**Abstract**—Recomposing channel state information (CSI) from the beamforming feedback matrix (BFM), which is a compressed version of CSI and can be captured because of its lack of encryption, is an alternative way of implementing firmware-agnostic WiFi sensing. In this study, we propose the use of camera images toward the accuracy enhancement of CSI recombination from BFM. The key motivation for this vision-aided CSI recombination is to draw a first-hand insight that the BFM does not fully involve spatial information to recombine CSI and that this could be compensated by camera images. To leverage the camera images, we use multimodal deep learning, where the two modalities, i.e., images and BFMs, are integrated to recombine the CSI. We conducted experiments using IEEE 802.11ac devices. The experimental results confirmed that the recombination accuracy of the proposed multimodal framework is improved compared to the single-modal framework only using images or BFMs.

## I. INTRODUCTION

Currently, channel state information (CSI) in wireless local area networks (WLANs) has attracted increasing attention because of its fine-grained propagation characteristics. While CSI-based sensing has been widely studied, obtaining CSI from off-the-shelf WLAN devices requires customized firmware, whose custom can be applied only to a specific chipset and protocol [1], [2]. This is because off-the-shelf devices discard CSI after the beamforming operation in physical layer components. This constrains the range of CSI-based sensing applications.

To alleviate this limitation, some studies [3], [4] utilized the beamforming feedback matrix (BFM), which is a series of right singular matrices for CSI matrices. They capture BFMs by the medium-access-control (MAC) frame-capturing tool, such as Wireshark [5], because WiFi access points (APs) and stations (STAs) exchange BFMs without encryption [6]. In other words, BFMs are stored in MAC-layer frames and exchanged among APs and STAs. Because of this simplicity of availability of BFMs, BFMs would be the alternative features for CSI toward WiFi sensing.

However, BFM-based sensing has not been well studied, and its applicability in sensing tasks is unclear, whereas CSI-based sensing is well-studied in the literature such as human

TABLE I  
SUMMARY OF CSI RECOMPOSITION FRAMEWORKS

Framework	Input	Output	Model
[9]	BFM	CSI amplitude	SMI-BFM
(For comparison)	Image	CSI amplitude	SMI-image
Proposed	Image and BFM	CSI amplitude	MMI

localization and tracking [7], and heart rate estimation [8]. Furthermore, there is a performance gap between BFM- and CSI-based sensing, e.g. the gap in the respiration estimation error [4], [8].

One promising approach to study the performance of BFM as an alternative of CSI for sensing tasks is to directly recombine the CSI from the BFM and evaluate the prediction errors [9]. The intuition is that if one can predict CSI from the BFM, the aforementioned various CSI-sensing task is also possible based on BFM by orderly performing the recombination of CSI and sensing based on the recomposed CSI. In [9], they demonstrated the feasibility of the recomposing CSI amplitude from BFM by a simulation dataset. However, there still existed a recombination error between the ground-truth and recomposed CSI, and the input information that was additionally needed to enhance the prediction accuracy was not fully determined. Answering this question leads to further understanding the BFM as an alternative feature for CSI towards wireless sensing tasks.

To this end, we develop a vision-aided CSI recombination framework, using images alongside BFM. This is motivated by our key hypothesis that spatial information on propagation environments in camera images can aid in the compensation of the insufficiency of BFM to recombine CSI. This work is devoted to drawing first-hand insights into this hypothesis in the following two perspectives.

First, in view of the fact that the recombination involves the two different modalities (i.e., BFMs and images), we design a multimodal input (MMI) deep learning model. A brief summary of the proposed and comparison frameworks

are listed in TABLE I. The MMI model is constructed by two encoders, which we term as the BFM encoder and image encoder, and CSI decoder. The encoders extract information on the propagation environments from the BFMs and camera images, respectively, and the CSI decoder integrates them and recomposites the CSI amplitude. Leveraging this architecture, we compare its performance with that of single-modal input (SMI) models and demonstrate that the accuracy enhancement by additionally using camera images is feasible.

