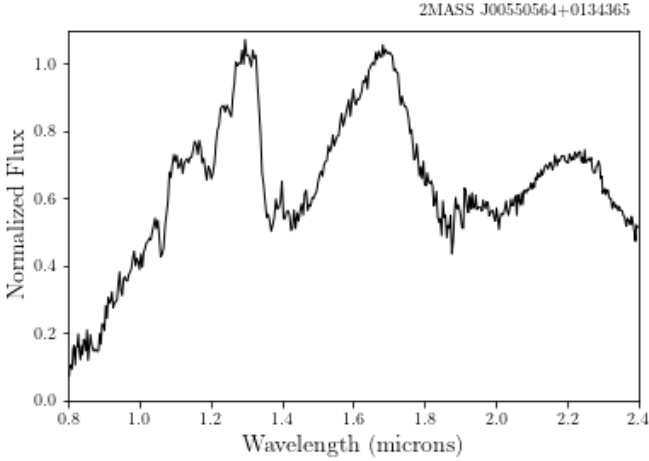

Figure 6. SpeX prism Spectrum ($R\sim 75$) of the L2 dwarf 2MASS J00550564+0134365 used in Section 3.1.1 for the wavelength calibration of the reference and survey sets. The flux has been normalized to the J -band peak at 1.27–1.28 μm . The spectrum illustrates the broad molecular absorption bands and lack of low-resolution continuum that epitomize brown dwarf spectra.

but low-resolution L and especially T dwarf spectra have little or no absorption-free continuum, so we opted to normalize each SPL spectrum to its J -band peak (1.27–1.28 μm), where absorption is minimized. As an example, we show the normalized spectrum of 2MASS J00550564+0134365 in Figure 6.

3.1.2 Determining Labels for Reference Objects

The reference labels used for this investigation include effective temperature (T_{eff}), numerical spectral type (SpT , where $L0 = 10$ and $T8.5 = 28.5$), bolometric luminosity ($\log L$), MKO and 2MASS photometry (JHK_{MKO} and $JHK_{2\text{M}}$) and the SpT -dependent spectral indices of Burgasser et al. (2006). To determine reference labels for T_{eff} and $\log L$ in a uniform fashion, we used a single photometry-based polynomial relation from the literature for each label, along with the photometry compiled in Table 1. The T_{eff} of each object in the SPL dataset was determined using the 2MASS M_H -based field-age polynomial of Filippazzo et al. (2015). Similarly, bolometric luminosities were determined using the 2MASS M_K -based field-age polynomial of Dupuy & Liu (2017). We note that the quality of the inferred survey labels is limited by the accuracy and precision of the reference labels (quoted RMS of 29 K for T_{eff} and 0.05 dex for $\log L$). Finally, the spectral indices of each object were measured using the SpeX Prism Library Analysis Toolkit¹. Table 6 shows all reference labels used for *The Cannon* models described here.

3.1.3 Identifying “Continuum Pixels”

The Cannon requires both the reference and survey sets to be normalized as independently of S/N as possible. To do this, *The Cannon* performs a “pseudo-continuum normalization” process in which continuum pixels are defined as pixels whose normalized flux values are consistently close to 1 for all training spectra and vary minimally with changes in the label values. These pixels are identified using a

running quantile of the spectra for user-specified wavelength ranges that are known to not be strongly affected by absorption features. Once these pixels are determined, *The Cannon* applies a continuum mask based on a fraction of the continuum pixels. For our data sets, we used label-dependent regions of the spectra (typically J , H , and K bands) to generate our models, and we chose 4–9 per cent of a running upper quantile (90th percentile) of the pixels in these regions as continuum pixels to be used for the continuum mask.

We then fit the continuum using an N -th order sinusoid or Chebyshev function. We note that the performance of *The Cannon* greatly relies on the manner in which the spectra is *Cannon*-normalized. We describe the specific choices we made for each model we tested in Section 3.2.

Since *The Cannon* relies on the continuum normalization of the set, and brown dwarf spectra have little to no absorption-free regions, it proved challenging to determine the most appropriate application of this pseudo-continuum normalization step for our data sets.

We learned that adjustments are necessary for an improved continuum mask and satisfactory fit, depending on the labels used and the objects in the reference set. We found the most appropriate method was typically to treat the J , H , and K bands as three distinct spectral regions for *The Cannon* to normalize separately. Overall, it is important to specify wavelength ranges to which the labels are correlated. For example, if photometry measurements are used as labels, the wavelength ranges for these bands should be included in the continuum masking steps. We determined the best values for the parameters described here through repetitive trials, checking the normalization plots and identified continuum pixels in each case.

3.2 Models and Results

3.2.1 M_1 Model: T_{eff} , $\log L$, and SpT

We first constructed a simple *Cannon* model using only three labels: T_{eff} , SpT , and $\log L$. For the reference set, we used L0–T8.5 dwarfs with $9.4 \leq M_H \leq 18.1$ mag (2MASS) and $8.8 \leq M_K \leq 16.6$ mag (2MASS); these are the valid ranges for the polynomials of Filippazzo et al. (2015) and Dupuy & Liu (2017) that we used to determine the T_{eff} and $\log L$ reference labels, respectively. We included only objects with parallax uncertainty ≤ 20 per cent for a final set of 390 L and T dwarfs. We used this same set for the survey set as well, to evaluate the quality of the label transfer. Figure 7 shows diagnostic plots for this set comparing each label. We note the expected trends between T_{eff} , SpT , and $\log L$: decreasing effective temperature and bolometric luminosity with increasing spectral type (early-L to late-T dwarfs) and the strong positive correlation of T_{eff} and $\log L$. To identify the continuum pixels we used a 90th percentile cutoff across three wavelength regions: 1.10–1.35 μm , 1.50–1.80 μm , and 2.0–2.35 μm . The ranges contain important label-dependent information in the J , H , and K bands while largely avoiding the H_2O absorption features at ~ 1.4 μm and ~ 1.9 μm . 6 per cent of the pixels were identified for the continuum mask, which we fit with a second-order sinusoid function.

Figure 7 can be used to visually assess the performance of the model. Comparing these diagnostic plots for the reference and survey sets, we see that the correlations between the reference labels are reproduced well in the inferred survey labels. Figure 8 compares the reference labels to the inferred survey labels for each object. The quality of the label transfer can be assessed by the scatter (i.e., RMS) and bias (i.e., offset) with respect to the equality (i.e., $x = y$) line. These values are provided in Table 5 for each model. In general, *The Cannon* infers greater values (i.e., higher T_{eff} and $\log L$, later

Notes. Reference labels used for all L0–T8.5 dwarfs: numerical spectral type (SpT), effective temperature (T_{eff}), bolometric luminosity ($\log L$), MKO and 2MASS photometry (JHK bands), and SpT -dependent spectral indices (H_2O_J , H_2O_H , and CH_4_K). The table is available in its entirety in a machine-readable form in the online journal. A portion is shown here.

