Abstract

The recent introduction of gradient-based MCMC for discrete spaces holds great promise, and comes with the tantalising possibility of new discrete counterparts to celebrated continuous methods such as MALA and HMC. Towards this goal, we introduce several discrete Metropolis-Hastings samplers that are conceptually-inspired by MALA, and demonstrate their strong empirical performance across a range of challenging sampling problems in Bayesian inference and energy-based modelling. Methodologically, we identify why discrete analogues to *preconditioned* MALA are generally intractable, motivating us to introduce a new kind of preconditioning based on auxiliary variables and the 'Gaussian integral trick'.

1 Introduction

Gradient-based Markov Chain Monte Carlo (MCMC) offers an efficient, robust way to sample from a wide-class of probability distributions. The gradient serves as a concise descriptor of local geometry, which can be exploited when designing MCMC transition operators. In continuous spaces, such operators are often based on the Langevin diffusion (Roberts & Tweedie, 1996; Roberts & Rosenthal, 1998) or Hamiltonian Monte Carlo (Duane et al., 1987; Neal et al., 2011), which can be unified under a single complete framework (Ma et al., 2015). Until recently, gradient-based operators were only viable for continuous distributions—after all, the standard gradient is undefined for discrete domains. However, Grathwohl et al. (2021) made the important observation that many probability mass functions are naturally thought of as the restriction of a continuous function (defined in e.g. \mathbb{R}^d) to a discrete subset (e.g. \mathbb{N}^d). Gradients in this ambient space can thus inform the design of a transition operator in the restricted

Figure 1: Metropolis-Hastings proposal distributions for an existing gradient-based sampler (left) and our proposed ones (centre & right). The blue contours delineate a continuous function that, when restricted to the discrete lattice, equals the target log-probability function (up to a constant). The dots represent the proposal distribution given the current state of the Markov chain (black X). The new samplers can update multiple dimensions at a time, which can lead to more efficient mixing of the Markov chains. In addition, the preconditioned sampler (right) accounts for the strong positive correlation between the two dimensions.

discrete space. They demonstrate this via a promising new method, Gibbs-with-Gradients (GWG), that can be seen as a gradient-based version of the 'locally informed proposals' introduced by Zanella (2020).

Whilst the use of gradient-information makes GWG appealing, the method has multiple unresolved limitations. It:

- (L.1) cannot update more than one dimension at a time.
- (L.2) uses a first-order Taylor expansion, which does not exploit second-order interactions in the target distribution.

In this paper, we will address these shortcomings via the introduction of several new discrete gradient-based samplers. Our strategy will be to first take a *continuous* gradient-based sampler that does not have these limitations, namely the celebrated (preconditioned) Metropolis-Adjusted Langevin Algorithm (MALA), and use this as the conceptual basis for defining discrete analogues. This is not a straightforward task: MALA is typically viewed through the lens of stochastic differential equations (SDEs), which are not easily translated into discrete state-spaces. Fortunately, we identify two non-SDE characterisations of MALA that are more readily imported into the discrete setting, resulting in the following methods:

- The Norm-Constrained Gradient (NCG) sampler is constructed by viewing MALA as a locally-informed proposal (Zanella, 2020) whose domain is restricted to a discrete space. NCG essentially replaces the Hamming-ball constraint in Gibbs-with-Gradients with a soft norm constraint, enabling multiple dimensions to be updated at a time, thereby addressing limitation L.1. Unfortunately, preconditioning this sampler in a manner analogous to preconditioned MALA does not appear possible, leaving limitation L.2 unresolved.
- The Auxiliary-Variable gradient (AVG) sampler is constructed by viewing MALA as a marginalised auxiliary sampler (Titsias & Papaspiliopoulos, 2018) whose domain is restricted to a discrete space. The resulting sampler is conceptually and algebraically similar to NCG, but incurs extra computations that make it less appealing. However, AVG has the major advantage that it can be extended to include a kind of preconditioning, thereby addressing limitation L.2. Intriguingly, this Preconditioned AVG (PAVG) generalises an existing auxiliary-variable scheme (Martens & Sutskever, 2010) that is only applicable to pairwise Markov Random fields (a.k.a. Boltzmann machines).

We believe the value of these new methods is two-fold: 1) Empirically, they show superior sampling efficiency compared to several important baselines across a range of problems. In particular, they outperform Gibbs-with-Gradients, validating our hypothesis that L.1 and L.2 are indeed limitations that should be addressed. 2) Methodologically, they demonstrate how new discrete gradient-based samplers can be derived via the frameworks of Zanella (2020) and Titsias & Papaspiliopoulos (2018). To our knowledge, we are the first paper to use the latter framework for discrete problems, and our derivation of PAVG shows that auxiliary variables open up fundamentally new possibilities for constructing gradient-based samplers.

2 Background

Our aim is to sample from distributions $p(\mathbf{s})$ defined over a discrete domain $\mathcal{S}^d \subset \mathbb{R}^d$,

$$\log p(\mathbf{s}) = f(\mathbf{s}) - \log Z, \qquad Z = \sum_{\mathbf{s} \in \mathcal{S}^d} \exp(f(\mathbf{s}))$$
 (1)

where Z is presumed unknown. For ease of exposition, we consider two important cases: binary vectors for which $S = \{0,1\}$ and finite ordinal data for which $S = \{s^1, \ldots, s^k\}$ is an ordered set of increasing real numbers. We show in Appendix A that our methods are also easily applicable to unordered categorical data represented as one-hot vectors. We assume f is the restriction of a differentiable function defined over \mathbb{R}^d , and use ∇f to refer to its gradient. This assumption was first introduced by Grathwohl et al. (2021) and it holds for many important distributions such as restricted Boltzmann machines, Ising models and deep energy-based models.

2.1 Metropolis-Hastings

A common approach to sampling such distributions is to use Metropolis-Hastings (MH) Metropolis et al. (1953); Hastings (1970), which evolves a chain of samples by iteratively sampling a proposal $\mathbf{s}_{t+1} \sim q(\mathbf{s}_{t+1}|\mathbf{s}_t)$ and accepting with probability

$$\min\left\{1, \frac{\exp(f(\mathbf{s}_{t+1}))}{\exp(f(\mathbf{s}_t))} \frac{q(\mathbf{s}_t \mid \mathbf{s}_{t+1})}{q(\mathbf{s}_{t+1} \mid \mathbf{s}_t)}\right\}. \tag{2}$$

The key challenge here is the choice of proposal. Roughly speaking, there are four desiderata (Robert et al., 1999) i) tractable to sample ii) tractable to evaluate iii) has reasonable acceptance rates and iv) the resulting chains have weak dependencies between successive states. Satisfying all four criteria is difficult, especially in high dimensions. Most 'obvious' approaches fail to meet at least one criterion; for instance a uniform distribution over neighbouring states of s_t can satisfy the first three criteria, but fail dramatically on the last.

2.2 MALA and its preconditioned variant

Metropolis-Adjusted Langevin Algorithm (MALA) (Roberts & Tweedie, 1996; Dwivedi et al., 2018) is an effective continuous-space MH sampler that uses gradient-based proposals of the form

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_{t}) = \mathcal{N}(\mathbf{s}; \mathbf{s}_{t} + \frac{\epsilon}{2} \nabla f(\mathbf{s}_{t}), \epsilon \mathbf{I}). \tag{3}$$

where ϵ is a tunable step-size. If we were to skip the MH accept/reject step, then iteratively sampling this proposal corresponds to a discrete-time simulation of an SDE whose stationary distribution is the target $p(\mathbf{s})$. Such time-discretisations induce errors which the MH step corrects for.

Many target distributions exhibit strong second-order interactions between dimensions. A natural way to handle this is via a suitable linear change of coordinates; a technique known as *preconditioning*. Preconditioned MALA has proposals of the form

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_{t}) = \mathcal{N}(\mathbf{s}; \mathbf{s}_{t} + \frac{\epsilon}{2} \Sigma \nabla f(\mathbf{s}_{t}), \epsilon \Sigma), \tag{4}$$

where Σ is a user-specified symmetric semi-positive-definite matrix. This proposal also corresponds to a discretised SDE whose stationary distribution is $p(\mathbf{s})$.

2.3 Locally-informed proposals

Zanella (2020) proposed a different framework for incorporating local geometry into an MH proposal, with the advantage of being applicable to discrete spaces. They define *pointwise-informed proposals* of the form

$$q(\mathbf{s}_{t+1} \mid \mathbf{s}_t) = \frac{g(\exp(f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t)))K_{\sigma}(\mathbf{s}_{t+1} \mid \mathbf{s}_t)}{Z_q(\mathbf{s}_t)}$$
(5)

where g is a non-negative 'balancing' function, K_{σ} is a symmetric kernel whose 'width' is controlled by σ (e.g. a uniform distribution over a local ball of radius σ) and $Z_g(\mathbf{s}_t)$ is a normalising constant.

The intuition here is that we take an 'uninformed' kernel and re-weight it according to the target distribution, biasing our proposal in favour of higher density regions. Zanella (2020) identify a class of balancing functions g that are optimal when the kernel is sufficiently local (i.e. σ is small); an important member of that class is the square-root function $g(x) = \sqrt{x}$.

