We derive a theoretically guaranteed compressive sensing method for acoustic field reconstructions using spherical field measurements on a predefined grid. This method can be used to reconstruct sparse band-limited spherical harmonic or Wigner D-function series. Contrasting typical compressive sensing methods for spherical harmonic or Wigner D-function series that use random measurements on the sphere or rotation group, the new method samples on an equiangular grid in those domains, which is a commonly used sampling pattern. Using the periodic extension of the Wigner *D*-functions, we transform the reconstruction of a Wigner D-function series (of which spherical harmonics are a special case) into a multi-dimensional Fourier domain reconstruction problem. We establish that this transformation maintains sparsity in cases of interest and provide numerical studies of the transformation's effect on sparsity. We also provide numerical studies of the reconstruction performance of the compressive sensing approach compared to classical Nyquist sampling. In the cases tested, we find accurate compressive sensing reconstructions need only a fraction of the measurements dictated by the Nyquist sampling theorem. Moreover, using one-third of the measurements or less, the compressive sensing method can provide over 20 dB more denoising capabilities than oversampling with classical Fourier theory.

I. INTRODUCTION

Band-limited Spherical Wavefunction (SW) expansions in 3D and its restriction to a sphere. Spherical Harmonic (SH) expansions, have become a key tool in many acoustics applications. Recent high-interest applications of these series expansions range from surround sound¹⁻³, spherical acoustic holography⁴⁻⁶, and acoustic levitation^{7,8} to beam-forming/source localization^{9,10}, directivity characterization 11,12, ultrasonic medical imaging^{13,14}, and using ultrasonics to non-destructively characterize crystalline structures^{15,16}. Beyond these acoustical applications, SWs and SHs are key tools in electromagnetic (EM) applications. See for example, spherical near-field to far-field transformations (SNF2FFTs)¹⁷. The utility of the SW and SH expansions are quite broad. In surround sound settings^{1–3}, spherical acoustic hologra phy^{4-6} , and directivity characterizations^{11,12}, one needs explicit knowledge of the SW or SH series to reconstruct or reproduce a given sound field. A similar situation is present in ultrasonic medical imaging 13,14 , where SH series coefficients are needed to model the shape of various organs inside of the body. The usage of SWs and SHs in crystallography is slightly different; in this application the SW or SH coefficients are used to relate an easily measureable quantity to the crystalline texture of polychristalline material^{15,16}. Moreover, in acoustic levitation, ultrasound, and even room transfer function estimation¹⁸, the need to know the acoustic field of a device to a high level of detail presents a future application for SW/SH characterizations, in particular acoustic SNF2FFTs¹⁹. Such characterizations are especially important for spherical arrays that are being used to generate or characterize sound fields because minor transducer errors in the array can lead to major performance degradation in certain scenarios²⁰.

Estimating the SW or SH expansion coefficients of an acoustic field requires first taking measurements on a fixed radius sphere using a spherical array of microphones^{1,3} or, in the more general case, higher-order probes¹⁹. From these measurements, one can then use integral approaches 1,15,16 or, as has become quite common, a linear inverse $problem^{1-3}$ to solve for the SW coefficients. From the Nyquist sampling theorem, the number of measurements M, required to accurately estimate a field's coefficients in the band-limited SW/SH series scales with the square of the band-limit 1,19 . Depending on whether a classical integration or linear inverse problem is used, the constant scaling coefficients of this quadratic can vary^{1,15}. Under certain assumptions about the measurement probe, this also holds for vector SWs/SHs in EM applications¹⁷. For even small band-limits, the number of measurements can be timeconsuming and turn into hundreds or even thousands

of measurements^{1,15}. Thus, characterizing an acoustic field can require many microphones in a spherical array (i.e., in spherical holography, source localization/beamforming, directivity characterization, etc.) or be time consuming for using if re-positioning the experimental apparatus (the source/receiver microphone/higher-order probe or a polycrystalline material). As a note, in EM SNF2FFTs, measurement numbers fare even worse since typical devices can require hundreds of thousands of measurements due to their band-limit and noise requirements^{21,22}.

In many of the above-mentioned applications, methods relating to sparse signal processing have been of interest in order to speed up measurement times and reduce the need for many measurement devices or decrease the number of transducers needed to reproduce a sound field $^{2,6,23-25}$. When the sound fields of interest satisfy certain properties, e.g., the sound field from a symmetric loudspeaker or only low-frequency sounds, the SW/SH coefficients can be considered as sparse or compressible (i.e., approximately sparse). Here, sparse means that the coefficients contain mostly zero entries with few non-zero values. In these cases where the coefficients are sparse or compressible, Compressive Sensing (CS) can be used to accurately solve the linear inverse problem for the SW/SH coefficients while requiring fewer measurements than needed in integral approaches or to make the linear inverse problem fully determined $^{26-32}$. Such a reduction in the required number of measurements can allow for reduced measurement times and for microphone arrays, requires fewer microphones to be used.

For a particular linear inverse problem, the number of measurements required and where these measurements should be taken are key factors in determining the success of CS. One approach is to use trial and error or to algorithmically find measurement positions that minimize the coherence of the measurement matrix in the inverse problem while remaining within constraints dictated by device properties, e.g. microphone radii, positioning accuracy, etc. ^{33–35}. However, such approaches do not establish the required number of measurements nor do they provide guarantees as to the robustness of the CS method. Alternatively, these drawbacks can be avoided if the measurement matrix (which depends on the number of measurements and their positions) satisfies certain properties. Conventionally, the Robust Nullspace Property (RNP) guarantees methods like Quadratically Constrained Basis Pursuit (QCBP) produce accurate solutions for the unknown signal. A sufficient condition that provides strong guarantees for satisfying the RNP is a measurement matrix that satisfies the Restricted Isometry Property (RIP). Verifying the RIP for a given measurement matrix is NP-hard³⁶. Due to this fact, probabilistic approaches showing that a measurement matrix satisfies the RIP with high probability are normally used^{31,35,37}. The drawback of the existing probabilistic RIP-based guarantees is that they require sampling at random positions. This requirement can be difficult or impossible for most measurement systems or microphone arrays because arbitrary points on SO(3) or the sphere can be too close physically in multi-probe systems and highly time-inefficient in single probe systems. This situation contrasts the coherence-based methods like those in^{33–35}, where hard/impossible measurement patterns can be deliberately excluded from use. In this article, we develop a CS method with robust theoretical guarantees for the number of measurements and coefficient reconstruction accuracy that can be used for SW or SH expansions where measurements are taken *from a fixed grid*. Thus, our work negates the problematic need for sampling at arbitrary positions in space as present in existing approaches^{31,35,37}

A. Contributions and Relation to Other Work

To derive a CS approach for SW or SH expansions applicable to the many acoustics applications described above and that can even be applied in EM applications like SNF2FFTs, we prove a CS guarantee for a more general series SW or SH series. In particular, our result holds for a series of band-limited Wigner *D*-functions. For the case where measurements are performed by moving a microphone to different measurement positions or using a spherical array of microphones, the Wigner D-function expansion reduces to the SH (thus SW) expansion by using only a certain subset of Wigner *D*-functions. For the case where measurements are taken using a high-order probe, the Wigner *D*-function series is required unless simplifying assumptions are made, e.g., using an ideal measurement probe. This is a direct result of accounting for the probe's sensitivity to SWs in its coordinate frame and carrying out the appropriate transformations to relate the measurements taken and the SW expansion coefficients of interest¹⁹. For mathematical context, the Wigner *D*-functions are an irreducible representation of the symmetry group of the sphere, the rotation group SO(3), and they form an orthogonal basis for bandlimited functions on $SO(3)^{38}$.

There has been a considerable push for reducing the measurement times for applications where one needs to accurately solve for the coefficients in a Wigner Dfunction series with sparse coefficients, in particular in the EM community 21, 22, 33, 35, 39, 40. In the existing literature, one main approach is to apply CS. In particular, this has been done by using RIP based guarantees^{35,37} or minimizing the coherence of the measurement matrix of Wigner D-functions^{33–35}. However, the drawback of the RIP approach is that it requires sampling at random positions on SO(3) to get robust theoretical guarantees. In contrast, the coherence-based methods have non-random sampling patterns but do not give robust theoretical guarantees. In this paper, we give an approach that avoids the drawbacks of both of the existing approaches. Specifically, our CS approach to solving for the coefficients in a Wigner D-function series, thus also SW/SH expansions, only requires sampling from a fixed grid on SO(3) and provides theoretical guarantees regarding the number of measurements needed for recovery, M, along with the reconstruction accuracy. Thus, we show that CS guarantees can be applied to the linear inverse problem arising from solving for the Wigner D-function coefficients without arbitrarily positioned measurements SO(3). Additionally, our approach requires fewer measurements than the classical Nyquist sampling theorem requires. To the best of our knowledge, this is the first result giving theoretical guarantees for CS recovery of the coefficients in a series of SWs, SHs, or Wigner Dfunctions where measurements are selected from a fixed grid on SO(3), or from a fixed grid on the sphere in the SW/SH cases.