Secondly, to demonstrate the feasibility of the proposed CSI recombination, we conduct experiments using IEEE 802.11ac devices. Despite the simplicity of the availability of BFMs, it was difficult to simultaneously obtain the corresponding CSI and BFM using off-the-shelf devices to create the datasets of the MMI learning. To address this issue, we introduce an experimental system obtaining corresponding CSI and BFM, which was developed in [10]. In this system, BFM are emulated by computing singular value decomposition (SVD) instead of capturing frames, where CSI is obtained by the customized firmware [2] installed in ASUS RT-AC86U WLAN AP.

The main contributions of this paper are summarized as follows:

- Toward firmware-agnostic WiFi sensing, i.e., sensing without using CSI, we propose a CSI recombination framework using camera images in addition to BFMs. This framework is devoted to demonstrating that BFM may not involve sufficient spatial information on propagation environments for CSI recombination, which could be compensated by camera images. To realize this framework, we design an MMI learning model with the input of the combination of BFM and image.
- We conduct experiments to demonstrate the feasibility of improving the CSI recombination accuracy using an MMI model. The experimental results confirm that the recombination accuracy of the proposed multimodal framework is more than that of the single-modal frameworks, using only images or BFMs.

The remainder of this paper is organized as follows. The system model is introduced in Section II. Section III presents the vision-aided CSI recombination framework. Section IV presents the experimental evaluation. Finally, Section V concludes the paper.

## II. SYSTEM MODEL

Fig. 1 presents a system model of our proposed framework, which consists of an AP with  $M$  antennas, STA with  $N$  antennas, red-green-blue (RGB) camera, sniffer, and estimator. The STA receives frames transmitted by the AP, measures the CSI, calculates the BFM from the CSI, and sends back the BFM to the AP by transmitting beamforming feedback frames. The sniffer captures the feedback frames to obtain the BFMs. Because BFMs are sent without encryption, they can be captured by frame-capturing tools, such as Wireshark [5].

The estimator recomposites the amplitude of the CSI elements. Unlike in a previous study [9], the estimator uses not

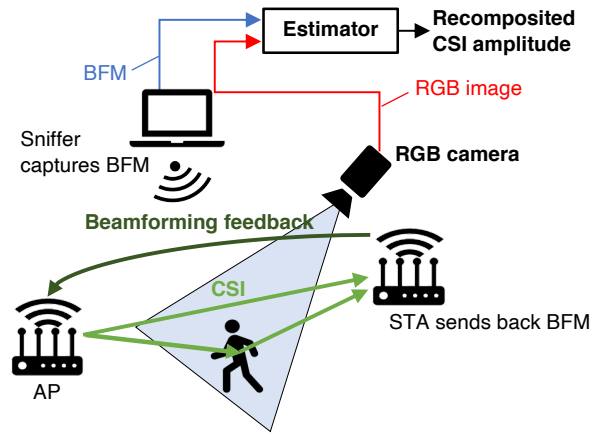

Fig. 1. System model. Estimator recomposites CSI amplitude using the BFMs obtained from the sniffer and the RGB images obtained by the RGB camera.

only BFMs but also RGB images captured by the RGB camera. Let the CSI at time  $t \in \mathbb{Z}$  and subcarrier  $k \in \{1, 2, \dots, K\}$  be denoted by  $\mathbf{H}_t[k] \in \mathbb{C}^{N \times M}$ ; then, the corresponding BFM  $\mathbf{V}_t[k] \in \mathbb{C}^{M \times N}$  is given by:

$$\mathbf{H}_t[k] = \mathbf{U}_t[k] \boldsymbol{\Sigma}_t[k] \mathbf{V}_t[k]^H, \quad (1)$$

where  $\mathbf{U}_t[k]$  and  $\mathbf{V}_t[k]$  are unitary matrices, and  $\boldsymbol{\Sigma}_t[k]$  is a diagonal matrix with singular values. The notation  $\mathbf{V}^H$  denotes the Hermitian transpose of  $\mathbf{V}$ . Let subcarrier-integrated CSI and BFM be denoted by  $\{\mathbf{H}_t[k]\}_k$ ,  $\{\mathbf{V}_t[k]\}_k$ , respectively. The RGB image denoted by  $\mathbf{I}_t$  has the shape of  $H \times W \times 3$ , where  $H$  and  $W$  are the height and width of the image, respectively and 3 represents color channel, red, green and blue. Using the data for  $\{\mathbf{V}_t[k]\}_k$  and  $\mathbf{I}_t$ , the estimator recomposites the amplitude of the  $\{\mathbf{H}_t[k]\}_k$ .