2.4 Gibbs-with-Gradients

A major challenge when using locally-informed schemes in discrete spaces is the cost of normalising and sampling the proposal distribution. Even for the most simple choice of kernel—a uniform distribution over a Hamming ball of radius 1—the cost is $\mathcal{O}(d)$ evaluations of f for a d-dimensional problem. To reduce this cost, Grathwohl et al. (2021) use the innovative trick of treating f as a continuous function and approximating it with a first-order Taylor expansion about the current state \mathbf{s}_t , giving the 'first-order local proposal'

$$q(\mathbf{s} \mid \mathbf{s}_t) = \frac{\exp\left(\frac{1}{2}\nabla f(\mathbf{s}_t)^T(\mathbf{s} - \mathbf{s}_t)\right)\mathbb{I}(\mathbf{s} \in H_1(\mathbf{s}_t))}{\sum_{\mathbf{s} \in H_1(\mathbf{s}_t)} \exp\left(\frac{1}{2}\nabla f(\mathbf{s}_t)^T(\mathbf{s} - \mathbf{s}_t)\right)}$$
(6)

where $H_1(\mathbf{s}_t)$ is a Hamming ball of radius 1 around \mathbf{s}_t . The normalising constant of this distribution is cheap to compute: a single gradient computation and a sum over d inexpensive terms.

Unfortunately, there are two significant limitations with this proposal: i) updating *one* dimension at a time can be slow, and a straightforward approach to 'broaden' this proposal by using a larger radius is prohibitively expensive due to the rapidly increasing size of the Hamming ball ii) linear approximations of the target distribution combined with symmetric kernels cannot account for second-order interactions between dimensions.

3 Discrete analogues to MALA

Our goal in this section is to design new discrete gradient-based MCMC schemes that overcome the aforementioned limitations. We achieve this by 'importing' two different characterisations of the Metropolis-adjusted Langevin Algorithm (MALA) into a discrete setting.

3.1 Norm-constrained gradient sampler: NCG

As discussed, the use of Hamming balls in Gibbs-with-Gradients makes it challenging to update more than one dimension at a time. Instead, we propose to use a soft norm 'constraint', transforming equation 6 into

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_t) \propto \exp\left(\frac{1}{2}\nabla f(\mathbf{s}_t)^T(\mathbf{s} - \mathbf{s}_t)\right) \exp\left(-\frac{1}{2\epsilon} \|\mathbf{s} - \mathbf{s}_t\|_2^2\right).$$
 (7)

Such a first-order informed proposal was already discussed by Zanella (2020) in the context of *continuous spaces*, where, after normalising, it corresponds exactly to the proposal distribution used by Metropolis-adjusted Langevin Algorithm (MALA) in equation 3.

If we instead restrict s to a discrete state-space $\mathcal{S}^d \subset \mathbb{R}^d$, we obtain the fully factorised distribution¹

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_{t}) = \prod_{i=1}^{d} \sigma\left(\left[\frac{1}{2}\nabla f(\mathbf{s}_{t})_{i} + \frac{1}{\epsilon}\mathbf{s}_{t,i}\right]\mathbf{s}_{i} - \frac{1}{2\epsilon}\mathbf{s}_{i}^{2}\right), \qquad \sigma(\mathbf{x}) := \frac{\exp(\mathbf{x})}{\sum_{\mathcal{S}} \exp(\mathbf{x})}$$
(8)

Due its factorised structure, this proposal is efficient to evaluate and sample, making it straightforward to use in a Metropolis-Hastings scheme; see Algorithm B.1 2 . Like MALA, it has a step-size parameter ϵ that controls the 'width' of the distribution and larger step-sizes enable proposals \mathbf{s}_{t+1} that differ from \mathbf{s}_t in multiple dimensions. We note that NCG should be viewed as an alternative to (and not a generalisation of) GWG, since there is no setting of the step-size ϵ that recovers GWG.

3.1.1 The problem of preconditioning

A natural way to precondition NCG would be to cast PMALA (equation 4) as a first-order informed proposal and then restrict the domain to a discrete subspace. Unfortunately, we find that this approach is not viable. To see why, we first note that by replacing the Euclidean-norm $\|\mathbf{s} - \mathbf{s}_t\|^2$ in equation 7 with a Mahalanobis-norm $(\mathbf{s} - \mathbf{s}_t)^T \Sigma^{-1} (\mathbf{s} - \mathbf{s}_t)$, we obtain a proposal distribution that, for continuous $\mathbf{s} \in \mathbb{R}^d$, corresponds exactly to PMALA. However, when we restrict \mathbf{s} to a discrete domain, this distribution becomes a pairwise Markov random field that, in general, is intractable to normalise and sample from, making it unusable as an MH proposal.

One could avoid this intractability by choosing a highly restricted, sparse form for Σ^{-1} (e.g. diagonal); we leave this direction to future work, and instead focus on the more general problem of constructing a gradient-based sampler that can work with arbitrary Σ . To solve this challenge, we depart from the locally-informed framework of Zanella (2020) and introduce an alternative MH-framework that operates in an extended state-space. This framework also contains a discrete analogue to MALA that resembles NCG, with the key distinction that it admits a kind of tractable preconditioning.

¹The definition of $\sigma(x)$ abuses notation by assuming x is a function of $s \in S$, and that we sum over all values of s in the denominator.

²The NCG method was independently discovered by (Zhang et al., 2022), see related work discussion in Section 4

3.2 (Preconditioned) Auxiliary Variable Gradient sampler: AVG and PAVG

As explained by Titsias & Papaspiliopoulos (2018), MALA can be derived as an auxiliary variable scheme. To see this, we first augment our continuous state $\mathbf{s} \in \mathbb{R}^d$ with Gaussian auxiliary variables $\mathbf{z} \in \mathbb{R}^d$, such that our unnormalised target density becomes $\pi(\mathbf{s}, \mathbf{z}) = \exp(f(\mathbf{s})) \mathcal{N}(\mathbf{z}; \mathbf{s}/\sqrt{\epsilon/2}, \mathbf{I})$. In theory, this distribution could be sampled in a block-Gibbs fashion, by first sampling $\mathbf{z}_t \sim \mathcal{N}(\mathbf{z}; \mathbf{s}_t/\sqrt{\epsilon/2}, \mathbf{I})$, and then sampling $\mathbf{s}_{t+1} \sim \pi(\mathbf{s} \mid \mathbf{z}_t) \propto \pi(\mathbf{s}, \mathbf{z}_t)$. However, for general functions f this second sampling step is intractable, so we replace it with an MH accept-reject step using the proposal distribution:

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_t, \mathbf{s}_t) \propto \exp(f(\mathbf{s}_t) + \nabla f(\mathbf{s}_t)^T (\mathbf{s} - \mathbf{s}_t)) \mathcal{N}(\mathbf{z}_t; \mathbf{s} / \sqrt{\epsilon/2}, \mathbf{I})$$
 (9)

$$= \mathcal{N}(\mathbf{s}; \sqrt{\epsilon/2}\mathbf{z}_t + (\epsilon/2)\nabla f(\mathbf{s}_t), (\epsilon/2)\mathbf{I}), \tag{10}$$

where equation 9 approximates $\pi(\mathbf{s}, \mathbf{z}_t)$ via a Taylor expansion. Equipped with this proposal, we can now perform block-wise MH sampling in the extended state space. However, we could also chose to marginalise out the latent variables, and doing so yields the MALA proposal

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_{t}) = \int N(\mathbf{z}; \mathbf{s}_{t} / \sqrt{\epsilon/2}, \mathbf{I}) q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_{t}, \mathbf{s}_{t}) d\mathbf{z} = \mathcal{N}(\mathbf{s}; \mathbf{s}_{t} + (\epsilon/2) \nabla f(\mathbf{s}_{t}), \epsilon \mathbf{I}). \tag{11}$$

The auxiliary variable procedure just described is equally applicable to discrete state-spaces, using the discrete Taylor approximation 'trick' of Grathwohl et al. (2021). If we take \mathbf{s} to belong to a discrete state-space $\mathcal{S}^d \subset \mathbb{R}^d$ (but continue to use Gaussian auxiliary variables), then the proposal $q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_t, \mathbf{s}_t)$ in equation 9 can be written as a fully-factorised distribution $\prod_{i=1}^d q_{\epsilon,i}(\mathbf{s}_i \mid \mathbf{z}_{t,i}, \mathbf{s}_t)$ where each factor has the form

$$q_{\epsilon,i}(\mathbf{s}_i \mid \mathbf{z}_{t,i}, \mathbf{s}_t) = \sigma\left(\left[\nabla f(\mathbf{s}_t)_i + \sqrt{\frac{2}{\epsilon}} \mathbf{z}_{t,i}\right] \mathbf{s}_i - \frac{1}{\epsilon} \mathbf{s}_i^2\right), \qquad \sigma(\mathbf{x}) = \frac{\exp(\mathbf{x})}{\sum_{\mathcal{S}} \exp(\mathbf{x})}.$$
(12)

We can easily evaluate and sample this proposal distribution, enabling us to perform block-wise MH sampling as summarised in Algorithm B.2. We refer to this method as the Auxiliary Variable Gradient (AVG) sampler.

Instead of using block-wise MH, one might try to marginalise out \mathbf{z}_t , giving $q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_t) = \prod_{i=1}^{d} \mathbb{E}_{\mathbf{z}_{t,i}} \left[q_{\epsilon,i}(\mathbf{s}_i \mid \mathbf{z}_{t,i}, \mathbf{s}_t) \right]$. However, we do not use such a marginalised proposal in this paper, since the required expectations have no closed-form solution, necessitating careful numerical approximations. More fundamentally, we focus on the block-wise scheme as it admits an effective kind of preconditioning.