B. Outline of Results

In the present article, we provide a method to apply CS to recover the coefficients of a series of Wigner D-functions, and thus SW or SW series, that only requires selecting samples from a pre-defined grid on SO(3)(sphere in the special case of SWs/SHs). In this problem we assume that the field measured, $w(\alpha, \beta, \gamma)$, can be written as a series of the Wigner *D*-functions. The arguments α , β , and γ parametrize a point in SO(3) corresponding to a physical position where the field can be measured. In this setup, α and γ are 2π periodic while β is typically taken to be in $[0, \pi]$. It is well known, however, that the Wigner *D*-functions naturally possess a periodicity when taking $\beta \in [0, 2\pi)^{38}$. Moreover, this periodicity is captured in a well-known Fourier expansion for the Wigner D-functions¹⁷. Thus, the approach we take to solve for the coefficients of a Wigner D-function series is to utilize this natural domain extension, periodicity, and Fourier expansion. Since we assume $w(\alpha, \beta, \gamma)$ is a series of Wigner *D*-functions, the periodic extension of the Wigner D-function naturally induces one in w and makes w periodic in all of its arguments by letting β be in $[0, 2\pi)$. This domain extension takes the function w on SO(3) and maps it to the 3-torus T^3 , which is a double cover of SO(3).

Now considering the periodically-extended Wigner D-functions and $w(\alpha, \beta, \gamma)$, we transform the problem to the Fourier basis. This allows us to treat the solution of the Wigner D-function inverse problem as a multidimensional Discrete Fourier Transform (DFT) problem. Moreover, this transformation is carried out in a way that preserves important sparsity structures in w. In this multi-dimensional DFT form, we can then sample a subset of the positions from the DFT formulation to achieve compressive sampling for the band-limited series of Wigner D-functions (see Theorem 6), which contains as special cases of SW or SH series.

In a bit more mathematical detail, we start with the problem of solving for the vector a from the inverse problem,

$$w = \Phi_D a + \eta, \tag{1}$$

where w is the vector of measurements of $w(\alpha, \beta, \gamma)$ at a set of points $(\alpha_j, \beta_j, \gamma_j) \in SO(3)$, Φ_D is the measurement matrix whose rows contain the Wigner *D*-functions $D_n^{\mu m}(\alpha_j, \beta_j, \gamma_j)$, a is the vector of coefficients in the Wigner *D*-function series for $w(\alpha, \beta, \gamma)$, and η is additive measurement noise. Here, we have standard ranges for the arguments of the Wigner *D*-function, $\alpha \in [0, 2\pi)$, $\beta \in [0, \pi]$, and $\gamma \in [0, 2\pi)$. Note, the Wigner *D*-functions relate to the spherical harmonics in a form like $D_n^{\mu 0} = c_n^{\mu} Y_n^{-\mu}(\beta, \alpha)$ or $D_n^{0m} = c_n^m Y_n^{-m}(\beta, \gamma)$, where the *c* coefficients are constants depending on its indices³⁸. Thus, SW/SH series can be considered a special case of (1).

Without making any further assumptions beyond $w(\alpha, \beta, \gamma)$ being representable as a series of Wigner Dfunctions, we recognize that if we extend β to be in $[0, 2\pi)$, the Wigner *D*-functions in Φ_D become periodic in all three arguments $(\alpha, \beta, \gamma)^{38}$. With this periodic domain extension, instead of (α, β, γ) being on SO(3), they are taken to be on \mathbf{T}^3 . Since $w(\alpha, \beta, \gamma)$ is the Wigner Dfunction series with coefficients in a, $w(\alpha, \beta, \gamma)$ also becomes periodic. In terms of measurements, this amounts to letting the polar angle of measurements wrap completely around the sphere on which measurements are taken. For a spherical microphone array, this is a reinterpretation of the existing microphone positions. Each microphone would have one position with $0 < \beta \leq \pi$ and a second position with $\pi \geq \beta < 2\pi$. As discussed later, this means the measurements from a specific microphone may be used twice. Additionally, for a high-order probe like those $in^{17,19}$, the domain extension means the second rotation in the set of Euler rotations in the zyz' convention is extended to a full 2π range. With these physical pictures in mind, the periodicity of $w(\alpha, \beta, \gamma)$ with an extension in β become more intuitive.

Due to the periodicity of the Wigner *D*-functions, there is a transformation, which we denote with *B*, that takes the problem from a Wigner *D*-function basis with arguments α , β , $\gamma \in [0, 2\pi)$ to the Fourier series basis. That is, we can write the problem as

$$w = \Phi_F b + \eta, \tag{2}$$

$$b = Ba, (3)$$

where $\Phi_D = \Phi_F B$. Here Φ_F is the measurement matrix whose rows contain the basis functions for the threedimensional Fourier series, and b is the vector containing the Fourier coefficients for w on \mathbf{T}^3 . Fortunately, the B matrix derives from the well-known Fourier expansion for the Wigner *D*-functions and can be computed directly from the Wigner *D*-functions. Importantly, it is the case that B is well-conditioned and preserves sparsity in situations where the sparsity comes from only using a few m, μ subspaces or needing only low-frequency functions in the Wigner *D*-function basis. Thus, to solve (1), we can first solve for the Fourier coefficients b, and then solve for the Wigner D-function (or SW/SH) coefficients a. When one is simply interested in the special cases of SW or SH series, this directly gives the coefficients desired. For high-order probes (e.g., in SNF2FFTs), a can be used to calculate the SW coefficients of the speaker/emitter after factoring out the appropriate transformation infor $mation^{17,19}$).

In the above, we transformed the problem in (1) from a Wigner *D*-function series on SO(3) to a Fourier problem on \mathbf{T}^3 . If we suppose that measurements are taken at a selection of points from an equiangular grid covering \mathbf{T}^3 at the Nyquist rate (which is also a Nyquist sampling on SO(3)), then Φ_F becomes a sub-sampled three dimensional DFT (3DDFT) matrix. We denote the 3DDFT matrix as U_F . Since the measurements form a sub-sampled 3DDFT, we can write the problem as

$$w = P_{\Omega} U_F a + \eta, \tag{4}$$

where P_{Ω} is the matrix selecting a subset of M rows from U_F . With the problem in (1) cast in this way, we can apply standard CS recovery guarantees for sub-sampled unitary measurement matrices³². Thus, we achieve compressive measurements from a sub-selection of measurements from a pre-defined grid on \mathbf{T}^3 (and so SO(3)). To get these robust reconstruction guarantees from CS, the number of measurements, M, must scale as

$$M \ge \tilde{C}s_F \ln^4(N_F),\tag{5}$$

where N_F is the size of the band-limited threedimensional Fourier basis, s_F is the sparsity in this basis, and \tilde{C} is a constant. Transforming this equation for Minto a form depending only on Wigner *D*-function basis information, one gets a *worst-case* scaling of

$$M \ge \widetilde{C}' N_D^{1/3} s_D \ln^4(N_D), \tag{6}$$

where \widetilde{C}' is a constant, s_D is the sparsity in the Wigner D-function basis, and N_D is the size of the Wigner D-function basis.

C. Structure of this Paper

The remainder of this paper is structured as follows. Section ID provides the notation used throughout the paper. Section II contains the background information on the Wigner D-functions and field measurements in the general case of using high-order probes in Section IIA along with the results we need from the CS literature in Section IIB. Section III then gives the transformation of the inverse problem in (1) from the Wigner *D*-function formulation to the Fourier formulation as well as the CS guarantees for this problem with the gridded sampling of \mathbf{T}^3 . We follow with numerical examples in Section IV. This section includes investigations into the effect that transforming from the Wigner *D*-function formulation to the Fourier formulation has on the sparsity of the coefficient vector, Sections IV A and IV C, and then examples of CS recovery in the Fourier formulation, Section IV D. Lastly, we provide a conclusion in Section V.

D. Notation

Throughout this paper, we use the following notation and conventions. The sum $\sum_{m,\mu,m'=-n}^{n}$ is used to mean $\sum_{m=-n}^{n} \sum_{\mu=-n}^{n} \sum_{m'=-n}^{n}$. We use $i = \sqrt{-1}$ as the

unit imaginary number. An over-line represents complex conjugation, e.g., \overline{a} . We represent the Hermitian conjugate of a vector or matrix with *, e.g., $a^* = \overline{a^T}$, where T denotes the transpose operation. The norm $\|\cdot\|_2$ is the standard ℓ_2 vector norm. $\|\cdot\|_{\infty}$ is either the ℓ_{∞} or L_{∞} norm, which should be discernible from context. As usual, for a vector, $\|a\|_{\infty} = \max_i(|a_i|)$, and for a function, $\|f\|_{\infty} = \inf\{c \ge 0 : |f(x)| \le c$ for almost every $x\}$. For Euler rotations, we use the zyz' and passive transformation conventions³⁸. We use i.i.d. to abbreviate independently and identically distributed.

II. BACKGROUND

In this section, we develop the background for our work in the context of spherical field measurements with general probes and also state the requisite CS reconstruction guarantees from the literature.