RGB cameras are typically used as surveillance cameras in office rooms, where WLANs are employed. Therefore, the cameras can be used for other applications such as surveillance to reduce the initial and running costs of deploying the cameras.

## III. MULTIMODAL LEARNING-BASED CSI RECOMPOSITION FRAMEWORK

### A. Data Preprocessing for CSI Recombination

The dataset for the CSI recombination is generated through preprocessing, as shown in Fig. 2. The dataset is composed of the input and supervised data. The proposed CSI recombination framework adopts an MMI model. The BFMs are obtained by the frame-capturing tool, and the RGB images are obtained by the RGB camera. Before being fed to the machine learning (ML) model, the obtained RGB image  $\mathbf{I}_t$  is downsampled to  $h \times w \times 3$ , where  $h \leq H$  and  $w \leq W$ , to reduce the calculation complexity. Let the downsampled image be denoted by  $\mathbf{I}'_t$ .

The obtained BFM is preprocessed as follows: First, the subcarrier-integrated BFM  $\{\mathbf{V}_t[k]\}_k$  is flattened; namely, the shape of the BFM data is converted into  $K \times MN \times 1$ . Subsequently, the absolute value and argument of the flattened

Fig. 2. Overview of the proposed CSI reposition framework. The CSI estimator is represented as the MMI model. Before being fed to the MMI model, first, the BFMs and RGB images are preprocessed. Multimodal inputs are concatenated at the concatenation layer to complement each other.

complex BFM elements are calculated and concatenated to form the input BFM data  $V'_t$ . The shape of the input BFM data is  $K \times MN \times 2$ .

The supervised data, denoted by  $H'_t$ , is the amplitude of the complex CSI elements corresponding to the input BFM elements. The obtained CSI is preprocessed as follows: First, as in the preprocessing of the BFMs, the obtained CSI is flattened to  $K \times MN \times 1$ . Subsequently, each element of the flattened data is normalized. The normalized data is used as the supervised data  $H'_t$  whose shape is  $K \times MN \times 1$ .

### B. Multimodal Input Model

This section details the MMI model used in the vision-aided CSI reposition framework. As previously mentioned, the preprocessed RGB image data  $I'_t$  and BFM data  $V'_t$  were fed to the MMI model. The model was trained by computing the loss function between the output and supervised data  $H'_t$ .

Fig. 3 shows the structure of the MMI model, which consists of two encoders, i.e., BFM encoder and image encoder, a concatenation layer, and CSI decoder. The model is constructed as a convolutional neural network (CNN) including 0.92 million parameters. This CNN consists of several layers: 2D convolution (2Dconv), 2D max pooling, batch normalization (BN) [11], concatenation, 2D upsampling, and linear layers. Each 2Dconv layer is activated by the rectified linear unit except for the last 2Dconv layer.

The kernel and filter size of each layer are shown in Fig. 3. To ensure the consistency with the previous work [9], the kernel size of the element domain is set to 1 in the BFM encoder, such that the 2Dconv and max pooling layers are utilized to extract inter-subcarrier features of each BFM. The BFM and image encoder output features have the same shape. In the concatenation layer, these features are concatenated and fed to the CSI decoder. All 2Dconv layers conduct padding. Finally, the CSI decoder is activated by a linear layer, and it outputs the recomposited CSI amplitude.

Fig. 3. Structure of MMI model. The model consists of the BFM encoder and image encoder, CSI decoder, and concatenation layer.

## IV. EXPERIMENTAL EVALUATION

### A. Experimental Setup

This section details the experimental setups. We develop an experimental system to obtain simultaneously corresponding CSI and BFM using off-the-shelf devices for creating the datasets. Fig. 4 illustrates the experimental equipment layout, where an AP, STA, camera, and measurement device (MD) are used. The MD captures frames transmitted by the AP to calculate the CSI. Thus, the CSI represents the channel characteristic between the MD and AP. In other words, the MD exhibited the characteristics of the STA, which was merely the receiver of the frames. To obtain the corresponding CSI and BFM, the BFM of the input data is not obtained by the sniffer but obtained from the MD by applying SVD to the CSI. Details

(a) Equipment layout.