3.2.1 The promise of preconditioning

A straightforward attempt to discretise PMALA via auxiliary-variables runs into difficulties. To obtain the PMALA proposal in equation 4, we need to replace the conditional Gaussian in equation 9 by $\mathcal{N}(\mathbf{z}_t; (\epsilon/2\Sigma)^{-1/2}\mathbf{s}, \mathbf{I})$. Unfortunately, the corresponding discrete proposal distribution is an intractable pairwise Markov random field—see Appendix C, for details.

However, we now show that a different kind of 'preconditioning' is viable. We start by making a second-order approximation of the target

$$f(\mathbf{s}) \approx f(\mathbf{s}_t) + \nabla f(\mathbf{s}_t)^T (\mathbf{s} - \mathbf{s}_t) + (1/2)(\mathbf{s} - \mathbf{s}_t)^T \Sigma (\mathbf{s} - \mathbf{s}_t), \tag{13}$$

where the second-order term uses a global (independent of t) matrix Σ . The nature of this approximation, and how to choose Σ , will be discussed in the next section.

We then define an unnormalised joint distribution $\pi(\mathbf{s}, \mathbf{z}) = \exp(f(\mathbf{s})) \mathcal{N}(\mathbf{z}; \Sigma_{\epsilon}^{1/2} \mathbf{s}_t, \mathbf{I})$, where $\Sigma_{\epsilon} := \Sigma + (2/\epsilon)\mathbf{I}$. Just like in our derivation of AVG, block-Gibbs sampling of \mathbf{z} and \mathbf{s} is prevented by the intractable $\pi(\mathbf{s} \mid \mathbf{z}_t) \propto \pi(\mathbf{s}, \mathbf{z}_t)$. So we use an MH step, approximating $\pi(\mathbf{s}, \mathbf{z}_t)$ to obtain the proposal

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_{t}, \mathbf{s}_{t}) \propto \exp(f(\mathbf{s}_{t}) + \nabla f(\mathbf{s}_{t})^{T}(\mathbf{s} - \mathbf{s}_{t}) + (1/2)(\mathbf{s} - \mathbf{s}_{t})^{T} \Sigma(\mathbf{s} - \mathbf{s}_{t})) \mathcal{N}(\mathbf{z}; \Sigma_{\epsilon}^{1/2} \mathbf{s}, \mathbf{I})$$
(14)

$$\propto \exp\left(\left[\nabla f(\mathbf{s}_t) - \Sigma \mathbf{s}_t + \Sigma_{\epsilon}^{1/2} \mathbf{z}_t\right]^T \mathbf{s} - (1/\epsilon) \mathbf{s}^T \mathbf{s}\right). \tag{15}$$

$$= \prod_{i=1}^{d} \sigma \left(\left[\nabla f(\mathbf{s}_{t})_{i} - (\Sigma \mathbf{s}_{t})_{i} + (\Sigma_{\epsilon}^{1/2} \mathbf{z}_{t})_{i} \right] \mathbf{s}_{i} - \frac{1}{\epsilon} \mathbf{s}_{i}^{2} \right), \quad \text{where} \quad \sigma(\mathbf{x}) = \frac{\exp(\mathbf{x})}{\sum_{\mathcal{S}} \exp(\mathbf{x})}, \quad (16)$$

which is fully-factorised and thus tractable to evaluate and sample. The resulting block-wise MH sampling scheme is called Preconditioned AVG (PAVG) and is summarised in Algorithm B.3. By comparing equation 12 and equation 16, we see that setting $\Sigma = 0$ recovers AVG.

The key step in obtaining a factorised proposal occurs when going from equation 14 to equation 15, since the quadratic terms in \mathbf{s} cancel out. Using Gaussian auxiliary variables to induce such cancellations actually has a long history in statistical physics where it is known as the Hubbard-Stratonovich transform (Hubbard, 1959) or the "Gaussian integral trick" (Hertz et al., 1991). The trick has also been used in the Machine learning literature; first by Martens & Sutskever (2010) and then extended by Zhang et al. (2012). In both these prior works however, the target function was exactly quadratic i.e. $f(\mathbf{s}) = \mathbf{b}^T \mathbf{s} + \mathbf{s}^T \Sigma \mathbf{s}$, in which case the proposal distribution above is 'exact' and an MH accept/reject step is unnecessary. Thus, our proposed approach, which we refer to as PAVG, can be seen as an extension of Martens & Sutskever (2010) to more general target distributions.³

3.2.2 Choice of matrix Σ

The above derivation assumed a kind of quadratic approximation of $f(\mathbf{s})$ in equation 13. We may hope that such an approximation is reasonable whenever there are global second-order interactions in the target distribution. We propose to capture such interactions by building on ideas from adaptive continuous-space MCMC (Rosenthal et al., 2011), where one can, for instance, estimate an empirical covariance/precision matrix Σ_{emp} from a 'dataset' of samples \mathcal{D} obtained during an initial burn-in period. Given this matrix, we then use a common procedure (e.g. see Algorithm 4 of Andrieu & Thoms (2008)) of re-scaling it by an adaptively learned parameter γ . We give full details of our adaptive procedure in Appendix D. A benefit of this re-scaling is that we can automatically 'fallback' to AVG by learning $\gamma = 0$. However, in practice, we often find that values of γ far from 0 or 1 are learned.

4 Related Work

Most closely related to our work is the concurrent paper of Zhang et al. (2022), who introduce a discrete 'langevin-like' sampler called DMALA that coincides with NCG. Beyond this shared method, our two works diverge in multiple ways. Zhang et al. (2022) explore variants of DMALA that drop the Metropolis accept-reject step, or use *diagonal* preconditioning; a possibility we briefly discussed in Section 3.1.1. In contrast, our work is the first to identify the intractability of general preconditioning matrices within the DMALA/NCG framework, which motivated our novel MALA-inspired auxiliary variable schemes.

A range of prior works have 'mapped' discrete spaces into continuous ones, thereby enabling MALA/HMC in the continuous space. These methods are generally specialised to particular forms of target distribution (Zhang et al., 2012), or to certain data types e.g. binary data (Pakman & Paninski, 2013) or trees (Dinh et al., 2017). More problematically, the embedded distributions are typically piece-wise continuous (Nishimura et al., 2017) and highly multi-modal, which may explain their limited empirical success (Zanella, 2020; Grathwohl et al., 2021).

5 Experiments

We evaluate the newly proposed methods—NCG, AVG & PAVG— on four problem types: 1) sampling from highly correlated ordinal mixture distributions 2) a sparse Bayesian variable selection problem 3) estimation of Ising models and 4) sampling a deep energy-based model parameterised by a convolutional neural network.

Our key baselines are Gibbs-with-Gradients (GWG) and a standard Gibbs sampler (Geman & Geman, 1984). For our ordinal experiments, we also compare to a Metropolis-Hastings sampler with uniform proposal over a local ball of radius r and a simple effective extension of GWG that we introduce: 'ordinal-GWG'. In Appendix E, we provide details on these baselines, including how we tune step-size parameters to maximise $\|\mathbf{s}_{t+1} - \mathbf{s}_t\|_1$ between successive states of the MCMC chains, similar to e.g. (Levy et al., 2018).

 $^{^3}$ Important caveat: Martens & Sutskever (2010) allow Σ to have negative eigenvalues. We can also allow this, with small modifications to our proposal distributions as described in Appendix D

Figure 2: 20D mixture-of-polynomial results. Top row: results for 2nd order polynomial in equation 18. Bottom row: results for 4th order polynomial in equation 19. Left column: KL divergence between true and estimated marginals, averaged over all dimensions. Middle: Estimation error of the empirical covariance matrix. Right: Effective sample size per second; higher is better. All error bars computed across 100 parallel chains.

20D ordinal mixture-of-polynomials 5.1

We define highly-correlated ordinal target distributions $\log p(\mathbf{s}) = \exp(f(\mathbf{s})) - \log Z$ over 20dimensional lattices $\mathcal{S}^{20} \subset \mathbb{R}^{20}$, where \mathcal{S} contains 50 equally spaced points in the interval [-1.5, 3.0]. We construct these target distributions from mixtures of fully-factorised distributions, enabling exact sampling and evaluation of the normaliser Z. f has the form

$$f(\mathbf{s}) = \log\left(\sum_{k=1}^{50} \exp\left(\sum_{i=1}^{20} g_k(\mathbf{s}_i)\right)\right)$$
(17)

where k indexes a component of the mixture distribution, and $g_k: \mathcal{S} \to \mathbb{R}$ is a polynomial that we allow to take one of two forms:

(2nd order)
$$g_k(\mathbf{u}) = 1.5 - 2\mathbf{t}_k - 6\mathbf{t}_k^2,$$
 $\mathbf{t}_k := \mathbf{u} + k/25$ (18)
(4th order) $g_k(\mathbf{u}) = -\mathbf{t}_k + \mathbf{t}_k^2 - \mathbf{t}_k^3 - \mathbf{t}_k^4,$ $\mathbf{t}_k := (2\mathbf{u} - 1 + 3k/50).$ (19)

(4th order)
$$g_k(\mathbf{u}) = -\mathbf{t}_k + \mathbf{t}_k^2 - \mathbf{t}_k^3 - \mathbf{t}_k^4, \quad \mathbf{t}_k := (2\mathbf{u} - 1 + 3k/50).$$
 (19)

We visualise 2D versions of the resulting target distributions in Figure 3. The two dimensions are highly correlated with probability mass concentrating along the main diagonal. Similarly, in 20 dimensions, mass concentrates along the diagonal of a hypercube, meaning all dimensions are positively correlated.

