Space groups describing the symmetry of lattice structure allow the emergence of fermionic quasiparticles with various degeneracy in the band structure. Theoretical efforts have predicted many materials hosting fermions with the highest degeneracy, *i.e.*, eightfold fermions, yet lacking experimental realization. Here, we explore the band degeneracies in TaCo₂Te₂ crystals. Through systematic experimental and theoretical analyses, we establish TaCo₂Te₂ as a nonsymmorphic crystal with negligible spin-orbit coupling and magnetism. These properties guarantee the first realization of practical eightfold fermions and fourfold van Hove singularity, as directly observed by photoemission spectroscopy. We further show that TaCo₂Te₂ also points to a practical route towards the realization of long-sought hourglass fermions, providing a unique platform to explore states of matter intertwining correlation, symmetry, and band topology.

It has been an eternal theme in condensed matter physics to explore emerging low-energy elementary excitations from many-body interactions and/or symmetry constraints. In analog to high-energy physics where the Poincaré symmetry allows relativistic massless Weyl and Dirac fermions, in condensed matter physics Weyl and Dirac type low-energy quasiparticle excitations have been realized based on materials like graphene [1,2], topological insulator [3-6] and topological semimetals [7-14]. At zero momentum, Weyl and Dirac fermions are twofold and fourfold degenerate, respectively. Moreover, as subgroups of the Poincaré symmetry, the 230 space groups in condensed matter physics impose fewer constraints on the allowed types of fermions. New fermionic quasiparticles beyond high-energy physics, including threefold, sixfold, and eightfold fermions, can emerge as band degeneracy [15-26]. Experimental exploration of such band degeneracy represents a major and yet-to-be accomplished task.

In Table I, the spectroscopic observation of fermionic excitations as band degeneracy in crystalline materials is summarized according to the band degeneracy **g** and the order of

dispersion \mathbf{n} . According to theoretical analysis, there exist cubic ($\mathbf{n} = 3$) Weyl and Dirac fermions [22,24] yet lacking experimental observation. Quadratic ($\mathbf{n} = 2$) Dirac and sixfold fermions have been observed directly by angle-resolved photoemission spectraoscopy (ARPES) in α -Sn [49] and PdSb₂ [50-52], respectively. Besides that, all the experimentally realized fermionic quasiparticles are of linear dispersion ($\mathbf{n} = 1$) with band degeneracy $\mathbf{g} = 2, 3, 4, 6$. However, for quasiparticles with the highest band degeneracy, *i.e.*, eightfold fermions, despite its theoretical prediction based on space groups 130, 135, 218, 220, 222, 223, 230 [16,20,22,25,26], the spectroscopic observation is still missing. This is particularly due to the difficulty in growing or handling the candidate materials [53-55]. Our approach to overcome this is to seek materials with negligible spin-orbit coupling (SOC) effect, which looses symmetry constraints and expands the space group selection.

In this work, we report the practical realization of eightfold fermion in a nonsymmorphic (space group 62) crystal TaCo₂Te₂ with negligible SOC. ARPES measurement revealed a double Dirac cone (DDC) feature at the Brillouin zone (BZ) \bar{X} point. Density functional theory (DFT) analysis prove this feature as an eightfold degenerate node at the S point of bulk BZ, protected by the combination of crystalline and time-reversal symmetry. Including SOC opens a negligible gap, rendering practical realization of eightfold fermions. Such symmetry combination also protects a fourfold (robust against SOC) van Hove singularity (VHS) at Z close to the Fermi level (E_F), which represents a new type of VHS beyond the recent classifications of high-order VHSs [56,57]. These features, as proved via ARPES, host enhanced density of states at E_F , amplify electron correlation, potentially resulting in various ordering instabilities. Through DFT calculation, we further prove that enhancement of SOC, say, in TaIr₂Te₂, would promote the practical observation of bulk hourglass fermions for the first time. These results suggest TaCo₂Te₂ as a unique platform to explore emergent physics intertwining correlation, symmetry, and band topology.