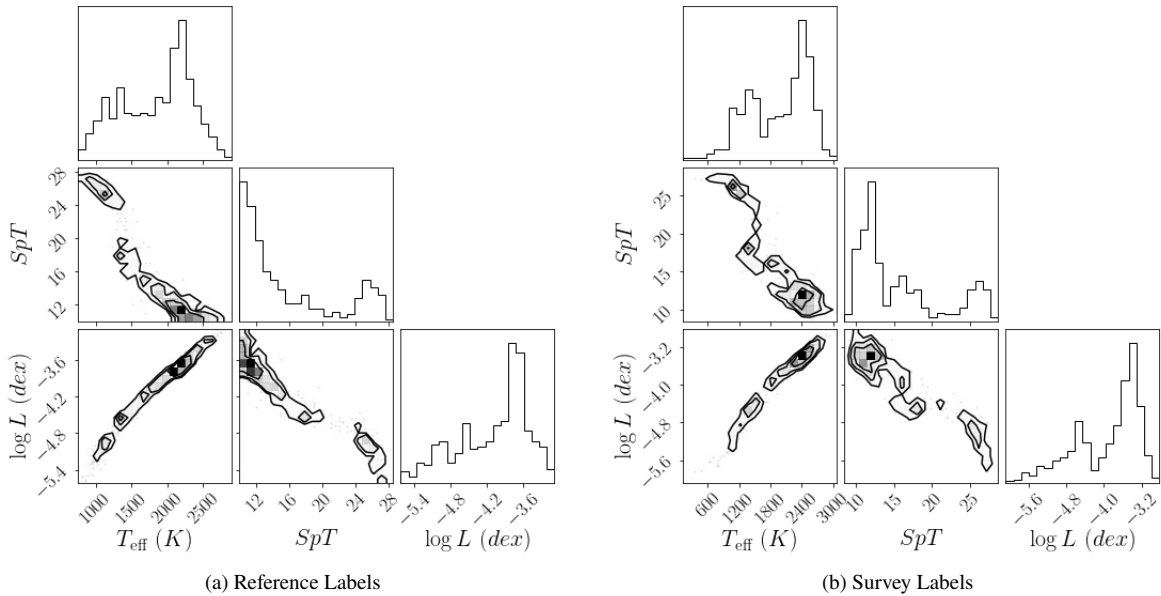

Figure 7. Diagnostic plots of the reference (i.e., previously known) and survey (i.e., *Cannon*-determined) labels for a three-label *Cannon* model (Section 3.2.1) using effective temperature (T_{eff}), numerical spectral type (SpT), and bolometric luminosity ($\log L$). Numerical spectral types are defined such that L0 = 10 and T8.5 = 28.5. The histograms represent the distribution of the reference and survey labels of our sample. The contour plots show the density of labels within the label space. The distributions and correlations of the labels in the reference set are clearly reflected in the survey set, indicating that *The Cannon* can accurately infer information from the spectra of brown dwarfs.

spectral type) for the survey labels than the corresponding reference values for this M_1 model. We can compare these to the systematic uncertainties of the reference labels: 29 K for T_{eff} (Filippazzo et al. 2015), 0.05 dex for $\log L$ (Dupuy & Liu 2017), and (typically) 1 for spectral type classification. The uncertainty of the SpT label in *The Cannon* models is comparable to that of other spectral classification methods (e.g., Burgasser et al. 2010; Allers & Liu 2013), indicating that this model could be used as a tool to constrain the spectral types of brown dwarfs across broad surveys. (We note that specifying a single broad wavelength range across 1.1–2.3 μm for continuum normalization decreases the scatter of the label transfer for T_{eff} and $\log L$, but increases it for SpT by ~ 0.3 .) Overall, this model infers more accurate labels for T dwarfs than L dwarfs. This likely arises from the dramatic changes in spectral morphology that occur across types T0–T8 (e.g., Kirkpatrick 2005), allowing *The Cannon* to more easily detect prominent features such as the shape of flux peaks and band strengths and determine more accurate label values, even at lower spectral resolution.

3.2.2 M_2 Model: Including Photometry as Labels

We then constructed a second *Cannon* model with the same T_{eff} , $\log L$, and SpT labels but also including MKO and 2MASS photometry in J , H , and K bands. We used reference spectra from the same initial set of L and T dwarfs as in Section 3.2.1, this time extracting objects with absolute magnitude errors <0.2 mag in each band and parallax uncertainties ≤ 20 per cent for a final set of 339 objects. However, when determining the wavelength ranges about which *The Cannon* creates the continuum mask, we found that specifying one wavelength range from 1.1–2.35 μm provided the best spectral model with the lowest scatter and bias for the inferred labels. This suggests that excluding H_2O features in the pseudo-continuum normalization process may remove informative pixels whose flux correlates with the J , H , or K photometry labels, or that the overall spectral slope similarly correlates with the photometry. We identified the continuum mask using 4 per cent of the flux and fit this with a second-order sinusoid function.

Figure 9 shows the reference and inferred labels with the scatter and bias of each, and we also present these values in Table 5. We again

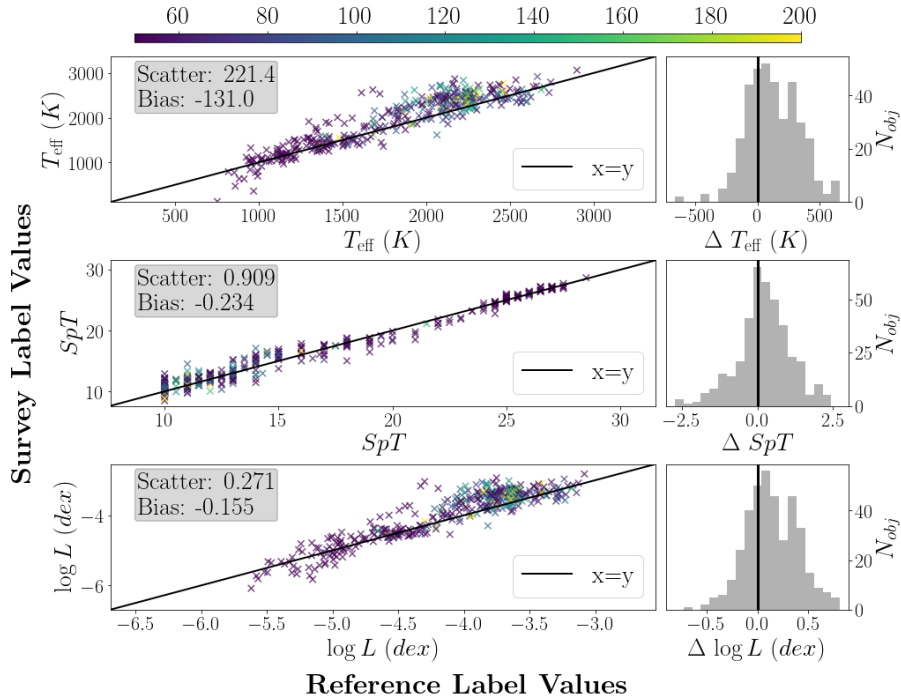

Figure 8. Diagnostic plots for the three-label model M_1 (Section 3.2.1) shown in Figure 7, comparing the reference labels (horizontal axis) to the *Cannon*-generated survey labels (vertical axis). Each object is colour-coded by its spectroscopic S/N (colour bar at top). The histograms show the number of objects N_{obj} in each label bin. There are clear correlations between the known and inferred values (albeit with significant bias and scatter in this simple model), showing that *The Cannon* can determine physical properties from the spectra of brown dwarfs.

find tighter agreement between the reference and inferred values for T dwarfs. The inclusion of photometry labels and the modification to the continuum mask creates an improved fit for the T_{eff} , SpT , and $\log L$ labels (36 per cent, 7.7 per cent, and 45 per cent decrease in scatter, respectively, relative to the M_1 model). The scatter of the inferred values for MKO photometry are comparable to the total RMS of the polynomial relations determined in Section 2.