Figure 3: 2D ordinal illustrations. tion 18 & equation 19 correspond to top & bottom, respectively.

We track the similarity between the empirical distribution of MCMC samples $q(\mathbf{s})$ and the target distribution $p(\mathbf{s})$ using the following two metrics i) marginal estimation error: the average KL-divergence between marginals $(1/d)\sum_{i=1}^{d} D_{KL}(q_i \parallel p_i)$ and ii) covariance estimation error: the difference, in Frobenius norm, between the empirical covariance matrices estimated under both distributions. We also track the Effective Sample Size (ESS) of each sampler. Full details of these evaluation metrics in Appendix F.

Figure 4: 100D Sparse Bayesian linear regression results. The proposed samplers (NCG, AVG & PAVG) converge faster as measured by bivariate marginals (middle) and are competitive or better as measured by univariate marginals (left) and Effective Sample Size (ESS) (right).

5.1.1 Results

Figure 2 shows the results, with the top & bottom rows corresponding to the 2^{nd} & 4^{th} order polynomials, respectively. In the 2^{nd} order case, the evaluation metrics imply the following ranking:

$$PAVG > NCG > AVG = Gibbs > MH-uniform > GWG-ordinal > GWG$$
 (20)

This ranking shows that all newly proposed samplers are either competitive or superior to baselines, with the preconditioned sampler, PAVG, showing especially strong performance. It is slightly surprising that GWG-based methods would perform *worse* than a standard Gibbs sampler, however this is partly due to higher wall-clock costs; GWG-ordinal actually matches Gibbs *per-iteration*.

For the 4th order polynomial (bottom row), the estimation error metrics (columns 1 & 2) imply a similar ranking to before. The main difference is that PAVG and NCG are now matched in performance. This relative reduction in the performance of PAVG is not entirely surprising: the derivation of PAVG relied on a kind of global quadratic approximation of $f(\mathbf{s})$ (equation 13). Intuitively, it makes sense that our approximation degraded with the addition of 3rd and 4th order terms in the polynomial of equation 19.

Finally, we note that whilst the ESS estimates in the top row correlate well with the other two metrics, the ESS estimates in the bottom row are less concordant. We believe this may indicate sub-optimal estimation of ESS that can occur when the target distribution is heavy-tailed (Vehtari et al., 2021).

5.2 100D Sparse Bayesian linear regression

A common use-case of MCMC is sampling posterior distributions that arise in Bayesian analysis. We consider a Bayesian treatment of sparse variable selection in linear regression models, using an experimental setup inspired by that of Titsias & Yau (2017). Given an $n \times d$ design matrix X, the response $y \in \mathbb{R}^n$ is modelled as

$$y = X(\mathbf{s} \odot \boldsymbol{\omega}) + \sigma \boldsymbol{\nu} \qquad \qquad \boldsymbol{\nu} \sim \mathcal{N}(0, \boldsymbol{I}_n), \tag{21}$$

where $\boldsymbol{\omega} \in \mathbb{R}^d$ is a vector of weights and $\mathbf{s} \in \mathbb{R}^d$ is a binary random vector that masks out certain covariates. We place a conjugate normal-inverse-gamma prior over weights and noise-variance $(\boldsymbol{\omega}, \sigma^2)$, which can then be analytically marginalised out. Combined with a sparsity-promoting prior over \mathbf{s} , we obtain an unnormalised expression for the posterior over binary masks $p(\mathbf{s} \mid X, \boldsymbol{y})$ —see Appendix G for a complete description. This posterior tells us which covariates are 'relevant' for predicting the response \boldsymbol{y} , and which are 'irrelevant'. Thus, it can be viewed as a kind of sparse variable selection procedure.

This posterior is a 20D distribution over binary vectors, implying ~ 1 m possible states, which we can sum over (enabling normalisation). To make the sampling problem more challenging, whilst keeping normalisation tractable, we append additional 'irrelevant' dimensions by multiplying the posterior with $\prod_{i=1}^{80} \mathcal{B}(0.001)$, where \mathcal{B} is Bernoulli distribution. The fact that we can normalise (and sample) the resulting target distribution, $p(\mathbf{s})$, enables us

Table 1: Estimation error of an Ising Lattice matrix learned with persistent contrastive divergence. Error bars are standard deviations across 5 runs. Each run uses a different seed for all sources of randomness.

	K=1*		K=5		K=10		K=15		K=20	
NCG	0.837	(±.05)	0.117	$(\pm .0003)$	0.117	$(\pm .0004)$	0.117	$(\pm .0005)$	0.117	$(\pm .0005)$
AVG	5.535	$(\pm .002)$	5.452	$(\pm .003)$	5.273	$(\pm .007)$	4.814	$(\pm .029)$	0.120	$(\pm .0006)$
PAVG model-specific [†]	0.120	$(\pm .003)$	0.118	$(\pm .0003)$	0.118	$(\pm .0003)$	0.118	$(\pm .0004)$	0.118	$(\pm .0005)$
PAVG model-agnostic	5.521	$(\pm .002)$	0.124	(± 0.0005)	0.121	(± 0.0004)	0.119	(± 0.0004)	0.119	(± 0.0007)
GWG	5.271	$(\pm .0038)$	0.163	$(\pm .0009)$	0.138	$(\pm .0004)$	0.132	$(\pm .0002)$	0.128	$(\pm .0008)$
Gibbs	4.825	$(\pm .002)$	0.805	$(\pm .003)$	0.167	$(\pm .0005)$	0.136	$(\pm .0003)$	0.132	$(\pm .0005)$

^{*} K refers to the number of MCMC steps used by AVG; suitable multipliers are used so each method has the same budget.

to compare it to the empirical distribution of MCMC samples $q(\mathbf{s})$ using the following two metrics i) marginal estimation error: $(1/d)\sum_{i}^{d}|q_{i}(\mathbf{s}_{i}=1)-p_{i}(\mathbf{s}_{i}=1)|$ and ii) pairwise estimation error: $\frac{1}{d^{2}}\sum_{i,j}^{d}\sum_{k,l\in\{0,1\}}|q_{i,j}(\mathbf{s}_{i}=k,\mathbf{s}_{j}=l)-p_{i,j}(\mathbf{s}_{i}=k,\mathbf{s}_{j}=l)|$. These metrics, as well as ESS, are described more fully in Appendix F.

5.2.1 Results

Figure 4 shows the results. Under all evaluation metrics, the methods rank as follows: $PAVG \ge NCG \ge AVG \ge GWG \ge Gibbs$, with the pairwise-error metric indicating that these inequalities are strict. This ranking matches our findings from the previous experiment, except for the swapping of GWG and Gibbs. Most interestingly, we continue to see a clear benefit from preconditioning, even though the target log-probability is far from quadratic.

5.3 Estimation of Ising models via persistent-contrastive divergence

Pairwise undirected graphical models are an important class of distributions used in physics, proteomics and economics (MacKay et al., 2003; Lapedes et al., 1999; Sornette, 2014). Here, we consider the Ising model

$$\log p(\mathbf{s}) = \mathbf{b}^T \mathbf{s} + \frac{1}{2} \mathbf{s}^T J \mathbf{s} - \log Z, \qquad \mathbf{s} \in \{-1, 1\}^d$$
 (22)

where J is a binary matrix multiplied by a constant and Z is the (generally intractable) normaliser.

Following Grathwohl et al. (2021), we define a 100-dimensional Ising model with ground-truth parameters $\mathbf{b}^* = 0$ and J^* is set to a cyclic lattice as depicted in Appendix I. We then obtain 'ground-truth' samples from this model by running a Gibbs sampler for one million iterations. These samples are then used as a dataset from which we reestimate the Ising model using Persistent Contrastive Divergence (PCD) (Neal, 1992; Younes, 1999; Tieleman, 2008; Du & Mordatch, 2019), which is an approximation to gradient-based maximum likelihood learning that requires an MCMC sampler; see pseudocode in Algorithm H.6.

PCD has two key free-parameters: the MCMC sampler itself and the number of sampling steps K per parameter update. Better samplers enable lower values of K to obtain a desired level of estimation error. For the Ising model, we quantify estimation error in terms of Frobenius norm $||J - J^*||_F$, where J is a matrix of free parameters, and the model's bias \mathbf{b} is fixed at the ground-truth value.

PAVG for log-quadratic targets.

For this experiment, we compare two types of PAVG: model-specific and model-agnostic. The latter is simply the approach we used in previous experiments as discussed in Section 3.2.2. The model-specific version uses J as the preconditioning matrix. As described at the end of 3.2.1, this renders PAVG identical to the log-quadratic Block-Gibbs sampler of Martens & Sutskever (2010).

5.3.1 Results

Table 1 shows the results. As one might expect, the model-specific method of Martens & Sutskever (2010) performs best, achieving low estimation error even when K = 1. The superiority of this model-specific sampler over GWG is

[†] This corresponds precisely to the Block-Gibbs sampler introduced by Martens & Sutskever (2010)

Table 2: Estimation error of quadratic term when sampling from a quadratic-ConvEBM product distribution. Error bars are standard deviations across 5 runs. Each run uses a different seed for all sources of randomness.