TaCo₂Te₂ crystallizes in an orthorhombic structure [58]. Using single-crystal X-ray diffraction (SCXRD) we determine its lattice structure as lattice constants $a = 6.6116 \text{ \AA}$, $b = 6.5735 \text{ \AA}$, $c = 17.783 \text{ \AA}$ in space group 62 (*Pmcn*). The corresponding BZ is shown in Fig. 1(b). The crystallinity of as-grown single crystals was examined by XRD. As shown in Fig. 1(c), all the diffraction peaks can be well indexed by the (00l) reflections with $c = 17.783 \text{ \AA}$. The magnetic property of TaCo₂Te₂ is shown in Fig. 1(d). First, no order behaviour can be observed from $\chi - T$ measurement, indicating the absence of antiferromagnetic or ferromagnetic order in the current temperature region. Between 100 K and 300 K, the slope of $\chi - T$ curves can be positive or negative depending on the specific sample, neither of which can be fitted by Curie-Weiss law, suggesting this temperature dependence is extrinsic. Secondly, the value of χ in TaCo₂Te₂ is 3 orders of magnitude lower compared to the typical cobalt compound Co₃Sn₂S₂ [59,60], suggesting negligible Co moment. Thirdly, the field-dependent magnetization ($M - H$) curves also show no

signature of saturation or hysteresis behaviour. All the above magnetic properties enable us to omit the magnetism of TaCo_2Te_2 in the following electronic structure study.

FIG. 1. Eightfold fermions and fourfold VHS in nonsymmorphic TaCo_2Te_2 with negligible magnetic order. (a) Crystal structure of TaCo_2Te_2 . (b) Three-dimensional BZ of TaCo_2Te_2 . (c) Single crystal x-ray diffraction (XRD) result taken at 300 K. (d) Zero-field-cooled (ZFC) and field-cooled (FC) magnetic susceptibility (χ) vs temperature (T) for magnetic field $H = 0.2 \text{ T}$ parallel to the c axis. Inset: Field-dependent magnetization (M) at 1.8 K. (e, f) DFT calculated dispersions along the high-symmetry path without considering SOC (e) and with SOC (f).

Figures 1(e) and 1(f) show the band structure of TaCo_2Te_2 along the high-symmetry path calculated by DFT without and with considering SOC, respectively. Two exotic features in the $k_z = 0$ plane ($\Gamma - X - M - Y - \Gamma$ plane) are noticeable. The first one is a DDC feature ($\sim -0.17 \text{ eV}$) at X point (highlighted by red ellipses). Fig. 2(f) shows that this DDC has two fourfold degenerate points separated by a Dirac gap $\sim 0.7 \text{ meV}$. The second one is a double VHS feature close to E_F at Γ point (highlighted by blue ellipses). Along $\Gamma - X$ direction they are electron pockets centered at Γ and crossing E_F , while along $\Gamma - X$ they are hole-like, yielding two saddle point VHSs.

When moving to $k_z = \pi$ plane ($Z - S - R - T - Z$ plane), the energy splitting between band pairs decreases and even vanishes, resulting in doubled band degeneracy. The DDC feature at X merges into a single, fourfold Dirac cone with a gapless, eightfold degenerate point at S (Fig. 2(h)). This eightfold fermion is symmetry-protected without SOC, determined by the projective irreducible representations (IRPs) of the little group at S . Since the system is nonmagnetic without considering SOC, we only need to consider single-valued IRPs. Nonsymmorphic group