3.2.3 M_3 Models: Including Spectral Indices as Labels

Spectral types, while useful labels for stellar and substellar classification, may not be as useful for *The Cannon* to model and infer from the spectra of brown dwarfs. *The Cannon* was designed to work with labels that vary continuously with changes in flux in the spectroscopic pixels, whereas spectral types are typically discrete values determined by visually comparing spectroscopic features to a spectral standard. An alternative classification method utilizes spectral indices which are readily calculated from the flux in specified wavelength ranges and can identify differences between spectra that track with spectral types but using continuous variables (e.g., Burgasser et al. 2006). Such indices can also indicate binarity and unusual surface gravity (Allers et al. 2007; Allers & Liu 2013; Burgasser et al. 2010; Bardalez Gagliuffi et al. 2014).

We therefore constructed a new Cannon model replacing spectral types with spectral indices. We extracted 338 L and T dwarfs, using the same absolute magnitude and parallax uncertainty cutoffs as in the M_2 model but now replacing spectral types with three SpT -sensitive indices for labels: H_2O_J , H_2O_H , and CH_{4K} (Burgasser et al. 2006). We used 0.90–1.40 μm , 1.50–1.79 μm , and 1.99–2.35 μm as wavelength regions for the continuum mask, utilizing 6 per cent of all pixels and a first-order sinusoid function.

In addition to using the full reference set as the survey set (model M_3 ; Figure 10), we also ran this model with survey sets of L0–L8 dwarfs and L8–T8.5 dwarfs (models M_{3L} and M_{3T} ; Figure 11), in order to separately evaluate the model’s performance on L and T dwarfs. The scatter and bias for each label are provided in Table 5 for all three models. We note a decrease in the scatter and bias for all labels with respect to the previous models that used numerical SpT as labels, indicating that *The Cannon* infers labels with higher fidelity when given spectral indices rather than spectral types as labels. The inferred JHK_{MKO} for both the M_{3L} and M_{3T} survey sets have a lower RMS than the total RMS of our polynomial fits (Section 2). It is clear that *The Cannon* determines more accurate labels for T dwarfs than L dwarfs, as the scatter for the L dwarf survey set in each label is two or three times greater than for the corresponding label in the T dwarf survey set.

3.2.4 M_4 Models: Separating L and T Dwarfs in the Reference Set

We constructed a final pair of models by separating L and T dwarfs in the reference set. For the L-dwarf model, M_{4L} , we extracted 287 objects from the previous M_3 model set with spectral types L0–L8 (inclusive). We used the same labels as for the M_3 model. We used 0.90–1.10 μm , 1.10–1.4 μm , 1.50–1.79 μm , and 1.99–2.35 μm as wavelength regions for the continuum mask, now identifying Y band as a distinct region. The T-dwarf model, M_{4T} , contained 109 objects with spectral types L8–T8.5 (inclusive), including the L8 and L9 dwarfs at the warm end of the L/T transition. Due to the limited number of T dwarfs with precise 2MASS photometry measurements, we excluded JHK_{2M} as labels for this M_{4T} model. We used 0.90–1.15 μm , 1.15–1.4 μm , 1.50–1.79 μm , and 1.99–2.35

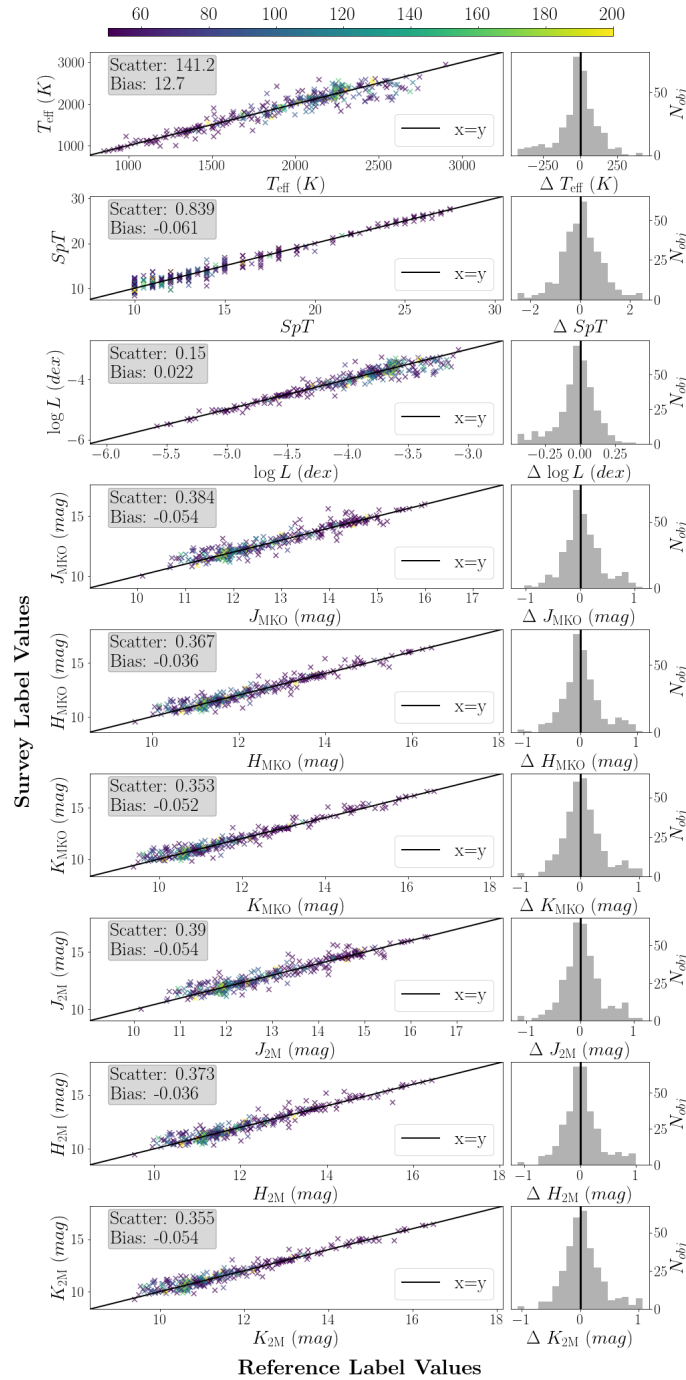

Figure 9. Same as Figure 8 but comparing the reference and survey values for *The Cannon* model M_2 (Section 3.2.2) including effective temperature (T_{eff}), numerical spectral type (SpT), bolometric luminosity ($\log L$), and absolute magnitudes (JHK_{MKO} and JHK_{2M}). Including photometry labels generates an improved *Cannon* model with lower scatter and bias for the T_{eff} , SpT , and $\log L$ survey labels than those from the M_1 model (Figure 8).