	K=5*		K=10		K=15		K=20	
$\overline{\text{NCG}}$	0.128	(±.001)	0.116	(±.0002)	0.112	$(\pm .0009)$	0.112	$(\pm .0004)$
AVG	3.310	$(\pm .078)$	2.599	$(\pm .051)$	0.496	$(\pm .119)$	0.114	$(\pm .0006)$
PAVG	3.212	$(\pm .079)$	0.117	$(\pm .0004)$	0.114	$(\pm .0006)$	0.112	$(\pm .0007)$
GWG	0.732	$(\pm .013)$	0.156	$(\pm .003)$	0.120	$(\pm .001)$	0.114	$(\pm .0005)$
Gibbs	3.121	$(\pm .146)$	2.270	$(\pm .067)$	1.637	$(\pm .007)$	1.204	$(\pm .008)$

^{*} K = number of MCMC steps for AVG; suitable multipliers are used so each method has the same budget.

a new finding; indeed Grathwohl et al. (2021) perform multiple experiments with log-quadratic target distributions but do not compare to Martens & Sutskever (2010).

Amongst the non model-specific methods, the results imply the following ranking: NCG > PAVG (model-agnostic) > GWG > Gibbs > AVG. In contrast to previous experiments, we now see a modest but clear advantage for NCG over PAVG, and that AVG underperforms all other samplers. It's important to note that, throughout learning, the ϵ step-size parameter used by NCG and (P)AVG is held fixed. This means that the same step-size must be effective across a range of target distributions (since the target changes every time we update the model's parameters). The results show that NCG and PAVG work robustly with a fixed step-size, whilst AVG is less robust. We suspect that all three methods would benefit from adaptively-tuning the step-size throughout learning, but leave this possibility to future work.

5.4 Sampling deep convolutional energy-based models

Deep energy-based models (EBMs) take the form $\log p(\mathbf{s}) = \exp(f_{\theta}(\mathbf{s})) - \log Z$, where f_{θ} is parameterised as a deep neural network. Such models have attracted significant attention for continuous data (Du & Mordatch, 2019; Arbel et al., 2020; Qin et al., 2022) where Langevin-based samplers are the default approach. In the discrete setting, less progress has been made, with Grathwohl et al. (2021) (GWG) being the first paper to showcase the potential of high-dimensional discrete EBMs.

A major challenge in comparing the efficacy of different samplers for deep EBMs is the lack of an easy-to-compute evaluation metric. Unlike the Ising model, parameter estimation error is not meaningful since the models are not identifiable. We propose a novel strategy for dealing with this problem consisting of the following steps:

- i) Given a real dataset, fit a ground-truth 'quadratic-EBM' product distribution $f_{J^*,\theta^*}(\mathbf{s}) := \frac{1}{2}\mathbf{s}^T J^*\mathbf{s} + f_{\theta^*}(\mathbf{s})$ to the data using PCD with GWG and a large number of sampling steps K (we use 50).
- ii) Sample a 'ground truth' dataset $\mathcal{D}_{J^*,\theta^*}$ from the quadratic-EBM by running GWG for many (e.g. 50k) iterations.
- iii) Freeze the neural parameters θ^* , and re-estimate J from the dataset $\mathcal{D}_{J^*,\theta^*}$ using PCD with any choice of MCMC sampler and value of K. Holding θ^* fixed means J is identifiable, and the estimation error, $||J J^*||_F$, is a valid performance metric.

We apply this methodology to the USPS 256-dimensional image dataset of binarised handwritten digits (Hull, 1994) and parameterise f_{θ} as a 7-layer convolutional network as detailed in Appendix J.

5.4.1 Results

Table 2 shows the results. Roughly speaking, we can rank the methods as $NCG > PAVG \approx GWG > AVG \approx Gibbs$ where the \approx symbol indicates that neither method is clearly superior. This ranking is similar that obtained in the previous experiment, except that PAVG is no longer clearly superior to GWG and Gibbs is no longer clearly superior to AVG. We note that the estimation errors in Table 2 correlate well with visual sample quality; see images in the appendix, Figure 8.

6 Discussion

We have presented multiple discrete gradient-based MCMC samplers that show strong performance across a range of problem types in Bayesian inference and energy-based modelling. In particular, we obtained the NCG sampler by viewing the Metropolis-adjusted Langevin Algorithm through the lens of locally-informed proposals (Zanella, 2020) and the PAVG sampler through the lens of gradient-based auxiliary samplers Titsias & Papaspiliopoulos (2018).

Depending on the task, we saw that either NCG or PAVG show the strongest performance, and both generally outperform Gibbs-with-Gradients (GWG) by a clear margin. This demonstrates the value of using proposal distributions that update multiple dimensions at once, and do so in a correlated way. However, it is important to note that these advantages do not come for free: GWG requires no tuning, whereas both NCG and PAVG have step-size parameters. In practice, we would recommend running GWG alongside the new methods when facing a new sampling problem, as it provides a strong and reliable baseline.

To our knowledge, we are the first to adapt the auxiliary variable framework of Titsias & Papaspiliopoulos (2018) to discrete state-spaces. We believe there is significant scope to build on this idea, by investigating different choices of continuous conditional distributions, and understanding how/when marginalised auxiliary proposals can be leveraged. In the context of PAVG, a natural question is what happens if one replaces the global preconditioning matrix with a state-specific matrix such as the Hessian, in a similar vein to Manifold MALA (Girolami & Calderhead, 2011).

One-hot categorical random variables

A categorical random variable with k possible values can be represented as a one-hot vector belonging to the set

$$S = \{ \mathbf{s} : \mathbf{s}_i \in \{0, 1\}, \sum_{i=1}^k s_i = 1 \} \subset \{0, 1\}^k \quad \text{where } |S| = k$$
 (23)

A d-length vector of k-valued categorical random variables thus belongs to the set $\mathcal{S}^d \subset \mathbb{R}^{dk}$.

The methods introduced in this paper (NCG, AVG and PAVG) all use proposal distributions that, before normalisation, have the form $\exp(\boldsymbol{a}^T\mathbf{s} + \boldsymbol{b}^T(\mathbf{s} \odot \mathbf{s}))$ for some choice of \boldsymbol{a} and \boldsymbol{b} . Such formulas remain valid in the categorical case. However, the normalised versions of these distributions have a slightly different form. Specifically, to normalise this distribution, we note that there are d-independent groups of dimensions, and that within each group, there are only k possible settings, yielding

$$\prod_{j=1}^{d} \sigma(\mathbf{a}_{j}^{T} \mathbf{s}_{j} + \mathbf{b}_{j}^{T} (\mathbf{s}_{j} \odot \mathbf{s}_{j})) \qquad \qquad \sigma(\mathbf{x}) = \frac{\exp(\mathbf{x})}{\sum_{\mathcal{S}} \exp(\mathbf{x})},$$
 (24)

where $\mathbf{s}_j := \mathbf{s}_{(j-1)k:jk}$, $a_j := a_{(j-1)k:jk}$ and $b_j := b_{(j-1)k:jk}$.

Sampling algorithms

Algorithm B.1 NCG step

Require: Step-size ϵ . Unnormalised log prob function $f(\cdot)$. Triple $(\mathbf{s}_t, f(\mathbf{s}_t), \nabla f(\mathbf{s}_t))$.

Sample $\mathbf{s}_{t+1} \sim q_{\epsilon}(\mathbf{s} \mid \mathbf{s}_t)$ as in Eq. 8 (binary/ordinal) or the categorical equivalent implied by Eq. 24

Compute $f(\mathbf{s}_{t+1}) \& \nabla f(\mathbf{s}_{t+1})$

Accept
$$\mathbf{s}_{t+1}$$
 with probability $\min\left(1, \exp(f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t)) \frac{q_{\epsilon}(\mathbf{s}_t \mid \mathbf{s}_{t+1})}{q_{\epsilon}(\mathbf{s}_{t+1} \mid \mathbf{s}_t)}\right)$ (25)

Algorithm B.2 AVG step

Require: Step-size ϵ . Unnormalised log prob function $f(\cdot)$. Triple $(\mathbf{s}_t, f(\mathbf{s}_t), \nabla f(\mathbf{s}_t))$.

Sample $\mathbf{z}_t \sim \mathcal{N}(\mathbf{z}; \sqrt{2/\epsilon} \mathbf{s}_t)$

Sample $\mathbf{s}_{t+1} \sim q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_t, \mathbf{s}_t)$ as in Eq. 12 (binary/ordinal) or the categorical equivalent implied by Eq. 24 Compute $f(\mathbf{s}_{t+1}) \& \nabla f(\mathbf{s}_{t+1})$

Accept \mathbf{s}_{t+1} with probability

$$\min\left(1, \exp(f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t)) \frac{\mathcal{N}(\mathbf{z}; \sqrt{2/\epsilon} \mathbf{s}_{t+1})}{\mathcal{N}(\mathbf{z}; \sqrt{2/\epsilon} \mathbf{s}_t)} \frac{q_{\epsilon}(\mathbf{s}_t \mid \mathbf{z}_t, \mathbf{s}_{t+1})}{q_{\epsilon}(\mathbf{s}_{t+1} \mid \mathbf{z}_t, \mathbf{s}_t)}\right)$$
(26)

Algorithm B.3 PAVG step

Require: Step-size ϵ . Preconditioner Σ . Unnormalised log prob function $f(\cdot)$. Triple $(\mathbf{s}_t, f(\mathbf{s}_t), \nabla f(\mathbf{s}_t))$.

Sample $\mathbf{z}_t \sim \mathcal{N}(\mathbf{z}; \ \Sigma_{\epsilon}^{1/2} \mathbf{s}_t, \mathbf{I})$ for Σ_{ϵ} defined in Eq. 35.