A. Spherical Field Measurements and Compressive Sensing

When measuring acoustic fields, it is often assumed that the transducers used are omnidirectional point receivers that can measure the field of interest directly at their position, see for example¹. However, when highorder transducers or arrays are used for measurement, there will be inherent directional dependence on the directivity of the field probe. To account for this property in spherical field measurements, one must include the directionality of the measurement device in the calculation of the field from measurements. The directionality of the field probe can be defined in terms of its sensitivity to SWs, called the receiving coefficients and denoted by R^{μ}_{ν} . The inclusion of this directionality is called probe correction and is discussed in detail in¹⁹.

In summary, probe correction for spherical field measurements is carried out as follows. First one considers the field of interest as a band-limited series of outgoing spherical waves (if a radiator is contained in the sphere of measurements) or standing waves (if no source is in the sphere of measurements). We denote this band limit as n_{max} . As a note, if a radiator is present, n_{max} is related to the physical size of the radiator. In the no radiator case, $n_{\rm max}$ relates to the frequency content in the field of interest¹. A coordinate transformation is then performed so that the probe-centered coordinate system, which lies on the surface of the sphere enclosing the radiator, properly relates measurements to the coordinate system centered on the radiator. This is done using a rotation and translation. The rotation can be specified as a set of Euler rotations parametrized by in the zyz' and passive transformation conventions. The resulting expression for the measured field is

$$w_j = w(\alpha_j, \beta_j, \gamma_j)$$

=
$$\sum_{n=0}^{n_{\max}} \sum_{m=-n}^{n} \sum_{\mu=-n}^{n} a_n^{m\mu} D_n^{\mu m}(\alpha_j, \beta_j, \gamma_j) + \eta_j,$$
(7)

where η_j are elements of the additive measurement noise η . Here j indexes measurement positions $(\alpha_j, \beta_j, \gamma_j)$ on the rotation group SO(3). These coordinates in SO(3) relate to a measurement point j with Euler rotation given by $r_z, r_y, r_{z'}$ as $(\alpha_j, \beta_j, \gamma_j) = (-r_{z'}, -r_y, -r_z)$ or equivalently $(\alpha_j, \beta_j, \gamma_j) = (\pi - r_{z'}, r_y, \pi - r_z)^{38}$. Additionally, $D_n^{\mu m}(\alpha, \beta, \gamma)$ is the Wigner *D*-function and its indices satisfy $n \in \{0, 1, \dots, n_{\max}\}$ and $m, \mu \in \{-n, -n + 1, \dots, n-1, n\}$. The total number of Wigner *D*-functions and thus coefficients $N_D = (n_{\max}+1)(2n_{\max}+1)(2n_{\max}+3)/3$.

$$D_n^{\mu m}\left(\alpha,\beta,\gamma\right) = e^{-i\mu\alpha} d_n^{\mu m}(\beta) e^{-im\gamma},\tag{8}$$

where $d_n^{\mu m}$ is the purely real Wigner *d*-function defined by

$$d_{n}^{\mu m}(\beta) = (-1)^{\mu - m} \\ \times \sqrt{(n+m)!(n-m)!(n+\mu)!(n-\mu)!} \\ \times \sum_{\sigma=\max(0,m-\mu)}^{\min(n+m,n-\mu)} \xi_{\sigma}, \\ \xi_{\sigma} = \frac{(-1)^{\sigma} \left(\cos\frac{\beta}{2}\right)^{2n-2\sigma+m-\mu} \left(\sin\frac{\beta}{2}\right)^{2\sigma-m+\mu}}{\sigma!(n+m-\sigma)!(n-\mu-\sigma)!(\mu-m+\sigma)!}.$$
(9)

The Wigner d-function's indices satisfy the same restrictions as those of the D-function. The spherical harmonics are a special case of the the Wigner D-functions, given by,

$$Y_{n}^{\mu}(\beta,\alpha) = (-1)^{m} \frac{\sqrt{2n+1}}{4\pi} D_{n}^{-\mu 0}(\alpha,\beta,\gamma)$$
(10)

$$Y_n^m(\beta,\gamma) = \frac{\sqrt{2n+1}}{4\pi} D_n^{0-m}(\alpha,\beta,\gamma).$$
(11)

In (7) the coefficients $a_n^{m\mu}$ contain the original SW coefficients, the translation transformation information, and the probe receiving coefficients. In particular, the $a_n^{m\mu}$ take a form like $a_n^{m\mu} = A_n^m \sum_{\nu} S_{n\nu}^{\mu\mu}(r_m) R_{\nu}^{\mu}$, where A_n^m are the SW coefficients, and $S_{n\nu}^{\mu\mu}$ is the translation operator for SWs with a translation distance of r_m . The explicit form of $S_{n\nu}^{\mu\mu}$ depends on whether the original field expansion is outgoing or standing waves⁴¹).

In cases where the field of interest is highly symmetric with respect to the radiation coordinate system, there will be few non-zero A_n^m and so the $a_n^{m\mu}$ will be sparse/compressible^{42,43}. More importantly, if the probe is small, i.e., $k_{\lambda}r_{\text{probe}}$ is small (where k_{λ} is the wavenumber of the field of interest and r_{probe} is the smallest sphere circumscribing the probe) or highly rotationally symmetric, the R_{ν}^{μ} will be approximately zero for $\mu \geq |1|$ and larger ν , so again the $a_n^{m\mu}$ will be sparse/compressible. Thus, since it is a relatively simple linear problem to separate the SW coefficients from the *D*-function coefficients, CS might be used to solve for the coefficients in (7), from which the SW coefficients can be determined. In cases where an omnidirectional receiver that directly measures the field of interest is used, (7) is equal to the field sampled at the position j. This can be interpreted as the translation factors multiplied by the Wigner D-functions all collapse down to be the SW/SH expansion for the field at the point j^{19} . Due to this collapsing of the series expansion, the A_n^m must inherently be sparse/compressible for CS to be a possible solution approach.

There are currently various approaches to apply CS to recover the coefficients $a_n^{m\mu}$ 21,22,33,35,37,39,40 or the special case of a SW/SH expansion^{31,35,44}. These are mainly focused on using Quadratically Constrained Basis Pursuit (QCPB) with particular measurement patterns. Examples of measurement patterns include random measurements on $SO(3)^{35}$ or the sphere⁴⁴, deterministic sampling patterns to minimize mutual coherence $^{33-35}$, as well as measurements on a sub-domain of SO(3) for welllocalized functions $w(\alpha, \beta, \gamma)$ by using Slepian functions on $SO(3)^{37}$. The only theoretical guarantees for CS recovery are in the cases of random measurements either from all of SO(3) or the sphere or an angle restricted subset subset of SO(3) or the sphere, e.g., a hemisphere. In the case of measurements from all of SO(3), the number number of measurements must satisfy

$$M \ge \tilde{C}' N_D^{1/6} s_D \ln^4(N_D),$$
 (12)

where s_D is the sparsity in the Wigner *D*-function basis. Here $\tilde{C}' \geq 0$ is constant. For the case of the sphere, i.e. SW/SH expansion, *M* has the same form of scaling but with N_D replaced with the number of band-limited SHs, $N_{SH} = (n_{\max} + 1)^2$, and s_D replaced with the sparsity in the SH basis, s_{SH} , i.e.,

$$M \ge \tilde{C}' N_{SH}^{1/6} s_{SH} \ln^4(N_{SH}),$$
 (13)

Though the CS guarantees mentioned above are useful in establishing theoretical viability and requirements for using CS to solve (7) for its coefficients, their requisite random sampling is problematic. This is because many measurement systems struggle to reach arbitrary points on SO(3) or the sphere, and furthermore, random points in SO(3) or the sphere can be too close together for some measurement setups and even time-consuming when compared to regular patterns. Thus, these CS results provide mixed gains. On one hand, they reduce the required number of measurements. On the other hand, they can give impossible measurement positions (when they are too close for arrays) or increase measurement times due to random positioning requirements. In contrast, coherence-based analyses like those in^{33–35} provide regular patterns for measurements that can be carried out rapidly but these give no theoretical guarantees. As we demonstrate in Section III, it is possible to maintain theoretical recovery guarantees while using more regular sampling patterns on SO(3) or the sphere.

B. Compressive Sensing Preliminaries

For our results that follow, we will need the following definitions and results from the CS literature.

Definition 1 (Best *s*-Sparse Approximation Error³² (p. 42, def. 2.2)). Given a vector $x \in \mathbb{C}^N$, the best *s*-sparse approximation error in the ℓ_p norm is

$$\sigma_s(x)_p = \min_{z \in \mathbb{C}^N : \|z\|_0 \le s} \|z - x\|_p.$$
(14)

Definition 2 (Restricted Isometry Property (RIP) ³⁵, ³² (p. 133, def. 6.1)). A matrix $\Phi \in \mathbb{C}^{M \times N}$ satisfies the restricted isometry property of order *s* with constant $\delta \in$ (0,1) if the following holds for all *s*-sparse vectors in $x \in \mathbb{C}^N$

$$(1-\delta)\|x\|_{2}^{2} \le \|\Phi x\|_{2}^{2} \le (1+\delta)\|x\|_{2}^{2}, \qquad (15)$$

where the smallest δ denoted by δ_s is called the restricted isometry constant.