μm as wavelength regions for the continuum mask. We again utilized 6 per cent of all pixels and a first-order sinusoid function.

Figures 12 compares the inferred and reference values for these models. The RMS of the inferred labels for the L dwarf model is nominally reduced, but for T dwarfs the reduction in RMS is significant, with a 53 per cent decrease for T_{eff} , 24 per cent decrease for $\log L$, and 43 per cent decrease for JHK_{MKO} photometry. This indicates that separating L and T dwarfs in the reference set and utilizing spectral indices rather than spectral types produces the most accurate models

with *The Cannon*. This also shows that *The Cannon* can effectively transfer labels from reference sets as small as ≈ 100 objects, and that the modest S/N of the T dwarf spectra (typically 20–50) is not an impediment. Notably, the M_{4L} model produces labels for L dwarfs with higher RMS and bias, even though the L dwarf reference set is larger and the S/N are typically higher than in the T dwarf reference set.

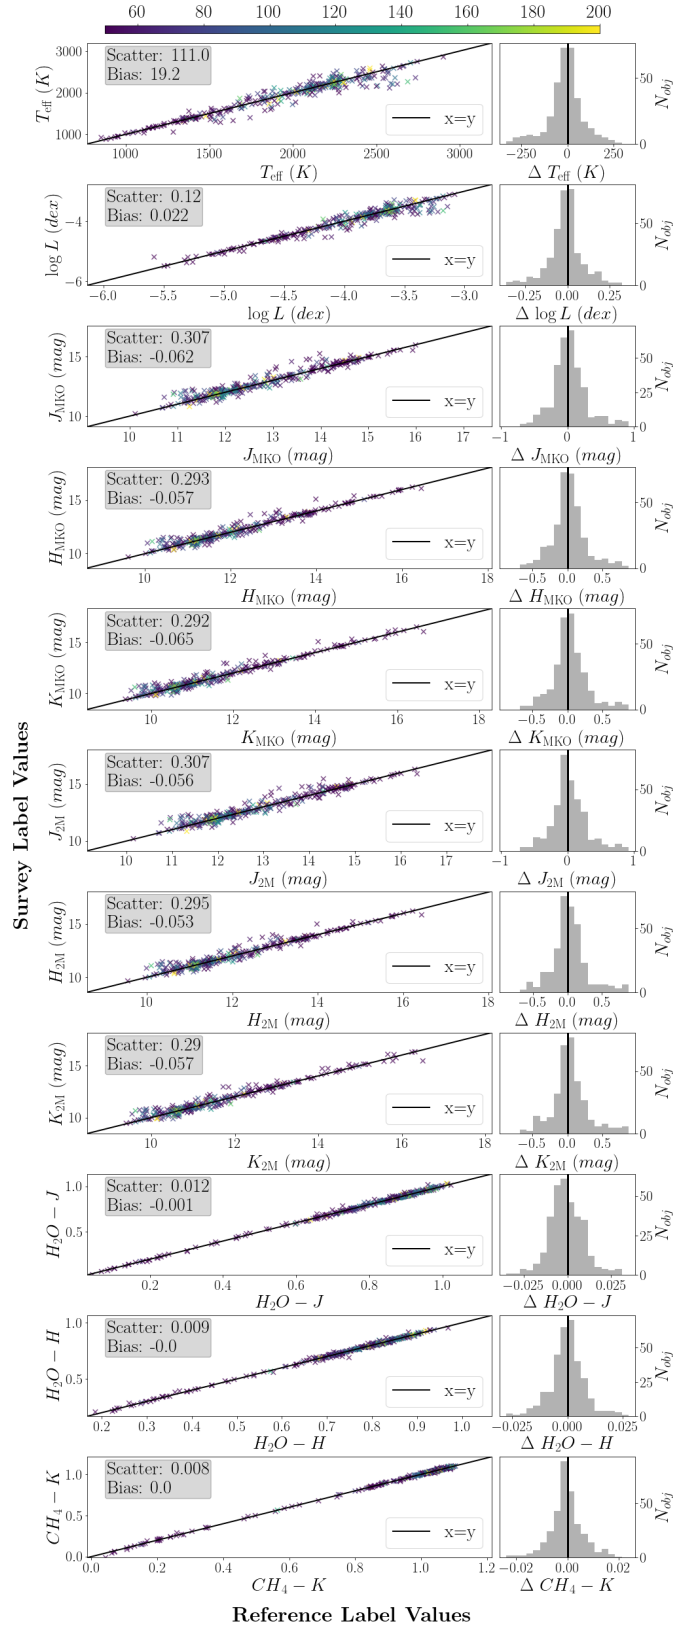

Figure 10. Same as Figures 8 and 9 but comparing the reference and survey values for *The Cannon* model M_3 (Section 3.2.3) including effective temperature (T_{eff}), bolometric luminosity ($\log L$), absolute magnitudes (JHK_{MKO} and JHK_{2M}), and H_2O_J , H_2O_H , and CH_4_K spectral indices for the L-dwarf (left) and T-dwarf (right) models. Including spectral indices generates an improved *Cannon* model with lower scatter and bias for all inferred labels that were also generated in M_2 (Figure 9).