(b) Snapshot.

Fig. 4. Experimental system to obtain corresponding CSI and BFM. The CSI captured by the MD represents the channel characteristic between the MD and STA. The MD behaves as the STA, which is just a receiver of the frames.

TABLE II  
DETAILS OF EXPERIMENTAL EQUIPMENT

Roles	Devices
AP	ASUS RT-AC86U
STA	ASUS RT-AC86U
Measurement device	ASUS RT-AC86U with custom firmware [2]
RGB camera	Intel RealSense D435 [12]

of the experimental equipment are presented in TABLE II. The equipment is all off-the-shelf, except for the firmware of the MD, which is customized according to [2]. To experiment in a dynamic environment, a pedestrian as an obstacle moves along with the paths indicated in Fig. 4(a). There are four paths perfectly included in the FOV of the camera. We conduct a total of four experiments using each path. The experimental parameters are presented in TABLE III.

The dataset with 24,000 samples of time-synchronized images and CSIs were obtained from the experimental data, and the corresponding BFMs were emulated from the CSIs. The dataset is divided into three portions: training, validation, and test data in the ratio of 72:18:10. The ML model was trained using the training data. The validation data was used to evaluate CNNs in each epoch. The training is said to be complete when the number of training epochs reaches 100 or when the validation loss increases by 10 epochs in a row, which is referred to as early stopping and prevents the CNNs from overfitting.

### B. Baselines

To evaluate the performance of the MMI model, we used two SMI baselines: SMI-BFM and SMI-image, whose inputs are the BFMs and images, respectively. The structures of the

TABLE III  
EXPERIMENTAL PARAMETERS

TABLE IV  
HYPERPARAMETERS OF TRAINING

Hyperparameters	Values
Batch size	64
Epochs	100
Downsampled image pixels ( $h \times w$ )	$96 \times 96$

SMI-BFM and SMI-image are shown in Fig. 6. They are constructed as CNN compliant with the MMI model, except for the concatenation layer and the layers before it. They do not have the concatenation layer, and their first halves are the BFM and image encoder. Their components are the same as the corresponding components in the MMI model. The SMI-BFM and SMI-image model include 0.78 and 0.82 million parameters, respectively.

The hyperparameters of the ML algorithm are listed in TABLE IV. We used Adam [13] with a learning rate of 0.001 for the optimizer and mean squared error for the loss function. To obtain the results without depending on the model initialization, all CNNs were trained based on five random seeds for initializing parameters.

### C. Results

Fig. 5 depicts an example of the frequency series of the amplitude of the CSI elements. The recomposition accuracy is visually confirmed by this figure. Fig. 5(a) shows that the recomposition of the MMI matches the ground truth the most compared with that of SMI-BFM. However, from Fig. 5(b) and (c), there are some elements in which the accuracy gap between the MMI and SMI-BFM model is not high.

TABLE V shows the recomposition root-mean-squared error (RMSE) with one standard deviation for five random seeds. The RMSE values in TABLE V are averaged over the samples. From TABLE V, the recomposition error in the MMI is smaller than that in the baselines. This result validates the feasibility of improving the recomposition accuracy using vision-aided CSI recomposition. Particularly, compared with SMI-BFM, it is implied that the RGB images should include the spatial information on the propagation environments to fill the gap between the BFM and CSI.

## V. CONCLUSIONS

In this study, we proposed a CSI recomposition framework leveraging camera images alongside the BFMs. The key idea was that the spatial information on the propagation environments included in the camera images could fill the gap between the BFM and CSI and improve the recomposition accuracy.

Fig. 5. Example of the recomposited CSI and ground truth. The graph is depicted about the amplitude of the (1, 1), (1, 2), and (1, 3) elements of  $H'_i$ .

To leverage the camera images, we used MMI deep learning, where the input of the BFMs and camera images were integrated to recombine the CSI amplitude. We conducted experiments using IEEE 802.11ac devices to demonstrate the feasibility of the proposed CSI recombination framework. The experimental results revealed that the recombination accuracy of the proposed multimodal framework was improved rather than that of the comparison single-modal frameworks.