Theorem 3 (RIP for Bounded Orthonormal Systems $(BOS)^{32}$ (p. 405, Thm. 12.31)). Consider a set of bounded orthonormal basis functions $\phi_i : \mathcal{D} \to \mathbb{C}, i \in \{1, 2, \dots, N\}$ that are orthonormal with respect to a probability measure ρ on the measurable space \mathcal{D} . Consider the matrix $\Phi \in \mathbb{C}^{M \times N}$ with entries

$$\phi_{ji} = \phi_i(t_j), \ j \in \{1, 2, \cdots, M\}, \ i \in \{1, 2, \cdots, N\}$$
(16)

constructed with i.i.d. samples of t_j from the measure ρ on \mathcal{D} . Suppose the orthonormal functions are bounded such that $\sup_{r \in \{1, \dots, N\}} \|\phi_r\|_{\infty} \leq K$. If

$$M \ge C_0 \delta^{-2} K^2 s \ln^4(N) \tag{17}$$

then with probability at least $1-N^{-\ln^3(N)}$, the restricted isometry constant δ_s of $\frac{1}{\sqrt{M}}\Phi$ satisfies $\delta_s \leq \delta$ for $\delta \in (0, 1)$. The constant $C_0 \geq 0$ is universal.

Corollary 4 (RIP For Unitary Matrices (BOS)³² (p. 405, Thm. 12.31 & p. 405, Cor. 12.38)). Let $U \in \mathbb{C}^{N \times N}$ be a unitary matrix with entries bounded from above by K/\sqrt{N} . Let $\Phi \in \mathbb{C}^{M \times N}$ be the sub-matrix of U acquired by selecting a subset of rows of size M from U uniformly at random among all subsets of size M. If

$$M \ge C_0 \delta^{-2} K^2 s \ln^4(N) \tag{18}$$

then with probability of at least $1 - N^{-\ln^3(N)}$, the restricted isometry constant δ_s of $\frac{1}{\sqrt{M}}\Phi$ satisfies $\delta_s \leq \delta$ for $\delta \in (0, 1)$. The constant $C_0 \geq 0$ is universal.

Theorem 5 (Sparse Recovery for RIP Matrices³² (p. 144, Thm. 6.12)). Suppose that the matrix $\Phi \in \mathbb{C}^{M \times N}$ has restricted isometry constant $\delta_{2s} < 4/\sqrt{41} \approx$ 0.6246. Suppose that the measurements are taken with Φ and are noisy, $y = \Phi x + \eta$, with $\|\eta\|_{\infty} \leq \epsilon$. If \hat{x} is solution to

$$\widehat{x} = \arg\min_{z \in \mathbb{C}^N} \|z\|_1 \text{ subject to } \|y - \Phi z\|_2 \le \sqrt{M}\epsilon \quad (19)$$

then

$$\|x - \hat{x}\|_2 \le C_1 \left(\frac{\sigma_s(x)_1}{\sqrt{s}} + \epsilon\right),\tag{20}$$

where $C_1 \geq 0$ only depends on δ_{2s} .

III. ON-GRID COMPRESSIVE SENSING FOR SPHERICAL FIELD MEASUREMENTS

A. Transformation to Fourier Basis

We now proceed with transforming the inverse problem in (7) to the three dimensional Fourier basis. First, we note that the Wigner *d*-function with integer *n* is periodic on $2\pi^{38}$ and can be expressed as a Fourier series. This Fourier series is band-limited and has the form¹⁷

$$d_{n}^{\mu m}(\beta) = i^{\mu - m} \sum_{m' = -n}^{n} \Delta_{n}^{m', \ \mu} \Delta_{n}^{m', m} e^{-im'\beta}, \qquad (21)$$

where

$$\Delta_n^{m',\mu} = d_n^{m'\mu} \left(\frac{\pi}{2}\right),\tag{22}$$

$$\Delta_n^{m',m} = d_n^{m'm} \left(\frac{\pi}{2}\right). \tag{23}$$

Substituting (8) and (21) into (7) gives

$$w_{j} = \sum_{n=0}^{n_{\max}} \sum_{m,\mu,m'=-n}^{n} \chi_{n}^{m\mu} e^{-im\gamma_{j} - i\mu\alpha_{j} - im'\beta_{j}} + \eta_{j} \quad (24)$$

$$\chi_n^{m\mu} = \mathbf{i}^{\mu-m} \Delta_n^{m',\mu} \Delta_n^{m',m} a_n^{m\mu} \tag{25}$$

We now reorder the sums so that the sum over n is on the inside, yielding

$$w_j = \sum_{m,\mu,m'=-n_{\max}}^{n_{\max}} \sum_{n=n_{\min}}^{n_{\max}} \chi_n^{m\mu} e^{-\mathrm{i}m\gamma_j - \mathrm{i}\mu\alpha_j - \mathrm{i}m'\beta_j} + \eta_j,$$
(26)

where $n_{\min} = \max(|m|, |\mu|, |m'|)$. In anticipation of benefits in terms of measurements (see Remark 9), we extend the ranges of the m', m, and μ sums to range from $n_{\max - 1}$ to n_{\max} , giving,

$$w_{j} = \sum_{m,\mu,m'=-n_{\max}-1}^{n_{\max}} \sum_{n=n_{\min}}^{n_{\max}} \chi_{n}^{m\mu} e^{-im\gamma_{j}-i\mu\alpha_{j}-im'\beta_{j}} + \eta_{j},$$
(27)

where we define $\Delta_n^{m',m}$ and $\Delta_n^{m',\mu}$ to be zero if m', m, or μ is $-n_{\max} - 1$. Next, define the sum over n in (27) as

$$b_{m'}^{m\mu} = \sum_{n=n_{\min}}^{n_{\max}} \chi_n^{m\mu}.$$
 (28)

Thus, we arrive at a restatement of our problem in two parts. First, we solve for the coefficients $b_{m'}^{m\mu}$ from the linear problem in (29) below. This amounts to finding the Fourier series coefficients of w, $b_{m'}^{m\mu}$, from a set of measurements. Then, we solve for the Wigner *D*-function coefficients $a_n^{m\mu}$ from the Fourier coefficients $b_{m'}^{m\mu}$ using the linear inverse problem in (30):

$$w_{j} = \sum_{m,\mu,m'=-n_{\max}-1}^{n_{\max}} b_{m'}^{m\mu} e^{-im\gamma_{j}-i\mu\alpha_{j}-im'\beta_{j}} + \eta_{j}, \quad (29)$$

$$\forall m, \mu \in \{-n_{\max} - 1, -n_{\max}, \cdots, n_{\max}\}$$
$$b_{m'}^{m\mu} = \sum_{n=n_{\min}}^{n_{\max}} \chi_n^{m\mu},$$
$$\chi_n^{m\mu} = \mathbf{i}^{\mu-m} \Delta_n^{m',\mu} \Delta_n^{m',m} a_n^{m\mu}.$$
(30)

These equations can be equivalently written as matrix equations

$$w = \Phi_F b + \eta, \tag{31}$$

$$\forall m, \mu \in \{-n_{\max} - 1, -n_{\max}, \cdots, n_{\max}\}, \qquad (32)$$
$$b^{m\mu} = B^{m\mu} a^{m\mu}.$$

where Φ_F is $M \times N_F$ with N_F being the number of bandlimited complex exponential functions $N_F = (2n_{\max} + 2)^3$. Here we have used

$$\left[\Phi_F\right]_{i,j} = e^{-\mathrm{i}m(j)\gamma_i} e^{-\mathrm{i}\mu(j)\alpha_i} e^{-\mathrm{i}m'(j)\alpha_i} \tag{33}$$

$$\widetilde{n}_{\min} = \max(|m|, |\mu|), \tag{34}$$

$$a^{m\mu} = [a^{m\mu}_{\widetilde{n}_{\min}}, a^{m\mu}_{\widetilde{n}_{\min}+1}, \cdots, a^{m\mu}_{n_{\max}}]^T,$$
(35)

$$b^{m\mu} = [b^{m\mu}_{-n_{\max}}, b^{m\mu}_{-n_{\max}+1}, \cdots, b^{m\mu}_{n_{\max}}]^T,$$
(36)

for some ordering m(j), $\mu(j)$, m'(j), with the vector *b* correspondingly arranged. The matrices $B^{m\mu} \in \mathbb{C}^{\dim_1 \times \dim_2}$ with $\dim_1 = 2n_{\max} + 2$ and $\dim_2 = n_{\max} + 1 - \tilde{n}_{\min}$ have elements

$$\begin{bmatrix} B^{m\mu} \end{bmatrix}_{i,j} = \begin{cases} \psi^{m\mu}, & |i - n_{\max} - 1| \le \widetilde{n}_{\min} - 1 + j \\ 0, & \text{otherwise} \end{cases},$$
$$\psi^{m\mu} = \mathbf{i}^{\mu - m} \Delta^{i - n_{\max} - 1, \mu}_{\widetilde{n}_{\min} - 1 + j} \Delta^{i - n_{\max} - 1, m}_{\widetilde{n}_{\min} - 1 + j}$$
(37)

where $i = 1, 2, \dots, 2n_{\max} + 2$ and $j = 1, 2, \dots, n_{\max} + 1 - \tilde{n}_{\min}$. The size of the matrix $B^{m\mu}$ can be seen from the fact that there are no $a_n^{m\mu}$ with $n < \tilde{n}_{\min}$. The restriction on the $B^{m\mu}$ values can be seen from the fact that $\Delta_n^{m',\mu} \Delta_n^{m',m} = 0$ when $|m'| \ge n$.