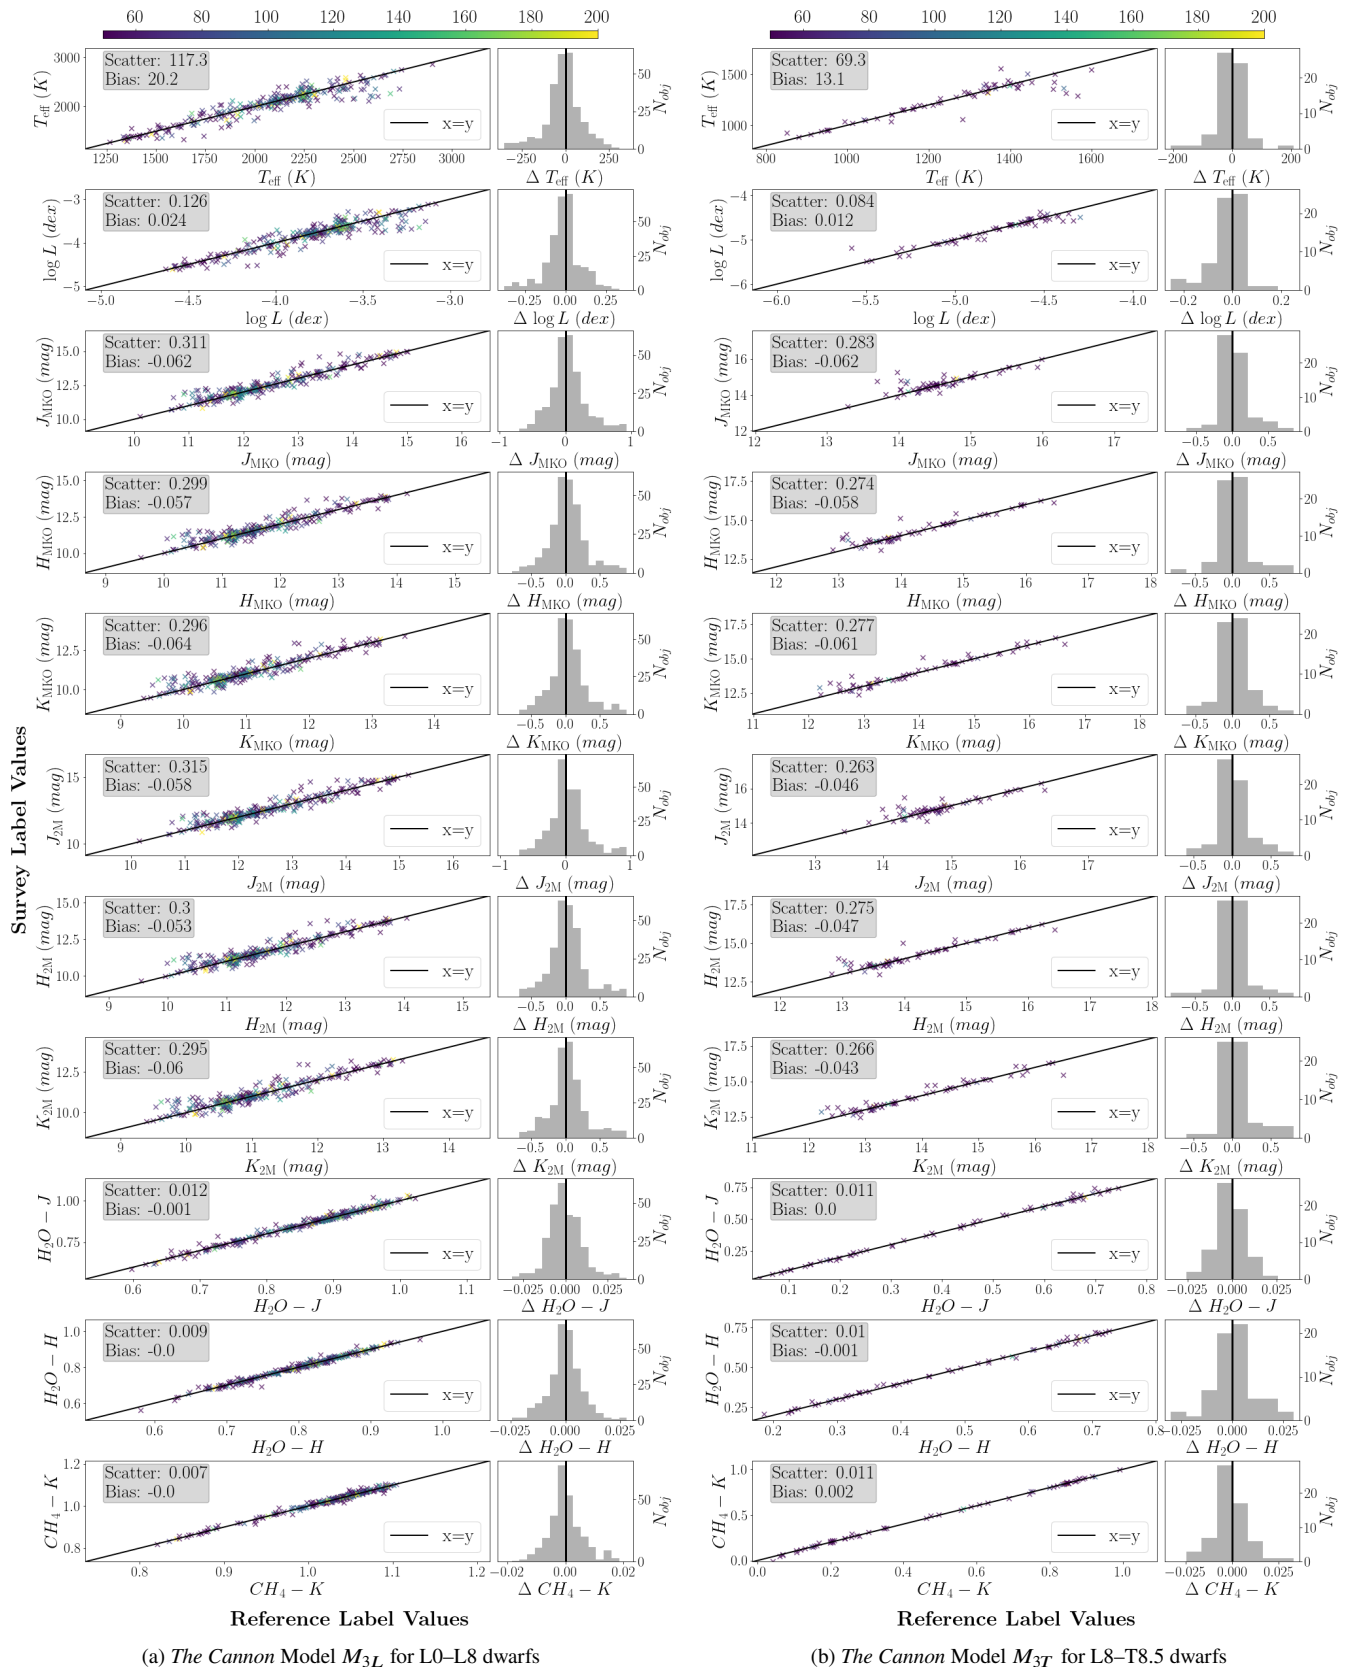

Figure 11. Same as Figure 10 but comparing the reference and survey values for distinct survey sets containing L0-L8 (Model M_{3L} , left) and L8-T8.5 (Model M_{3T} , right) dwarfs. These distinct survey sets show that *The Cannon* can infer properties of T dwarfs with lower scatter and bias than for L dwarfs.