Pmcn has higher dimension IREPs at the boundary of the first BZ [61]. At *S*, the little group has two two-dimension IREPs, which are conjugated to each other. Due to the time reversal symmetry, the two conjugated IREPs will become a four-dimension IRep through the direct sum. Moreover, since the SOC here is negligible, the spin space has SU(2) symmetry protecting the spin degeneracy. Therefore, the band at the point *S* is eightfold degenerate. On the other hand, when considering SOC, the degeneracy will be determined by the double-valued projective IREPs of the little group and the SU(2) symmetry will be broken. Although the double-valued IREPs of the little group at *S* also include a four-dimension IRep, the time reversal cannot lead to eightfold degeneracy [16,20]. Therefore, SOC will generally open a gap at *S*. But the following ARPES measurement (unresolvable) and DFT analysis ($\sim 0.4 \text{ meV}$) both manifest that this SOC induced gap is negligible.

Besides, the double VHSs at Γ merge into one single VHS at *Z*, forming a fourfold VHS, robust against SOC. First, *Z* is invariant under inversion symmetry *P* and a glide mirror $\tilde{M}_x: (x, y, z) \rightarrow (-x, y + \frac{1}{2}, z + \frac{1}{2})$. In this case, if a Bloch state $|u\rangle$ is an eigenstate of \tilde{M}_x with eigenvalue g_x , there is another state of the system $P|u\rangle$. Moreover, because of the fractional translation of \tilde{M}_x , the two operators are anticommutative, $\{P, \tilde{M}_x\} = 0$, which gives $M_x P|u\rangle = -P\tilde{M}_x|u\rangle = -g_x P|u\rangle$. Thus, $|u\rangle$ and $P|u\rangle$ must be linearly independent for their opposite eigenvalues. Then, since *Z* is a time reversal invariant momentum and the time reversal operator *T* has $T^2 = -1$, the band at this point has a Kramer double degeneracy. Therefore, for the states $|u\rangle$ and $P|u\rangle$, there must be linearly independent states $T|u\rangle$ and $TP|u\rangle$ having the same energy. Because $PT = TP$ here, $TP|u\rangle$ is equal to $PT|u\rangle$. So, the independence of $T|u\rangle$ and $TP|u\rangle$ can be also argued by the anticommutation relation. Furthermore, the *Z* point is also invariant under the combination of time reversal and inversion symmetries TP with $(TP)^2 = -1$. Thus, $TP|u\rangle$ is another Kramer-like double degenerate state of $|u\rangle$ at *Z*. Therefore, for any eigenstates $|u\rangle$ of \tilde{M}_x with momentum vector $(0, 0, \pi)$ in the crystal, there must be three linearly independent states $P|u\rangle, T|u\rangle$, and $TP|u\rangle$. Namely, the bands at *Z* are all fourfold degenerate.

Photon energy dependent ARPES measurement shown in Fig. 2(a) presents a periodic pattern of spectral intensity in the $k_x - k_z$ plane, helping to define the high symmetry points of Γ, Z, X, S , using lattice constant $c = 17.78 \text{ \AA}$ and inner potential $V_0 = 13.5 \text{ eV}$. Fermi surfaces mapped by ARPES at different k_z planes in Fig. 2(b) and 2(c) present features consistent with the DFT projection (Fig. 2(d)). Of particular interest are two elliptical features next to \bar{X} , which come from the DDC features along $\bar{\Gamma} - \bar{X} - \bar{\Gamma}$ direction. In Fig. 1(e-h), we compare the ARPES measured DDC spectra along $\Gamma - X - \Gamma$ and $Z - S - Z$ to the DFT calculated ones. For the DDC feature centered at *X*, the band pair splitting can be clearly resolved in the 2nd derivative plot shown in