As written, compressive measurements for (31) would require random sampling on all of \mathbf{T}^3 . This is problematic for measurement devices due to the arbitrariness of the measurement positions. However, instead of using any possible measurement position $(\alpha_j, \beta_j, \gamma_j) \in$ \mathbf{T}^3 , we pick a set of possible measurements from a grid that samples \mathbf{T}^3 at the Nyquist rate. In particular, we select possible measurement points given by $(\alpha_j, \beta_k, \gamma_l) =$ $(2\pi j/(2n_{\max}+2), 2\pi k/(2n_{\max}+2), 2\pi l/(2n_{\max}+2))$ for $j, k, l \in \{-n_{\max} - 1, -n_{\max}, \cdots, n_{\max}\}$. We call this the Nyquist grid on \mathbf{T}^3 . Thanks to the double covering of SO(3) by \mathbf{T}^3 , the Nyquist Grid on \mathbf{T}^3 straightforwardly maps to a grid of measurement points on SO(3). Rewriting (29) with these selected measurement points gives

$$w_{jkl} = w(\alpha_j, \beta_k, \gamma_l)$$

= $\sum_{\mu,m,m'=-n_{\max}-1}^{n_{\max}} b_{m'}^{m\mu} e^{\frac{-i2\pi(\mu j + mk + m'l)}{2n_{\max}+2}} + \eta_{jkl}.$ (38)

This can be recognized as the 3DDFT of the coefficients $b_{m'}^{m\mu}$. Thus, if we assume that we measure on a subset of size M of the Nyquist grid, we have the matrix problem,

$$w = \sqrt{(2n_{\max}+2)^3} P_{\Omega} U_F b + \eta, \qquad (39)$$

$$w = P_{\Omega} U_F b' + \eta. \tag{40}$$

Here U_F is the matrix representing the 3DDFT for some ordering of the terms, $b' = \sqrt{(2n_{\max} + 2)^3}b$ is correspondingly arranged, and P_{Ω} is the matrix that selects a subset, Ω , of M of rows of U_F . It is well-known that U_F is unitary.

Now, with the inverse problem in (7) written as a linear inverse problem with a unitary measurement matrix, we state the compressive sensing guarantee for the problem the Fourier basis. The SW/SH version of this result is stated in Remark 10.

Theorem 6 (Sparse Recovery for Spherical Field Measurements Using a Sub-sampled 3DDFT). Consider the linear inverse problem specified in (40). Suppose that $\|\tilde{\eta}\|_{\infty} \leq \epsilon$ and that Ω is a subset of the rows of Φ_F of size M selected uniformly at random from all subsets of size M. If

$$M \ge C_2 s_F \ln^4(N_F),\tag{41}$$

then with probability $1 - (N_F)^{-\gamma \ln^3(s_F)}$, if \hat{b}' is the solution to

$$\hat{b}' = \arg\min_{z \in \mathbb{C}^{N_F}} \|z\|_1 \text{ subject to } \|\widetilde{w} - P_{\Omega}U_F z\|_2 \le \sqrt{M}\epsilon$$
(42)

then

$$\left\| b' - \widehat{b}' \right\|_2 \le C_1 \left(\frac{\sigma_{sF}(b')_1}{\sqrt{s_F}} + \epsilon \right). \tag{43}$$

Here $\gamma, C_1 \geq 0$ and C_1 only depends on the restricted isometry constant of $P_{\Omega}U_F$, δ_{2s_F} .

Proof: The proof follows from noting U_F has elements bounded by $1/\sqrt{N_F}$ and then using Corollary 4 and Theorem 5.

Remark 7. Changing our problem in (7) from the Wigner *D*-function basis to the Fourier basis results in a change in sparsity. This is because the $B^{m\mu}$ sums the $a_n^{m\mu}$ along *n*. Typically, a device's coefficients only use a few *m*, μ subspaces. If the number of such subspaces used is $n_{m\mu}$, then the worst-case sparsity of b', s_F , is $(2n_{\max}+2)n_{m\mu} = (N_F)^{1/3}n_{m\mu}$. So the required number of measurements is

$$M \ge C_2 N_F^{1/3} n_{m\mu} \ln^4(N_F).$$
(44)

Moreover, we know $n_{m\mu} \leq s_D$, where s_D is the sparsity in the Wigner *D*-function basis. Noting that we can relate N_F to N_D as $N_F \leq C'N_D$ (set C' = 6 for example), we can also use the condition

$$M \ge C_2 (C'N_D)^{1/3} s_D \ln^4 (C'N_D).$$
(45)

When comparing the scaling of M in the Fourier basis to the Wigner *D*-function basis (12), we have (ignoring log factors) $N_D^{1/3}$ and $N_D^{1/6}$, respectively. By going

to the Fourier basis we gain a factor of $N_D^{1/6}$, which is slightly worse. However, the method presented here does not require sampling from arbitrary points on SO(3); it sub-samples the Nyquist grid, which is much easier for measurement devices to achieve. As a further note, the structure of the $B^{m\mu}$ is such that this worst case increase in sparsity when transforming from the Wigner *D*function to Fourier basis is attained only when $a_n^{m\mu} \neq 0$ for $n = n_{\text{max}}$. This is typically not the case, as larger $a_n^{m\mu}$ tend to be at lower *n*, so we expect better scaling with s_D than what we see in (45).

Remark 8. For emphasis, we compare the result of Theorem 6 to the classical Nyquist sampling approach in EM, which uses a $\mu = \pm 1$ probe. In the classical approach, the number of measurements must scales with $N_D^{2/3}$. The result in (45) requires that M scales with $N_D^{1/3}$ times log factors. Ignoring the constants and log factors, this beats the classical $\mu = \pm 1$ Nyquist approach by a factor of $N_D^{1/3}$. Importantly, the sampling required here is to take a size M subset of the grid on \mathbf{T}^3 (and so SO(3)). This requires accessing a subset of the positions the classical approach uses on the sphere enclosing a device, unlike the results in³⁵, which requires arbitrary positions.

Remark 9. In the manipulations to derive (27), we extended the limits of the Fourier series indices to contain an even number of frequencies in m, μ , and m'. The purpose of this is so that the Nyquist sampling grid given by $(\alpha_j, \beta_k, \gamma_l) = (2\pi j/(2n_{\max} +$ 2), $2\pi k/(2n_{\max}+2)$, $2\pi l/(2n_{\max}+2)$) with $j,k,l \in$ $\{-n_{\max}-1, -n_{\max}, \cdots, n_{\max}\}$ results in each measurement on SO(3) corresponding to two or more measurements on \mathbf{T}^3 . This implies that satisfying the bound on M in Theorem 6 requires the number measurements on SO(3) to be at most M/2. Contrast this with an odd grid, which has no repeated points and thus the number of measurements needed on SO(3) is M. In more detail, the even grid results in the points on the poles $\beta = 0$ or $\beta = \pi$ being sampled, thus there is a degeneracy in the choice of non-polar angles α_i and γ_l at the poles. At $\beta = 0$ any points with with $\alpha_i + \gamma_l = \rho$ for fixed ρ represent the same physical measurement. The condition for $\beta = \pi$ is $\alpha_j + \pi - \gamma_l = \rho$ for a fixed ρ . This fact results in $2n_{\max} + 2$ repeated points in \mathbf{T}^3 when a pole is measured in SO(3). Any other non-polar points have two repeated measurements where $(\alpha_i, \beta_k, \gamma_k)$ is the same measurement as $(\alpha_i + \pi, -\beta_k, \gamma_k - \pi)$.