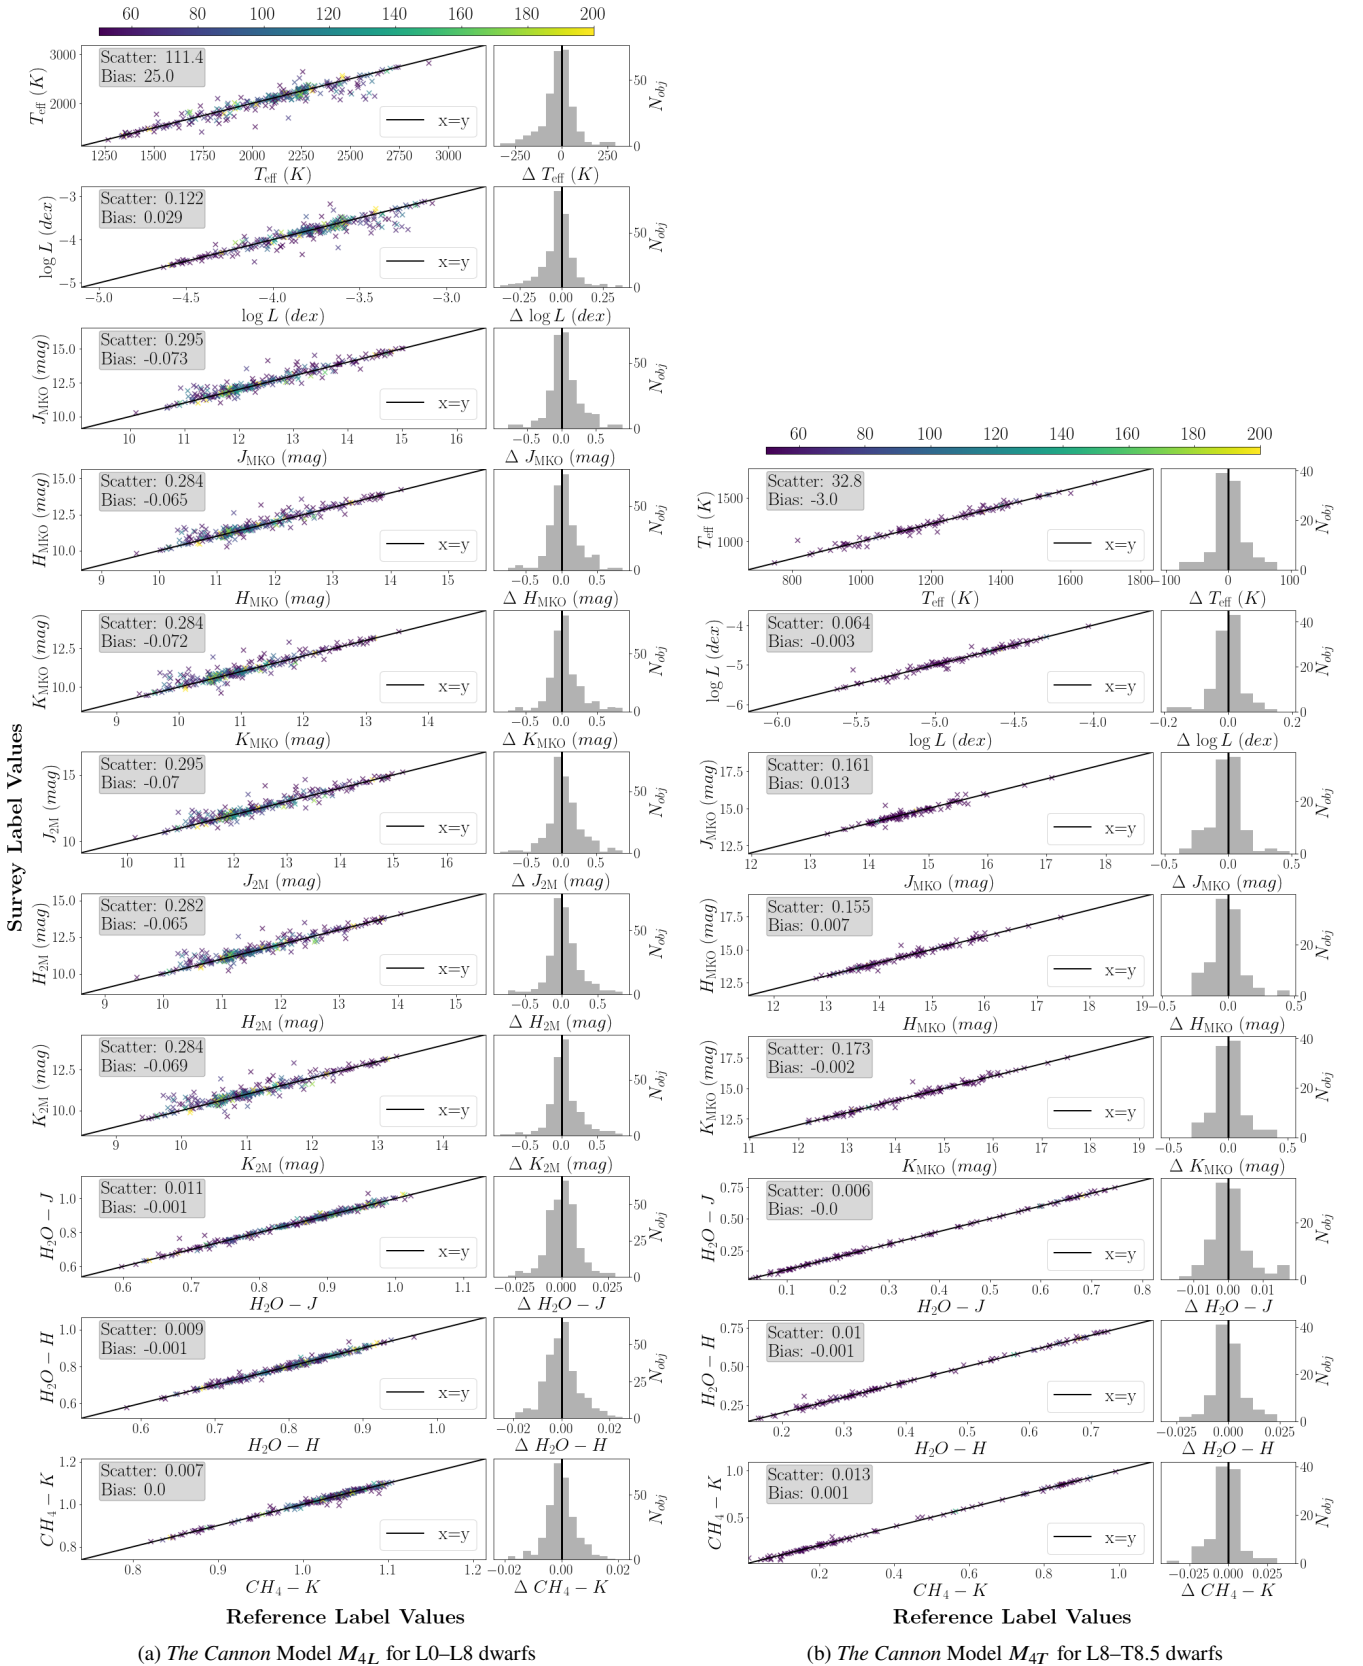

Figure 12. Same as Figure 11 but comparing the reference and survey values for *The Cannon* models M_{4L} and M_{4T} (Section 3.2.4) that use distinct reference sets containing L0–L8 (left) and L8–T8.5 (right). This produces the lowest scatter and bias for all labels, demonstrating that *The Cannon* infers more accurate physical quantities when limiting the spectral type ranges of the reference sets used to generate the model.

3.2.5 Discussion of Individual Objects of Interest

During our construction of *The Cannon* models described in this Section, we identified outlier objects, which we define as having inferred label values more than two standard deviations from the reference label space in more than one model. We identified 10 such objects, most of which are L0 dwarfs with no unusual spectral features or other properties noted in the literature. We suspect that *The Cannon* is returning less accurate survey labels for these objects because they lie near the edges of our reference label spaces. Three objects do have unusual properties which we discuss here.

2MASS J0859254–194926: This object is categorized as an optical L6 dwarf by Cruz et al. (2003, adopted by us) and a NIR L8±2 dwarf by Thompson et al. (2013). It is a faint outlier in absolute magnitude for an L6 dwarf in 2MASS and WISE bands (Figure 2). *The Cannon* models that include *SpT* as a label return inferred values that are 1.2–2 spectral types greater than the reference value. We conclude that this object is best classified as an L8 dwarf.