Sample $\mathbf{s}_{t+1} \sim q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_t, \mathbf{s}_t)$ as in Eq. 36 (binary/ordinal) or the categorical equivalent implied by Eq. 24 Compute $f(\mathbf{s}_{t+1}) \& \nabla f(\mathbf{s}_{t+1})$

Accept \mathbf{s}_{t+1} with probability

$$\min\left(1, \exp(f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t)) \frac{\mathcal{N}(\mathbf{z}; \ \Sigma_{\epsilon}^{1/2} \mathbf{s}_{t+1}, \mathbf{I})}{\mathcal{N}(\mathbf{z}; \ \Sigma_{\epsilon}^{1/2} \mathbf{s}_t, \mathbf{I})} \frac{q_{\epsilon}(\mathbf{s}_t \mid \mathbf{z}_t, \mathbf{s}_{t+1})}{q_{\epsilon}(\mathbf{s}_{t+1} \mid \mathbf{z}_t, \mathbf{s}_t)}\right)$$
(27)

Preconditioned MALA as an auxiliary variable scheme

Here, we explain how to frame preconditioned MALA (equation 4) as an auxiliary variable sampler, and why discretising it is problematic.

For a continuous state $\mathbf{s} \in \mathbb{R}^d$, consider the unnormalised target density $\pi(\mathbf{s}, \mathbf{z}) = \exp(f(\mathbf{s}))\mathcal{N}(\mathbf{z}; \Sigma^{-1/2}\mathbf{s}, \mathbf{I})$. We approximate $\pi(\mathbf{s} \mid \mathbf{z}_t) \propto \pi(\mathbf{s}, \mathbf{z}_t)$ by the proposal distribution

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_{t}, \mathbf{s}_{t}) \propto \exp(f(\mathbf{s}_{t}) + \nabla f(\mathbf{s}_{t})^{T}(\mathbf{s} - \mathbf{s}_{t})) \mathcal{N}(\mathbf{z}_{t}; \Sigma^{-1/2} \mathbf{s}, \mathbf{I})$$
 (28)

$$\propto \exp\left(-\frac{1}{2}(\mathbf{s} - \boldsymbol{\mu})^T \Sigma^{-1}(\mathbf{s} - \boldsymbol{\mu})\right) \qquad \text{where } \boldsymbol{\mu} := \Sigma^{1/2} \mathbf{z}_t + \Sigma \nabla f(\mathbf{s}_t)$$
 (29)

$$= \mathcal{N}(\mathbf{s}; \ \Sigma^{1/2}\mathbf{z}_t + \Sigma \nabla f(\mathbf{s}_t), \Sigma) \tag{30}$$

If we now marginalise out the latents, we obtain

$$\int \mathcal{N}(\mathbf{z}_t; \Sigma^{-1}\mathbf{s}_t, \mathbf{I}) \mathcal{N}(\mathbf{s}; \ \Sigma^{1/2}\mathbf{z}_t + \Sigma \nabla f(\mathbf{s}_t), \Sigma) d\mathbf{z}_t = \mathcal{N}(\mathbf{s}; \ \mathbf{s}_t + \Sigma \nabla f(\mathbf{s}_t), 2\Sigma)$$
(31)

which is equal to the PMALA proposal in equation 4 after redefining Σ as $\frac{\epsilon}{2}\Sigma$. Unfortunately, if we now assume $\mathbf{s} \in \mathcal{S}^d \subset \mathbb{R}^d$, then equation 29 is no longer proportional to a Gaussian distribution, but rather a discrete pairwise Markov random field that is generally intractable to normalise and sample.

D Choice of preconditioning matrix for PAVG

We use matrices of the form $\gamma\Sigma$, where γ is an adaptively learned scaling parameter. In general settings, when we have no domain-knowledge to help us select Σ , we choose it to be an empirical covariance/precision matrix (see next section for how to choose) computed from a set of initial samples obtained during the burn-in phase. The algorithm for this general case is presented in D.4.

However, when sampling from energy-based models (EBMs), we usually have access to a real-world dataset that the EBM is modelling. In this case, we can compute the empirical covariance/precision of this dataset, and use that as our Σ . This simplifies D.4: we drop lines 5-8, and no longer need a zero-initialisation of Σ in line 2.

D.1 Covariance or precision? Automatically picking Σ from a list of options.

If we were sampling continuous variables drawn from a Gaussian distribution, then the correct choice of Σ , based on the approximation we made in equation 13, would be the (negative) precision matrix. Not too surprisingly, this choice works best in our ordinal experiments in Section 5.1. However, in all of our binary experiments, the covariance matrix, not precision, works better (often substantially so).

The choice between covariance and precision (or, more generally, a list of candidate matrices) is a hyperparameter. To avoid manual tuning, we propose a simple heuristic to automatically select the 'best' matrix from a list of options. We define 'best' as the matrix that (after rescaling) minimises the approximation error in equation 13 across pairs of adjacent states accumulated during a burn-in phase. Specifically, we do the following

- 1. During the burn-in period, collect $(\mathbf{s}_t, f(\mathbf{s}_t), \nabla f(\mathbf{s}_t))$ into a 'dataset' \mathcal{D} .
- 2. Assemble a list of candidates $[\Sigma_1, \Sigma_2 \dots \Sigma_m]$. In our experiments, we consider only two candidates: the empirical covariance & precision matrix of collected samples $\{s_t\}$.
- 3. For each Σ in our list, solve the least-squares linear regression problem

$$\arg\min_{\gamma_0} \sum_{t} ||y_t - \gamma_0 x_t||^2$$

$$y_t := f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t) - \nabla f(\mathbf{s}_t)^T (\mathbf{s}_{t+1} - \mathbf{s}_t), \qquad x_t := (1/2)(\mathbf{s}_{t+1} - \mathbf{s}_t)^T \Sigma (\mathbf{s}_{t+1} - \mathbf{s}_t)$$
(32)

where
$$y_t := f(\mathbf{s}_{t+1}) - f(\mathbf{s}_t) - \nabla f(\mathbf{s}_t)^T (\mathbf{s}_{t+1} - \mathbf{s}_t), \quad x_t := (1/2)(\mathbf{s}_{t+1} - \mathbf{s}_t)^T \Sigma (\mathbf{s}_{t+1} - \mathbf{s}_t)$$
 (33)

4. Return the re-scaled matrix $\gamma_0 \Sigma$ which obtained the lowest least-squared loss.

Across many of our experiments, the returned matrix $\gamma_0\Sigma$ performed very well without any additional alterations. However, to maximise the performance of PAVG, we found it beneficial to only use the scaling factor γ_0 as an 'initialisation' and continue to update it adaptively using AdaptGamma as shown in Algorithms D.4 and D.5.

Algorithm D.4 Adaptive learning of preconditioning matrix. (Default values in brackets are used across all experiments)

```
Require: Integers N_{\text{iters}}, N_{\text{chains}} (100), N_{\Sigma} (1000) and N_{\text{adapt}} (100).
Require: Initial adaptation rate \delta (0.25) and decay factor \rho (0.99).
  1: Initialise chains S_1 = [\mathbf{s}^1, \dots, \mathbf{s}^{N_{\text{chains}}}] and history \mathcal{D} = [S_1]
 2: Initialise \Sigma = 0, \gamma = \gamma_{\rm old} = 1.0
 3: for t \in \{1, ..., N_{\text{iters}}\} do
          Compute S_{t+1} from S_t using one step of PAVG (Algorithm B.3) with preconditioner \gamma \Sigma
 4:
          if t < N_{\Sigma} then
 5:
               Append S_{t+1} to history \mathcal{D}
 6:
          else if t = N_{\Sigma} then
 7:
               Define new \Sigma as described in Section (D.1) using history \mathcal{D}
 8:
          else if t \mod N_{\text{adapt}} = 0 then
 9:
               \gamma, \gamma_{\text{old}} = \text{AdaptGamma}(\gamma, \gamma_{\text{old}}, \delta, N_{\text{adapt}}, \mathcal{D})
                                                                                                                          ▶ Update scaling factor
10:
               \delta \leftarrow \rho \delta
                                                                                                              ⊳ exponential decay of step-size
11:
          end if
12:
13: end for
```

Algorithm D.5 Adapt γ to maximise 'jump' distance $\|\mathbf{s}_t - \mathbf{s}_{t-1}\|_1$

```
function AdaptGamma(\gamma, \gamma_{\text{old}}, \delta, N_{\text{adapt}}, \mathcal{D})
     a_{\text{new}} \leftarrow \text{Average value of } \|\mathbf{s}_t - \mathbf{s}_{t-1}\|_1 \text{ computed over all chains in } \mathcal{D}[-N_{\text{adapt}}:]
     a_{\text{old}} \leftarrow \text{Average value of } \|\mathbf{s}_t - \mathbf{s}_{t-1}\|_1 \text{ computed over all chains in } \mathcal{D}[-2N_{\text{adapt}} : -N_{\text{adapt}}]
     Increased \leftarrow \gamma \geq \gamma_{\rm old}
     Improved \leftarrow a_{\text{new}} \geq a_{\text{old}}
     if (Increased and Improved ) or (not Increased and not Improved) then
           \hat{\delta} \leftarrow \delta
                                                                                                                                               ▷ Positive adjustment
     else
           \hat{\delta} \leftarrow -\delta
                                                                                                                                              ▶ Negative adjustment
     end if
     \gamma_{\text{old}} \leftarrow \gamma
     if |\gamma| \geq 1
           \gamma \leftarrow \gamma * (1 + \hat{\delta}) then
                                                                                                                                     ▶ Multiplicative adjustment
     else
           \gamma \leftarrow \gamma + \hat{\delta}
                                                                                                 \triangleright Additive adjustment (allows \gamma to change sign)
     end if
     return \gamma, \gamma_{\text{old}}
end function
```

D.2 Preconditioners with negative eigenvalues

When deriving PAVG in section 3.2.1, we defined a conditional Gaussian distribution of the form

$$\mathcal{N}(\mathbf{z}; \ \Sigma_{\epsilon}^{1/2} \mathbf{s}_t, \mathbf{I}), \qquad \qquad \Sigma_{\epsilon} := \Sigma + (2/\epsilon)\mathbf{I}. \tag{34}$$

We note that there are multiple types of matrix square-root, and any of them is valid here. However, such square-roots only exist if Σ_{ϵ} is semi-positive definite (i.e. all eigenvalues are non-negative). This is only guaranteed to be the case (for any value of ϵ) if Σ is also semi-positive. This is because the eigenvalues of Σ_{ϵ} are of the form $\lambda_i + (2/\epsilon)$, where λ_i is an eigenvalue of Σ .