Remark 10. Consider (38) and take the special case where one has a set of SW/SH coefficients. Assuming that the field is measured ideally at a point amounts to setting all $b_{m'}^{m\mu}$ with $\mu \neq 0$ or $m \neq 0$ to zero. In this case, (ignoring the noise) the measurements $w(\alpha_j, \beta_j, \gamma_j)$ depend only on (β_k, γ_l) or (α_j, γ_k) , respectively. The result is that we can consider this special case as a two dimensional Fourier Series after appropriate normalization. Thus, using nearly the same analysis that results in Theorem 6, we arrive at being able to use QCBP to solve for the non-zero $b_{m'}^{m\mu}$ from a sub-sampled 2DDFT so long as

$$M \ge C_2 s_F \ln^4(N_{F,2D}),$$
 (46)

where $N_{F,2D} = (2n_{\max} + 2)^2$ is the number of basis functions in the band-limited 2DDFT. Carrying out the same analysis as the above remarks and noting the worst case s_F is $2n_{\max} + 2 = \sqrt{N_{F,2D}} \leq \sqrt{C''N_{SH}}$ (using say C'' = 2) times the number of $m(\mu)$ subspaces used, which is at most s_{SH} , we can also use

$$M \ge C_2 \sqrt{C'' N_{SH}} s_{SH} \ln^4(C'' N_{SH}).$$
 (47)

As with the full SO(3) case, using the Fourier basis Nyquist grid on the sphere for CS results in an increase in the number of measurements required when compared to the best case scaling for SW/SH series of $O(N_{SH}^{1/6})$. Again, however, the Fourier method does not require being able to sample the sphere at any arbitrary point like the method achieving $O(N_{SH}^{1/6})$ does.

IV. EXAMPLES AND NUMERICAL INVESTIGATIONS

A. Analysis of Basis Transformation

The transformation from the Wigner *D*-function to Fourier basis given by (32) will affect the sparsity of the coefficients. In (37) we can see that this mapping is likely to increase the sparsity, but only within already populated m, μ subspaces. This becomes even more apparent if we look at the structure of the entries of $B^{m\mu}$.

Investigating many examples of $B^{m\mu}$ for a different m, μ , and n_{\max} reveals a common structure these matrices share. This structure can be seen in Figure 1, which shows that this structure is triangle-like, with zero entries in the grey regions and non-zero entries in the region containing the arrows. This structure is manifest in (37). However, (37) does not give straightforward insight into how the non-zero elements behave. Our investigations show that the overall trend is given by the two curves in the bottom of Figure 1 paired with their corresponding direction in the depiction of the matrix. Pairing these diagrams we see that rows tend to decrease as we increase along the columns (see the horizontal line) but not to zero. We also see that elements along the lines parallel to the |m'| = n line also decay, but not to zero.

The triangle-like structure of the of $B^{m\mu}$ also implies that we can make statements about the sparsity s_F in the Fourier basis if we know properties of the $a_n^{m\mu}$ in each m, μ subspace. For example, if we know that the different m, μ subspaces have different cutoffs in n, which we can label $n_{\max}^{m\mu}$, then the sparsity in the Fourier basis satisfies the bound

$$s_F \le \sum_{m,\mu: a_n^{m\mu} \neq 0} (2n_{\max}^{m\mu} + 1).$$
 (48)

As a note, the different $n_{\max}^{m\mu}$ for each m, μ subspaces can be seen as smoothness criteria on the function $w(\alpha, \beta, \gamma)$ if you take the $n_{\max}^{m\mu}$ to be decreasing with increasing |m|and $|\mu|$.

FIG. 1. $B^{m\mu}$ Structure. Depiction of the non-zero entries of the transformation matrix from the Wigner *D*-function basis to the Fourier. The triangle-like structure helps visualize how sparsity can change between bases.

B. Analysis of Sparsity Change with Random Coefficients

To get more intuition behind how the Fourier sparsity s_F depends on the Wigner D-function sparsity s_D in general, we numerically test this dependence as the basis is changed with a band-limit of $n_{\rm max} = 15$ for ease of computation. In particular, we look at an analog of the case where an ideal probe is used. This choice of probe means that the Wigner D-function coefficients are only non-zero for $\mu = 0$. For our analogous setup, we pick a sparsity s_D and uniformly at random set s_D coefficients $a_n^{m0} = 1$, and then transform to the Fourier basis and calculate s_F . This is repeated for 100 trials with each value of s_D and averaged over all trials for a given s_D . The results are plotted in Figure 2. While this is not exactly accurate for typical spherical field measurements, since the $a_n^{m\mu}$ will not all be equal, Figure 2 shows how s_F can begin to saturate (the maximum possible s_F is 1024) and become problematic for CS with lower s_D when there is no structure to the coefficients.

C. Ideal and Non-Ideal Probe Measurements of Directed Speaker

In actual measurement systems, it is typical to use devices that are as ideal as possible. In many acoustic systems this means an ideal probe is used and the field is measured directly. Such probes are only sensitive to $\mu = 0$ SW modes in its coordinate system. In the EM case, using an ideal probe means that the probe is only sensitive to $\mu = \pm 1$ SWs. Moreover, among the

FIG. 2. Average s_F Versus s_D . The average Fourier sparsity s_F as a function of s_D where Wigner s_D D-function coefficients are set to unity over 100 trials.

fields that one characterizes using spherical field measurements, it is common to see fields with varying levels of symmetry. For example, the sound field radiated from a box speaker, transducer, or a spherical array of transducers may have varying levels of rotational symmetry along their main beam. If this main beam is aligned along the azimuthal axis of the measurement system, then the more symmetric the field is, the fewer number of $m \neq 0$ SW modes will be needed. With this idea in mind, we investigate the change in sparsity transforming from the Wigner D-function to the Fourier basis for the coefficients of an example speaker at three frequencies:

- 1. Case 1 (C1): 1098 Hz
- 2. Case 2 (C2): 1400 Hz
- 3. Case 3 (C3): 1895 Hz

These frequencies are selected so that they provide various levels of axial symmetry as determined by the fractional contribution the speaker's $m \neq 0$ SW modes make to the square of the ℓ_2 norm of the SW coefficients.

The specific speaker we consider is driver 1 of the IEM Loudspeaker Cube⁴⁵, for which directivity measurement data is openly available at 46 . SH coefficients for the speaker at various frequencies are calculated using the open-source code made available by Ahrens et. al. $at^{11,47}$ (which also contains the directivity measurement data for the IEM Loudspeaker Cube). This code fits the loudspeaker measurements to a SH series with band-limit $n_{\rm max} = 17$. For ease of simulation we truncate this data to $n_{\rm max} = 15$. From the SH coefficients, we calculate the SW coefficients a_n^m by dividing out the appropriate spherical Hankel function evaluated at the distance between the probe coordinate system and the speaker coordinate system, $r_{ab} = 0.75$ m. In the original data output from the code in ⁴⁷, the main beam of the speaker is along the negative y axis. To get the beam along the azimuthal (z)axis of the spherical measurements, we rotate the output coefficients using Wigner D-functions³⁸. As a note, we normalize the coefficients to have an ℓ_2 norm of 1, i.e., $\sum_{n,m} |a_n^m|^2 = 1$. The relative magnitudes of the SW

coefficients in dB,

Rel. Mag.
$$a_n^m = 20 \log_{10} \left(\frac{|a_n^m|}{\max_{n,m} |a_n^m|} \right),$$
 (49)

are presented in Figure 3. As can be seen in Figure 3, the contribution of the $m \neq 0$ modes to the ℓ_2 norm squared increases with frequency. In particular, **C1** has 0.45% of the signal's ℓ_2 norm squared is in the $m \neq 0$ modes, **C2** 1.05%, and **C3** has a contribution of 2.22%.

FIG. 3. Source Spherical Wave Coefficients. Spherical wave coefficients magnitudes for the IEM loudspeaker cube driver 1 at 1098 Hz (a), 1400 Hz (b), and 1895 Hz (c).

The Wigner *D*-function coefficients for the speaker, $a_n^{m\mu}$, are a product of the SW coefficients of the source, a_n^m , and the response constants, C_n^{μ} . That is, $a_n^{m\mu} = a_n^m C_n^{\mu}$. Since the response constants also have an effect on the sparsity and are a result of the probe, we will test the change in sparsity from the Wigner *D*-function basis to the Fourier basis with an axisymmetric probe, as well as non-axisymmetric probes. The baseline probe we select is the ideal probe. In the axisymmetric case for each frequency, the response constants are taken to be ideal for the 1098 Hz signal and are equal to $C_n^0 = \frac{\sqrt{2n+1}}{4\pi} h_n^{(1)}(kr_{ab})$ with the remainder being zero. Here $h_n^{(1)}$ is the Spherical Hankel function of the first kind, and k is the wavenumber of the 1098 Hz sound field. We use this same probe for all fields so we avoid introducing variations in the ℓ_2 norm of the Wigner *D*-function coefficients by changing the probe. For non-ideal probe measurements, we assume the non-ideal nature of the probe comes from the probe being more sensitive to highorder μ modes at two increased levels (specified below). This sensitivity is set to be randomly selected. Thus, C1-C3 will have three sub-cases where the response constants will be:

(a)
$$C_n^0 = \frac{\sqrt{2n+1}}{4\pi} h_n^{(1)}(kr_{ab}), C_n^m = 0$$
 otherwise.
(b) $C_n^0 = \frac{\sqrt{2n+1}}{4\pi} h_n^{(1)}(kr_{ab}), \quad \Re(C_n^{\pm 1}), \Im(C_n^{\pm 1}) \sim \mathcal{N}(0, 0.01 \max_n |C_n^0|), C_n^m = 0$ otherwise.