DENIS J1707252–013809: This L2 dwarf (Martín et al. 2010) is a weak binary candidate whose spectrum best fits components with L0.7 and T4.3 spectral types (Bardalez Gagliuffi et al. 2014). *The Cannon* models that use both L and T dwarfs in the reference set infer values for T_{eff} , $\log L$, and photometry labels more than 2σ cooler and fainter than the reference label space, and *The Cannon* models that include *SpT* as a label return inferred values that are 1.5–2 spectral subtypes cooler than the reference value. However, when the reference set is restricted to L dwarfs, the inferred labels are consistent with reference labels. Including T dwarfs in the reference set could allow *The Cannon* to identify spectroscopic features that correspond to lower temperatures and fainter magnitudes.

SDSS J104409.43+042937.6: This object is ≈ 0.4 mag overluminous for its L7 spectral type (Knapp et al. 2004) in the near-infrared photometric bands when compared to its parallax-derived distance. It has no unusual spectroscopic features, so we consider it to be a candidate $\approx L7+L7$ binary. *The Cannon* models infer values for T_{eff} , $\log L$, and photometry labels more than 2σ cooler and fainter than the reference label space for both the M_3 model (L and T dwarfs in the reference set) and M_{4L} model (only L dwarfs in the reference set).

3.3 Application to SPHEREx-resolution Spectra

We briefly explored the efficacy of *The Cannon* to infer the same physical properties from spectra taken by future space missions. The Spectro-Photometer for the History of the Universe, Epoch of Reionization and Ices Explorer (SPHEREx; Crill et al. 2020) spacecraft, currently scheduled for launch in 2025, will survey the sky at wavelengths $0.75 < \lambda < 5.0 \mu\text{m}$. For near-IR wavelengths ($0.75 < \lambda < 2.4 \mu\text{m}$), the spectral resolution will be $R = 41$ (Doré et al. 2014), about half that of the SpeX prism spectra we have analysed in this work. To simulate SPHEREx spectra, we removed every other element (i.e., 220 of the 440 elements) from the wavelength grid of the same $R \sim 75$ spectrum we used in Section 3.1.1, re-interpolated the spectra onto this grid to obtain $R \sim 40$, and reevaluated *The Cannon* models described in Section 3.2.

For each model, we used the same labels, reference sets, and applied the same continuum estimation (i.e., wavelength ranges and percentile cutoffs) as described previously. The identified continuum pixels were fit using a first-order sinusoid function. When comparing the $R \sim 40$ spectra models to their respective $R \sim 75$ spectra models (*The Cannon* M_1 , M_2 , M_3) all models that used the lower resolution spectra in the reference set resulted in an increase in scatter for T_{eff}

(5 to 8 per cent), $\log L$ (4 to 8 per cent), and *MKO* and *2MASS* photometry (2 to 9 per cent). Figure 13 shows the results that use lower resolution spectra for *The Cannon* models M_{4L} and M_{4T} (Section 3.2.4), which separate L and T dwarfs in the reference sets. Using lower resolution spectra in the M_{4L} model, L0–L8 dwarfs reference set, increases the scatter 18 to 23 per cent for T_{eff} , $\log L$, and all *MKO* and *2MASS* bands. For the M_{4T} model, L8–T8.5 dwarfs reference set, we note a 5 to 8 per cent decrease in the scatter for T_{eff} and $\log L$, no change for J_{MKO} and H_{MKO} photometry labels, and a 3 per cent increase in scatter for the K_{MKO} label. *The Cannon* can determine labels for L dwarfs with lower precision, but infers physical properties for T dwarfs at the same or slightly greater precision. This indicates that physical properties can be inferred by *The Cannon* from a reference set of lower-resolution $R \sim 40$ spectra and, providing accurate reference labels, *The Cannon* should be useful for $R \sim 40$ spectra that are expected to come from SPHEREx.

4 DISCUSSION

We have demonstrated that the machine learning tool *The Cannon* can be used to accurately infer physical quantities (“labels”) such as effective temperature, photometry, and bolometric luminosity from low-resolution ($R \sim 75$) SpeX prism spectra of L and T dwarfs. Previous applications of *The Cannon* have analysed high-resolution spectra of stars that could be consistently normalized to a continuum. We have proven that physical information can similarly be extracted from the spectra of brown dwarfs, which are characterized by broad molecular absorption features and a lack of continuum.

The Cannon can infer numerical spectral types, absolute magnitudes, effective temperatures, and bolometric luminosities at precisions that are competitive with other methods, without the need for new parallax measurements. We find that using spectral indices instead of numerical spectral types for reference labels improves (i.e., decreases) the scatter and bias of the inferred values for all survey labels. Our best models can determine labels for L dwarfs with precisions of ≈ 100 K in T_{eff} , ≈ 0.12 dex in $\log L$, and ≤ 0.30 mag in *MKO* and *2MASS JHK* photometry. Similarly, properties of T dwarfs can be inferred with precisions of ≈ 30 K in T_{eff} , ≈ 0.06 dex in $\log L$, and ≤ 0.17 mag in *MKO JHK* photometry. Spectral indices can also be determined at precisions of ≈ 0.01 . These precisions for T_{eff} and $\log L$ in T dwarfs are comparable to methods that employ absolute magnitude-based polynomial relations (e.g., Filippazzo et al. 2015; Dupuy & Liu 2017), indicating that the *The Cannon* can reach the systematic uncertainty limit in the polynomial-determined reference labels. When comparing inferred labels to the absolute magnitudes determined with spectral type-based relations, we find *The Cannon* can infer photometry at lower uncertainties and without requiring trigonometric parallaxes. We briefly examine the efficacy of *The Cannon* models for future spectroscopic missions. Replicating the resolving power of SPHEREx, $R \sim 40$, we predict *The Cannon* will successfully infer physical properties with similar or lower precision than models that use higher-resolution spectra. We have not yet fully explored the possible combinations of data sets and parameters for *The Cannon*, and we expect future work to improve upon our results.

We have also investigated several factors that affect *The Cannon*’s ability to infer accurate labels. First, *The Cannon* relies on a continuum estimation that is used to identify wavelength regions in the spectra that do not change significantly with the labels and are near unity flux (a “continuum mask”). Typically, regions that are strongly affected by absorption are not identified for *The Cannon*’s continuum normalization. However, applying this continuum mask