We can specify an alternative definition of Σ_{ϵ} that ensures semi-positive definiteness

$$\Sigma_{\epsilon} := \Sigma + \underbrace{\left[\max(0, -\lambda_{\min}) + (2/\epsilon)\right]}_{:= d_{\epsilon}} I$$
(35)

where λ_{\min} is the most negative eigenvalue of Σ . This new definition of Σ_{ϵ} means that PAVG uses a different conditional Gaussian, and the MH-proposal distribution in equation 16 now becomes

$$q_{\epsilon}(\mathbf{s} \mid \mathbf{z}_{t}, \mathbf{s}_{t}) = \prod_{i=1}^{n} \sigma \left(\left[\nabla f(\mathbf{s}_{t})_{i} - (\Sigma \mathbf{s}_{t})_{i} + (\Sigma_{\epsilon}^{1/2} \mathbf{z}_{t})_{i} \right] \mathbf{s}_{i} - \frac{d_{\epsilon}}{2} \mathbf{s}_{i}^{2} \right), \quad \text{where} \quad \sigma(\mathbf{x}) = \frac{\exp(\mathbf{x})}{\sum_{\mathbf{x} \in \mathcal{S}} \exp(\mathbf{x})}, \quad (36)$$

What is the consequence of this new definition of Σ_{ϵ} ? Previously, we diagonally perturbed Σ by some value in $(0,\infty)$, where larger step-sizes ϵ meant smaller perturbations. Now, we diagonally perturb Σ by some value in (d_{∞},∞) , where $d_{\infty} := \max(0,-\lambda_{\min}) \geq 0$. Thus compared to the old regime, the new regime enforces a kind of maximum step-size (a.k.a. minimum perturbation).

E Baseline ordinal samplers

Our ordinal experiments use two additional baselines: Ordinal-GWG and MH-uniform. These are both Metropolis-Hastings samplers, with proposal distributions visualised in Figure 5. As can be seen from the figure, Ordinal-GWG, like GWG, can only update *one* dimension at a time. However, it can jump multiple states along any given dimension, with the maximum number of moves controlled by a radius parameter r. Thus, the support set of this proposal distribution is (at most) of size (2r-1)d, where d is the dimensionality. The Ordinal-GWG proposal has the same functional form as GWG in equation 6, except that the summation is no longer over a Hamming ball of radius 1, but instead over the aforementioned support set.

MH-uniform (final column of Figure 5) also has a radius parameter r. This radius controls the size of the hypercube over which the proposal is uniform.

Figure 5: Illustration of the different proposal distributions used by various baseline MH samplers. The darker blue contours represent the target distribution, the light-blue dots represent the proposal distribution around the current state (black X). Left: GWG Middle: Ordinal-GWG with radius 3 Right: Uniform MH with radius 2.

E.1 Tuning step-size parameters

NCG, AVG & PAVG have step-size parameters ϵ , whilst GWG-ordinal & MH-uniform have step-size-like parameters (a.k.a. radii) r. Our tuning procedure involves running each sampler for a short amount of time (e.g. 100-1000 iterations) with different step-sizes, and selecting the step-size that maximises the average L1-distance $\|\mathbf{s}_{t+1} - \mathbf{s}_t\|_1$ between successive states (averaged over all time-steps and parallel chains). For NCG, AVG & PAVG we first first identify the best order-of-magnitude, and then search each decile within that particular order of magnitude e.g. $\{0.1, 0.2 \dots, 0.9\}$. For Ordinal-GWG and MH-uniform, we first search $r \in \{1, 5, 10, 15, 20\}$ and then search within the best interval e.g. $r \in \{15, 16, 17, 18, 19\}$ (note: the maximum possible value of the radius parameter is 50 in our experiments, since this is the size of the state-space).

Experiment	NCG	AVG	PAVG	Ordinal-GWG	MH-Uniform
Ordinal (poly2)	0.05	0.02	1000.0	16	2
Ordinal (poly4)	0.05	0.02	0.06	8	1
Bayesian regression	0.03	1000.0	1000.0	-	-
Ising lattice	0.5	0.2	0.2	-	-
ConvEBM	0.2	0.1	0.1	-	-

Table 3: Step-sizes used across different experiments.

F Evaluation metrics for Ordinal & Bayesian regression experiments

The experiments in 5.1 and 5.2 use the same methodology for evaluating performance. In both cases we:

- Run 100 parallel chains for 10 minutes with a burn-in period of 1 minute.
- After the burn-in period, we begin saving the history of each chain.
- Every minute after the burn-in, we use the chain histories to compute estimation errors (Table 4) for each chain *separately*. We then compute a mean and standard error *across* our 100 parallel chains, and use these to construct Figures 2 and 4.
- At the end of the run, we estimate the Effective Sample Size (ESS) of each chain. Following Zanella (2020) and Grathwohl et al. (2021), we map every state s in our chains to a test statistic, namely $\|\mathbf{s} \mathbf{s}_{\text{random}}\|_1$, where $\mathbf{s}_{\text{random}}$ is a randomly selected point in the state-space. The resulting test statistics can be stored in a matrix S of shape num_iters ×100, and the ESS-per-chain is then estimated with tfp.mcmc.effective_sample_size(S, filter_beyond_positive_pairs=True). Finally, to construct the ESS plots in Figures 2 and 4, we compute box-plot statistics (median & quartiles) across the 100 ESS estimates.

Experiment	marginal error	covariance/pairwise error
Ordinal	$(1/d)\sum_{i=1}^{d} D_{KL}(q_i \parallel p_i)$	$\ \Sigma_q - \Sigma_p\ _F$
Bayesian regression	$(1/d) \sum_{i=1}^{d} q_i(\mathbf{s}_i = 1) - p_i(\mathbf{s}_i = 1) $	$\frac{1}{d^2} \sum_{i,j}^d \sum_{k,l \in \{0,1\}} q_{i,j}(\mathbf{s}_i = k, \mathbf{s}_j = l) - p_{i,j}(\mathbf{s}_i = k, \mathbf{s}_j = l) .$

Table 4: q_i refers to the ith univariate marginal distribution of the empirical samples accumulated across a single chain. Similarly, $q_{i,j}$ refers to a bivariate marginal of such empirical samples. p_i and $p_{i,j}$ refer to marginals of the target distribution, and are computed exactly (i.e. they are not empirical distributions). Σ_q and Σ_p are both empirical covariance matrices; the former is computed using samples accumulated across a single chain, whilst the latter is computed using 100,000 samples drawn from the target distribution.

G Posterior distribution for sparse Bayesian linear regression

We define a Bayesian regression model using a similar procedure to Titsias & Yau (2017). The regression takes the form

$$\mathbf{y} = X(\mathbf{s} \odot \boldsymbol{\omega}) + \sigma \boldsymbol{\nu}$$
 $\mathbf{y}, \boldsymbol{\nu} \in \mathbb{R}^N \ \mathbf{s}, \boldsymbol{\omega} \in \mathbb{R}^D$ (37)

Where the quantities in this equation are random variables described by the following generative process

1. Place a sparsity-promoting prior on ${\bf s}$

$$p(\mathbf{s}) = \Gamma\left(\sum_{i=1}^{D} \mathbf{s}_i + \alpha_{\pi}\right) \Gamma\left(D - \sum_{i=1}^{D} \mathbf{s}_i + \beta_{\pi}\right), \tag{38}$$

where $(\alpha_{\pi}, \beta_{\pi})$ are hyperparameters with default values (0.001, 10.0). This prior can itself be viewed as the marginal of a Bayesian model specified by $\mathbf{s} \mid \pi \sim \prod_{i=1}^{D} Bernoulli(\mathbf{s}; \pi)$ and $\pi \sim Beta(\pi; \alpha_{\pi}, \beta_{\pi})$.