(c)
$$C_n^0 = \frac{\sqrt{2n+1}}{4\pi} h_n^{(1)}(kr_{ab}), \quad \Re(C_n^{\pm 1}), \Im(C_n^{\pm 1}) \sim \mathcal{N}(0, 0.01 \max_n |C_n^0|), \quad \Re(C_n^{\pm 2}), \Im(C_n^{\pm 2}) \sim \mathcal{N}(0, 0.001 \max_n |C_n^0|), \quad C_n^m = 0 \text{ otherwise.}$$

To see the changes in sparsity for all of the above cases, we compare the non-zero coefficients (to floating point precision) sorted largest to smallest in both the Wigner D-function basis as well as the Fourier basis, where each set is normalized with respect to the largest coefficient in the given basis. Explicitly, we plot the Coefficient Relative Magnitude in dB given by

Coefficient Relative Magnitude =
$$20 \log_{10} \left(\frac{|c_j|}{|c_1|} \right)$$
,
(50)

where the c_j , $j = 1, 2, \cdots$ are the coefficients in either the Wigner *D*-function basis or the Fourier basis. Along with the coefficients, it is also informative to investigate the effect of keeping only the n_c largest coefficients in a given basis. To that end, we also plot the coefficient error normalized by the actual coefficient ℓ_2 norm squared in dB,

Normalized Error
$$(c, n_c) = 10 \log_{10} \left(\frac{\|c_{n_c} - c\|^2}{\|c\|^2} \right),$$
 (51)

where c is a vector of coefficients and c_{n_c} is the vector of with all but the n_c largest coefficients set to zero. We plot the normalized error in the Wigner *D*-function basis, in the Fourier basis, and then the in the Wigner *D*-function basis after keeping n_c coefficients in the Fourier basis and transforming back to the Wigner *D*-function basis.

The sorted coefficients and normalized errors for cases **C1a-c** can be seen in Figures 4 to 6. For the sake of brevity in the main text, the corresponding plots for cases **C2a-c** and **C3a-c** are included as supplementary files⁴⁸. If we compare the number of non-zero coefficients for a fixed frequency but increasing probe asymmetry,

e.g., C1a-c in Figures 4 to 6, then we see the number of non-zero coefficients increases by a factor of ≈ 3 from case **a** to **b** and then a factor of ≈ 5 from **a** to **c**, regardless of basis. These scaling factors are in line with the scaling in the number of non-zero response constants C_n^m between the cases. Thus, ideally the asymmetry of any probe used is small so that the additional non-zero coefficients induced will be smaller than the SW coefficients one is trying to recover. This trend continues for C2a-c and C3a-c in the supplementary material⁴⁸. Comparing the number of non-zero coefficients as we increase sound frequency but keep the same response constants by using Figures 4 to 6 and the supplementary material⁴⁸, we observe that the number of non-zero coefficients in the Fourier basis is approximately three times that of the Wigner *D*-function basis for each case. These results are much better than the worst case, which would be an increase by a factor of $\approx 2n_{\rm max} + 1$ (since one coefficient per m, μ subspace in the Wigner *D*-function basis can map to $2n_{\max} + 1$ in the Fourier basis).

In terms of the normalized error, in Figures 4 to 6 and the supplementary material⁴⁸ we see that the errors drop below -30 dB well before all coefficients are being kept. The most important of which is the dotted curve (keeping n_c coefficients in the Fourier basis and transforming back to the Wigner *D*-function basis), since this is the most relevant number for the method we propose. This implies that the coefficients in the Fourier basis are compressible and CS recovery with smaller sparsities s_F should be reasonably accurate. In fact, in all cases we see a very rapid drop to near -15 dB or better in the first ≈ 20 coefficients, with slower gains in accuracy after that. Lastly, we note that in almost all cases of the Fourier and Fourier transformed back to Wigner D-function basis have a larger tail. This is as expected from the broadened tail we see when looking at the sorted coefficients in the Fourier bases.

D. Compressive Sensing Recovery

In this section, we demonstrate the recovery of the sound field emitted by the IEM Loudspeaker Cube driver 1 at 1098 Hz by solving the two-step problem in (31)and (32) using compressive sampling according to Theorem 6. For this demonstration, we simulate noiseless measurements of the sound field emitted the IEM Loudspeaker Cube driver 1 at 1098 Hz taken by an ideal probe. Using the ideal probe implies that the coefficients $a_n^{m\mu}$ are zero for all μ except $\mu = 0$. Furthermore, since these coefficients are zero and the DFT associated with the μ index is no longer needed, the 3DDFT from Theorem 6 is reduced to a 2DDFT as discussed in Remark 10. We can compare this reconstruction with classical Nyquistbased measurements and the algorithm from acoustics¹⁹. In this classical algorithm, the number of measurements is dictated by the Nyquist sampling theorem and, for the band-limit $n_{\rm max} = 15$, requires a minimum of 496 measurements for a perfect reconstruction with no measurement noise¹⁹. In this experiment we randomly select

FIG. 4. Sorted Coefficients and Normalized Error Case C1a. The coefficient relative magnitude, (a), in the Wigner D-function and Fourier bases rapidly decays initially, indicating compressibility in either basis. The normalized error, (b), drops below -30 dB before all coefficients are kept in each case, indicating CS recovery with smaller sparsities s_F should give accurate results.

400 measurements, which results in 301 unique physical measurements (due to random selections repeating points on SO(3), see Remark 9). Since measurements are noiseless, Basis Pursuit, not QCBP, is used. The reconstructed sound field along with the original and the SNR along the $\phi = 0$ axis are shown in Figure 7. The reconstructions are plotted in terms of magnitude relative to the maximum actual field in dB,

Relative Magnitude =
$$20 \log_{10} \left(\frac{\left| \widehat{F} \right|}{\max_{\alpha,\beta,\gamma} \left| F \right|} \right)$$
, (52)

and the SNR is given in dB as

$$SNR = 20 \log_{10} \left(\frac{|F|}{\left| F - \widehat{F} \right|} \right).$$
 (53)

As can be seen, the sub-sampled 2DDFT performs well with the SNR near 30 dB over most of the θ range. As a note, using CS with SHs and random measurements on

FIG. 5. Sorted Coefficients and Normalized Error for Case **C1b**. The coefficient relative magnitude, (a), and the normalized error, (b), show similar trends to those seen in Figure 4, so the same conclusions apply. Any scaling in the number of nonzero coefficients and error decay proportional to the increased asymmetry of the selected probe.

the sphere can nearly halve the number of measurements reduced and maintain similar accuracy, as expected when comparing Theorem 6 to³¹. However, the sub-sampled 2DDFT method has the advantage of being sampled from a sub-selection of the Nyquist grid on the sphere.

E. Compressive Sensing Recovery Versus Measurement Number

In this section, we investigate CS recovery using the method developed in this paper for cases C1a, C2a, and C3a as we vary the number of measurements used. For each case we compare the actual SW coefficients versus those recovered using CS and the two-step problem in (31) and (32). We look at the total relative error in the recovered partial wave coefficients given by,

Normalized Error =
$$\frac{\sum_{n,m}^{n_{\max}} |a_n^m - \widehat{a}_n^m|^2}{\sum_{n,m}^{n_{\max}} |a_n^m|^2}, \quad (54)$$

FIG. 6. Sorted Coefficients and Normalized Error for Case C1c. Again, the coefficient relative magnitude, (a), and the normalized error, (b), show trends similar to those seen in Figures 4 and 5. Thus, the same conclusions apply. Scaling in the number of nonzero coefficients and error decay is again proportional to the increased as symmetry of the selected probe.

where \widehat{a}_{n}^{m} , as well as the coefficient SNR given in dB as

SNR =
$$10 \log_{10} \left(\frac{\sum_{n,m}^{n_{\max}} |a_n^m|^2}{\sum_{n,m}^{n_{\max}} |a_n^m - \widehat{a}_n^m|^2} \right).$$
 (55)

Here, the \hat{a}_n^m are the recovered SW coefficients and a_n^m are the actual SW coefficients. Again, as the number of randomly selected measurements and the number of unique "physical measurements" (simulated measurements corresponding to unique positions on the sphere) will be different, we plot the Relative Error as a function of the average number of unique physical measurements over 25 trials while varying the number of randomly selected measurements in the Fourier domain. The results of this are in Figure 8, where each case requires approximately the same number of measurements to reach similar reconstruction accuracies. In particular, using 300 "physical measurements" each case attains a coefficient SNR of over 33 dB. Moreover, as the number of "physical measurements" approaches the fully sampled grid (496 measurements), the accuracy of the reconstruction becomes nearly perfect, as expected.

FIG. 7. *Near-field Reconstruction*. Example field reconstruction for case **C1a**, (a), and signal to reconstruction noise ratio, (b), using the sub-sampled 2DDFT.