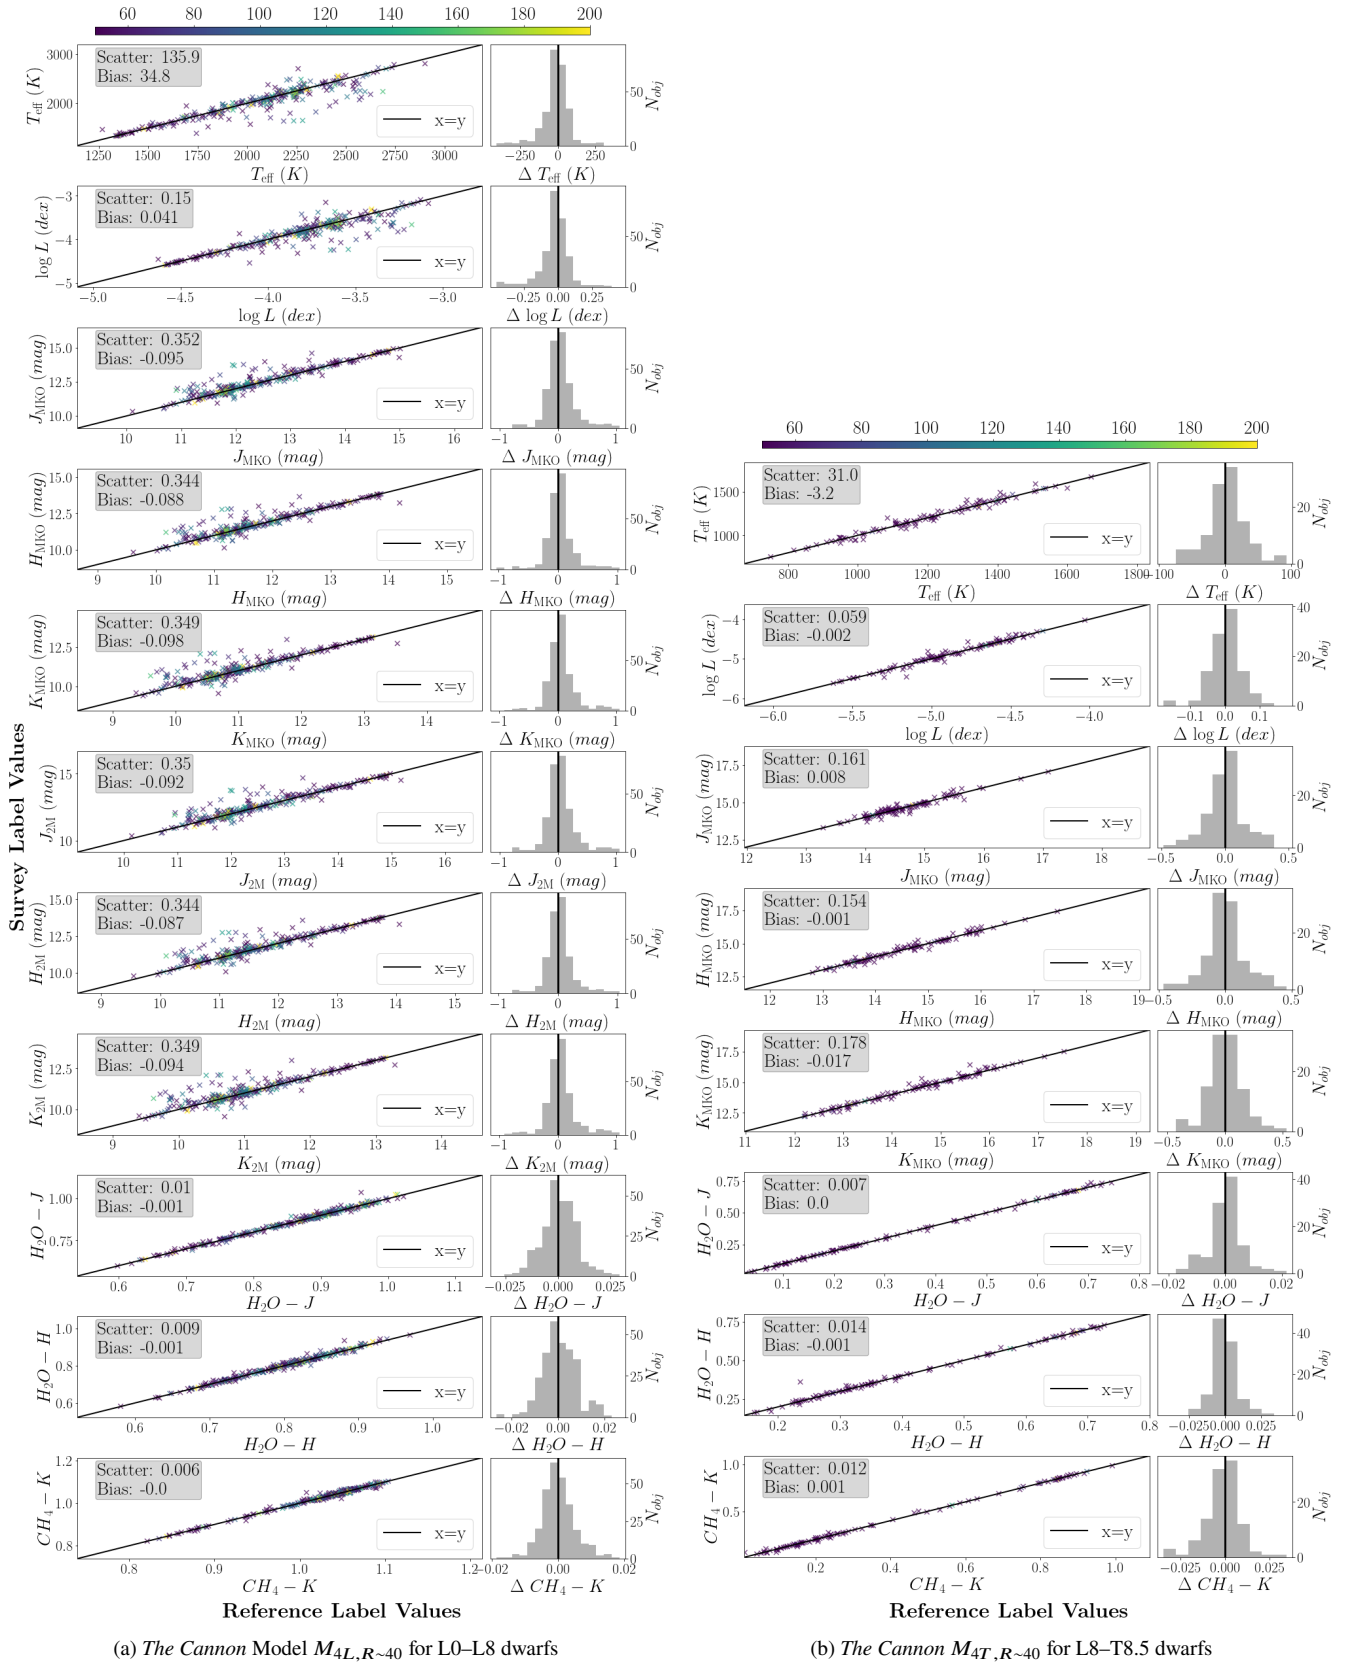

Figure 13. Same as Figure 12 but comparing the reference and survey values for *The Cannon* models that utilize spectra at a resolution $R \sim 40$ (Section 3.3). These models use the same reference set and labels of *The Cannon* models M_{4L} (L0–L8, left) and M_{4T} (L8–T8.5, right). Using lower-resolution spectra, *The Cannon* can determine labels for L dwarfs with $\approx 20\%$ less precision but infers labels for T dwarfs at the same or better precision.

for brown dwarf spectra is challenging since they contain few or no absorption-free regions. We found that typically, identifying J , H , and K bands as three distinct wavelength regions to be continuum-normalized separately is most appropriate for this process. Second, the accuracy of the inferred label values are limited by the quality of the reference labels given to train the model. We have assumed that the reference labels used for these models are accurate, but in reality they contain some uncertainty and potentially some bias. Including label uncertainties in *The Cannon* models as well as utilizing tailored methods to obtain more accurate reference label values (e.g., T_{eff} and $\log L$ from spectral energy distribution fitting) could improve the inference of properties for new spectra. In future work, label uncertainties could be used as variables in the label functions or as labels themselves.

ACKNOWLEDGEMENTS