- 2. Let $\boldsymbol{\nu} \sim \mathcal{N}(0, \boldsymbol{I}_N)$.
- 3. Define $X_{\mathbf{s}} = X \operatorname{diag}(\mathbf{s})$ and note that $X(\mathbf{s} \odot \boldsymbol{\omega}) = X_{\mathbf{s}} \omega$.
- 4. Place a conjugate normal-inverse-gamma prior over weights and noise-variance $(\boldsymbol{\omega}, \sigma^2)$. Namely,

$$p(\boldsymbol{\omega}, \sigma^2 \mid \mathbf{s}, X) = \mathcal{N}(\boldsymbol{\omega} \mid 0, g\sigma^2(X_{\mathbf{s}}^T X_{\mathbf{s}} + \lambda \boldsymbol{I}_D)^{-1}) \operatorname{InvGamma}(\sigma^2 \mid \alpha_{\sigma}, \beta_{\sigma})$$
(39)

We note that this choice of normal distribution is a kind of perturbed g-prior (Zellner, 1986), with hyperparameters (g, λ) with default values (20, 0.001). The inverse-gamma hyperparameters $(\alpha_{\sigma}, \beta_{\sigma})$ have default values (0.1, 0.1).

5. As implied by the regression formula in 37, our model of \boldsymbol{y} follows

$$p(\mathbf{y} \mid \mathbf{s}, X, \boldsymbol{\omega}, \sigma^2) = \mathcal{N}(\mathbf{y} \mid X_{\mathbf{s}} \boldsymbol{\omega}, \sigma^2 \mathbf{I}_N)$$
(40)

6. Putting the previous steps together, we arrive at a joint distribution of the form

$$p(\mathbf{s}, \sigma^2, \boldsymbol{\omega}, \boldsymbol{y} \mid X) = p(\mathbf{s})p(\boldsymbol{\omega}, \sigma^2 \mid \mathbf{s}, X)p(\boldsymbol{y} \mid \mathbf{s}, \boldsymbol{\omega}, \sigma^2, X)$$
(41)

The variables (σ^2, ω) can be analytically integrated out, resulting in the **posterior distribution**

$$p(\mathbf{s} \mid \boldsymbol{y}, X) \propto p(\mathbf{s}) \frac{|X_{\mathbf{s}}^T X_{\mathbf{s}} + \lambda \boldsymbol{I}_D|}{|(1+q)X_{\mathbf{s}}^T X_{\mathbf{s}} + \lambda \boldsymbol{I}_D|} \left(2\beta_{\sigma} + \boldsymbol{y}^T \boldsymbol{y} - g\boldsymbol{y}^T X_{\mathbf{s}} \left[(1+q)X_{\mathbf{s}}^T X_{\mathbf{s}} + \lambda \boldsymbol{I}_D\right] X_{\mathbf{s}}^T \boldsymbol{y}\right)^{-\frac{2\alpha_{\sigma} + N}{2}}$$
(42)

Finally, we use the following steps to construct 'observed data' (X, y) that we then plug into our posterior

- Let $x_1, \ldots x_5$ be 5 i.i.d random variables drawn from a uniform distribution over the discrete set $\{0, 1, 2\}$.
- Define the observed response $y_{\text{obs}} = \sum_{i=1}^{5} x_i$.
- 'Duplicate' the 5 covariates 3 times i.e. $x_j := x_{j \pmod{5}+1}$ for $j \in \{6, 7, \dots, 20\}$.
- Repeat the above steps N=20 times to obtain a 'design matrix' $X \in \mathbb{R}^{20 \times 20}$ and response $y \in \mathbb{R}^{20}$.

The duplication of covariates induces multi-modality in the posterior $p(\mathbf{s}|X, \mathbf{y}_{\text{obs}})$, since masking out x_1 and leaving its copy x_6 unmasked is equivalent to masking x_6 and leaving x_1 unmasked.

Algorithm H.6 Persistent contrastive divergence with buffer

Require: Discrete dataset \mathcal{D} . Integers N_{iters} , N_{batch} , N_{buffer} .

Require: Unnormalised log probability function $f(\cdot; \boldsymbol{\theta})$. Step-size ϵ . Optional regulariser $h(\boldsymbol{\theta})$.

Require: MCMC transition operator $\mathcal{T}(\cdot \mid \cdot)$. Number of MCMC steps K.

$$\mathcal{B} \leftarrow [\mathbf{s}^1, \dots \mathbf{s}^{N_{\text{buffer}}}]$$

▶ Initialise buffer of persistent chains

for
$$i \in \{1, \ldots, N_{\text{iters}}\}$$
 do

Sample minibatch B of size N_{batch} from buffer \mathcal{B}

for
$$j \in \{1, \dots, K\}$$
 do

$$B \sim \mathcal{T}(\cdot \mid B)$$

▶ Parallelised update to minibatch

end for

Update buffer \mathcal{B} with the new values in B

 \triangleright i.e. persist the chains

Sample minibatch X of size N_{batch} from dataset \mathcal{D}

$$\boldsymbol{g} \leftarrow \frac{1}{N_{\text{batch}}} \left[\sum_{\mathbf{s} \in X} \nabla_{\boldsymbol{\theta}} f(\mathbf{s}; \; \boldsymbol{\theta}) - \sum_{\mathbf{s} \in B} \nabla_{\boldsymbol{\theta}} f(\mathbf{s}; \; \boldsymbol{\theta}) \right] - \nabla_{\boldsymbol{\theta}} h(\boldsymbol{\theta})$$
(43)

$$\theta \leftarrow \theta + \epsilon g$$
 (44)

end for

H Persistent contrastive divergence (PCD)

The gold-standard approach for the estimation of statistical models is maximum-likelihood estimation (MLE). Unfortunately, for unnormalised models

$$\log p(\mathbf{s}; \; \boldsymbol{\theta}) = f(\mathbf{s}; \; \boldsymbol{\theta}) - \log Z(\boldsymbol{\theta}), \qquad Z(\boldsymbol{\theta}) = \sum_{\mathbf{s}} \exp(f(\mathbf{s}; \; \boldsymbol{\theta}))$$
 (45)

the normaliser $Z(\theta)$ is presumed intractable, and so we cannot actually compute $\log p(\mathbf{s}; \theta)$, which is required for MLE. However, we can conveniently express the gradient as

$$\nabla_{\boldsymbol{\theta}} \log p(\mathbf{s}; \; \boldsymbol{\theta}) = \nabla_{\boldsymbol{\theta}} f_{\boldsymbol{\theta}}(\mathbf{s}) - \mathbb{E}_{p(\mathbf{s}; \; \boldsymbol{\theta})} [\nabla_{\boldsymbol{\theta}} f_{\boldsymbol{\theta}}(\mathbf{s})] \tag{46}$$

and then use a Monte-Carlo estimate of the second term, where approximate samples are drawn from $p(\mathbf{s}; \boldsymbol{\theta})$ using an MCMC sampler.

Running an MCMC sampler afresh every time we wish to perform a gradient-based parameter update quickly becomes prohibitively expensive. Persistent contrastive divergence provides a solution to this problem, by not starting afresh each time, but by *persisting* MCMC chains across parameter updates. One version of PCD is given in Algorithm H.6. This implementation adopts vanilla stochastic gradient descent to update the model parameters, but alternative optimisers (e.g. Adam (Kingma & Ba, 2014)) can be substituted.

I Estimation of Ising models

The 100×100 Lattice Ising matrix used in our experiments was generated via igraph, specifically, we call ig.Graph.Lattice(dim=[10, 10], circular=True), which returns a binary adjacency matrix, and then multiply this by a 'connection strength' parameter $\theta = 0.2$. The resulting matrix, along with samples from the Ising model, is shown in Figure 6.

For learning, we use PCD as described in Algorithm H.6, replacing vanilla SGD with Adam. The dataset \mathcal{D} consists of 10,000 samples generated via 1,000,000 steps of Gibbs sampling. We set $N_{\text{iters}} = 2,000, N_{\text{batch}} = 50, N_{\text{buffer}} = 5000, \epsilon = 0.0003$. Our model takes the form $f(\mathbf{s}; J) = \mathbf{s}^T J \mathbf{s}$, where J is unconstrained. We use the regulariser $h(J) = 0.01 \sum_{i,j} |J_{i,j}|$.

Figure 6: Left: ground truth lattice Ising model with connection strength $\theta = 0.2$. Right: samples from this model generated with 1,000,000 steps of Gibbs sampling.

J Sampling convolutional energy-based models

The architecture of the convolutional neural network used in our experiments is shown in Table 7a, alongside images from the USPS dataset. To learn a ground-truth quadratic-EBM model of the form $\frac{1}{2}\mathbf{s}^TJ^*\mathbf{s} + f_{\theta^*}(\mathbf{s})$, we use PCD as shown in Algorithm H.6 with GWG as our sampler and K = 50. We set $N_{\text{iters}} = 10,000, N_{\text{batch}} = 50, N_{\text{buffer}} = 5,000, \epsilon = 0.0003$. We use weight decay of 0.0001 on the neural net weights.

After learning this ground-truth EBM, we then rerun PCD using the model $\frac{1}{2}\mathbf{s}^T J\mathbf{s} + f_{\theta^*}(\mathbf{s})$, where J is an unconstrained matrix of parameters. During this re-estimation phase, the settings of PCD remain the same, except for $N_{\text{iters}} = 2,000$.

Conv2d(1, 16, 3, 1, 1) SiLU()
$\begin{array}{c} \textbf{Conv2d} (16, 32, 4, 2, 1) \\ \textbf{SiLU} () \end{array}$
$\begin{array}{c} \textbf{Conv2d}(32,32,3,1,1) \\ \textbf{SiLU}() \end{array}$
$\begin{array}{c} \\ \hline \texttt{Conv2d}(32,64,4,2,1) \\ \\ \texttt{SiLU}() \end{array}$
$\begin{array}{c} \\ \hline \texttt{Conv2d}(64, 64, 3, 1, 1) \\ \\ \texttt{SiLU}() \end{array}$