It is also interesting to compare the performance of our proposed CS approach with that of a similarly sampled Wigner D-function-based approach. In particular, although there is no *a priori* reason to believe using a Wigner D-function measurement matrix sampled on the Nyquist grid should work, we can test to see if using the same samples as the proposed CS method gives reasonable results. To compare these we first reconstruct C1a by first randomly selecting measurements from the Nyquist grid on the sphere and carrying out our proposed Fourier approach. Then we reconstruct C1a by randomly selecting the same number of "physical measurements" from the Nyquist grid, but instead of using the DFT measurement matrix and transforming back to the Wigner D-function basis, we instead use a Wigner Dfunction measurement matrix with $\mu = 0$ functions only (i.e. re-scaled spherical harmonics) and the appropriate preconditioning from 35 . In the continuous case, the preconditioning is so that samples can be uniformly selected from the domain, so we heuristically view this approach as discrete samples from the appropriate uniform continuous case. The results of this can be seen over the range of possible measurements in Figure 9, where we average over 25 trials at each number of measurements. As

FIG. 8. Reconstruction Error and SNR Versus Measurement Number in Cases 1a, 2a, and 3a. For each number of measurment number, the normalized error, (a), and SNR, (b), is averaged over 25 trials. Increasing the sample number using the sub-sampled 2DDFT improves accuracy for cases C1a, C2a, and C3a. Using 300 "physical measurements" each case attains a coefficient SNR of over 33 dB.

can be seen in the figure, the Fourier-based CS approach outperforms the on-grid Wigner D-function approach for nearly all sampling numbers. This improved performance reiterates the method's benefits, among which is its theoretically guaranteed robustness that the gridded Wigner D-function approach does not share.

F. SW Coefficient Recovery in the Presence of Noise

The examples above all contained no measurement noise. In the presence of measurement noise, even classical Nyquist sampling approaches will have their performance degrade. However, in order to improve accuracy in the presence of noise, oversampling at a rate greater than the Nyquist rate is common. For example, we simulate measurements of the sound fields generated by **C1a**, **C2a**, and **C3a** with mean zero and variance that is -40 dB times the peak value for each case. Using these simulated mesurments then we plot the coefficient SNR, (53), resulting from the classical fully sampled Fourier method in¹⁹. The results are given in Figure 10. As can be seen

FIG. 9. Coefficient SNR for On-Grid Fourier CS versus On-Grid Wigner D-function CS. Averaging over 25 trials for each number of measurements, the proposed Fourier-based CS approach outperforms the on-grid Wigner D-function (which uses the same possible sampling positions), regardless of the number of measurements.

in Figure 10, increasing the sampling to five times the Nyquist rate results in increases in the SNR of nearly 15 dB for each case. Note the curves are split apart because the peak field value, and thus total noise, increases from C1a to C2a and again to C3a.

FIG. 10. Classical Fourier Reconstruction with Measurement Noise. SW coefficients from C1a, C2a, and C3a reconstructed according to¹⁹ with zero-mean Gaussian measurement noise whose variance is -40 dB times the maximum field value in each case. Sampling rates are increased from the Nyquist rate to over five times the Nyquist rate.

The approach in (31) and (32) and the statement of Theorem 6 do not explicitly allow for sampling grids that are denser than the Nyquist rate as they are written. However, a straight-forward generalization of Theorem 4 allows for a measurement matrix that is a selection of columns from a unitary matrix in a larger dimension. For example, one can choose a sampling grid that is a multiple of the Nyquist rate, select the columns of the Fourier matrix that correspond to the coefficients needed in the Nyquist rate version of (31) and (32), giving a tall matrix, and then consider the measurement matrix that is a random sub-selection of rows from this tall matrix. Going through such an analysis results in an identical scaling in the number of measurements as stated in Theorem 6 and the remarks following it. As a result, we can perform a CS version of (31) and (32) in the presence of measurement noise where measurements are selected from a grid that is some integer multiple denser than the Nyquist sampling grid. This allows us to directly compare our method with those results in Figure 10.

To that end, we first investigate the SNR from CS reconstructions of the SW coefficients in C1a, C2a, and C3a with the -40 dB Gaussian noise used in Figure 10 as a function of the number of "physical measurements" and the grid size. For each sampling number and grid density, we average the SNR over 25 trials in Figure 11. As can be seen in Figure 11, for a fixed number of measurements, the SNR slightly degrades as the grid density increases. One might assume the accuracy should be constant with the fixed number of measurements. However, using the noise-free case as heuristic, if we sample near the Nyquist rate then the recovery should be near perfect, but if the grid density increases, then measurements can clump in certain locations with larger gaps of the field unmeasured. Thus, at least near full sampling, the decrease in accuracy as the grid density increases becomes sensible. Further interpreting this result, if one fixes a number of measurements they would like to use, then increasing the grid density does not provide any gains. One should simply select the densest grid that allows for the desired number of measurements.

The intent of increasing the sampling rate in the classical Fourier approach to recover the SW coefficients in¹⁹ is to increase the method's robustness to noise. Figure 11 showed that increasing grid density and keeping the sample number the same does not improve performance when using CS to solve (31) and (32). However, if we consider fixed sampling densities (number of measurements used divided by the total possible number) as the density of the sampling grid is increased, we see improvements in our proposed CS approach. Figure 12 shows these results for C1a to C2a and again to C3a with the same noise as before. Similar to the classical Fourier case, for a fixed sample density and increased grid density, the SNR increases for each case tested. This can be interpreted as de-noising that occurs by promoting more sparse coefficients in QCBP. Interestingly, the de-noising from the proposed CS approach with a denser than Nyquist grid and sub-sampling gives better results than the de-noising attained from using oversampling with the method from¹⁹. This indicates, at least in this case, the de-noising benefits of CS via QCBP are an added benefit beyond simply decreasing the required number of measurements. Thus, if one is currently using Nyquist sampling at some denser grid than Nyquist, using the CS approach and fewer measurements may improve accuracy. For example, CS with a sample density of nearly 1/3 at two times the Nyquist rate beats the classical Fourier approach with sample density 1 at two times the Nyquist rate by nearly 20 dB or more in C1a, C2a, and C3a.

SW Coefficients SNR: Case C2a 0.4 80 Samples Density 0.3 $\begin{array}{c} 60 \\ \mathrm{GP} \\ \mathrm{40} \\ \mathrm{SNR} \end{array}$ 0.2 0.1 20 0 1.5 2 2.5 3 3.5 4 1 Grid Density (Fraction of Nyquist Rate) (b) SW Coefficients SNR: Case C3a0.4 80 Samples Density 0.3 $\begin{array}{c} 60 \\ \mathrm{GP} \\ \mathrm{40} \\ \mathrm{SNR} \end{array}$ 0.2 0.1 20 0 2.5 2 3 1.5 3.5 4 1 Grid Density (Fraction of Nyquist Rate)

FIG. 11. CS Coefficient SNR Versus Number of "Physical Measurements" in Cases C1a, C2a, and C3a. With added measurement noise, using the 2DDFT CS method for cases C1a, C2a, and C3a shows that using a fixed number of samples and increased grid density results in slightly degraded SNR.

FIG. 12. CS Coefficient SNR Versus Sample Grid Density in Cases C1a, C2a, and C3a. Fixing the sample density (measurement # divided by # of possible measurements) and increasing grid density for cases C1a, C2a, and C3a results in improved SNR. In other words, increasing the sampling rate and sample number improves the denoising achieved by the 2DDFT CS method and outperforms oversampling with the classical method in Figure 10.

SW Coefficients SNR: Case C1a

0.4

V. CONCLUSION

We have developed an approach to recover SW or SH expansion coefficients using compressive samples taken from a pre-defined grid. This approach not only provides a CS approach that avoids using measurements that are not at arbitrary positions on the sphere or SO(3), as is common for BOSs, but it does so while maintaining robust reconstruction guarantees. The number of measurements required for robust reconstruction, ignoring log factors, scales with the square root of the basis dimension multiplied by the sparsity in the SH special case and with the cubic root of the basis dimension multiplied by the sparsity when measurements are over the Wigner Dfunction basis. These scalings are slightly worse than the best cases from the literature 35,49 , however, these references methods require samples from arbitrary positions on the sphere and SO(3).

Using our proposed CS approach, we numerically compared its results with a commonly used Fourier approach to recover SW/ or SH expansion coefficients. In our tests, our on-grid CS approach performed comparably in the presence of noise when a Nyquist grid is used. However, when the grid sampling is increased to two times the Nyquist rate, our CS approach boasted increased de-noising capabilities while using fewer measurements. In the three examples we tested, the CS approach the SNR for the CS method beat the classical Fourier approach by 20 dB or better. Moreover, this was achieved while using a third of the measurements needed for the classical Fourier approach.

The CS approach developed in this paper allows for field reconstructions in various application areas like acoustic spherical holography, loudspeaker characterizations, and even EM antenna characterizations. In some of these cases, measurements are restricted to certain areas on the sphere or SO(3)³⁷. The work in ³⁷ can straightforwardly be generalized to the approach developed in this paper so that gridded and restricted measurements can be used for SQ or SH field reconstructions. However, the effect of compounding transformations (continuous Wigner *D*-function to discrete Fourier and then to a Slepian basis) on the conservation of sparsity throughout the bases requires further investigation and would be a suitable future direction of study.