Fig. 2(e). It is noted that this splitting in ARPES spectra is more evident for the outer cones than the inner ones, probably resulting from the fact that the inner ones are more dispersed along k_z direction and its projection into the $k_x - k_y$ plane may smear out its own splitting. According to the above symmetry analysis, moving to $k_z = \pi$ plane merges the DDC feature into a single but fourfold degenerate Dirac cone, with an eightfold degenerate Dirac point (Fig. 2(h)). This is indeed observed in the ARPES spectral along $Z - S - Z$ direction as shown in Fig. 2(g). Compared to ARPES spectra along $\Gamma - X - \Gamma$, spectra along $Z - S - Z$ show the absence of band pair splitting and the presence of a degenerate point with much enhanced spectral weight. These new features clearly prove the fourfold band degeneracy and the existence of eightfold fermion. The SOC induced gap (~ 0.4 meV according to DFT in Fig. 2(h)) is negligible as compared to the breadth of observed bands in ARPES spectra (Fig. 2(g)).

FIG. 2. Observation of practical eightfold fermions in TaCo_2Te_2 . (a) Fermi surface in the $k_x - k_z$ plane measured by varying photon energy. (b, c) Fermi surface in the $k_x - k_y$ plane measured with photon energies 24 eV and 90 eV, respectively. (d) Fermi surface calculated by DFT with projection to the $k_x - k_y$ plane. (e-h) ARPES measured spectra (2nd derivative plot) and corresponding DFT calculated dispersions along high-symmetry paths with SOC.

We then focus on the fourfold VHS at Z point as shown in Fig. 3(a). According to DFT, this VHS manifests itself as an electron pocket along $Z - S$ and hole pocket along $Z - T$, thus as a saddle point with divergent density of states. To measure the corresponding spectra, we first align the $Z - S$ direction parallel to the measurement plane and then make a Fermi surface mapping. As shown by the mapping in Fig. 3(b), the spectral weight is heavily suppressed at Z in the first BZ due to the measurement geometry and orbital symmetry of the contributing electrons. So we

choose the extended BZ to extract the cut along $S - Z - S$. As shown in Fig. 3(c), ARPES spectra indeed present an electron-like pocket centered at Z with its minimum binding energy $\sim 32 \text{ meV}$. Then the sample is rotated by 90° so that $Z - T$ is parallel to the measurement plane. The ARPES spectra along $T - Z - T$ are extracted from the corresponding Fermi surface mapping (Fig. 3(d)). As shown in Fig. 3(e), a hole-like pocket centered at Z can be resolved. Comparing Fig. 3(c) and 3(e), it is found that the minimum of electron pocket along $S - Z - S$ coincides with the maximum of hole pocket along $T - Z - T$, being evidence of a saddle point. As our previous symmetry analysis has proved Z as a fourfold degenerate point, this saddle point is thus a fourfold degenerate VHS, which goes beyond the recent classifications of high order VHSs [56,57].

FIG. 3. Observation of fourfold VHSs in TaCo_2Te_2 and predicted realization of hourglass fermions in TaIr_2Te_2 . (a) DFT calculated fourfold bands along $S - Z - T$. (b, d) Fermi surface in $k_x - k_y$ plane measured with photon energy 90 eV , with the measurement plane defined by the incident light and emitted electrons parallel to $Z - S$ (b) and $Z - T$ (d) directions, respectively. (c, e) 2nd derivative ARPES spectra taken from the momentum cut indicated by red lines in (b) and (d), respectively. (f) 2nd derivative ARPES spectra showing the feature of hourglass fermion predicted in TaCo_2Te_2 . (g, h, i) DFT predicted hourglass fermions.

Discussion:

Combining experimental and calculational analyses, we have proved that the SOC effect on the band structure is very weak in TaCo_2Te_2 , which results in negligible energy splitting between adjacent Dirac crossing and the practical realization of eightfold fermions. All of the observed features, including the fourfold degenerate Dirac cone, the eightfold degenerate point hosted

inside and the fourfold saddle point VHS, feature enhanced density of state close to E_F , amplify electron correlation, potentially resulting in various ordering instabilities and many-body interactions.

Such negligible SOC also has the disadvantage in realizing exotic electronic excitations. As shown in Fig. 3(g), the nonsymmorphic symmetry also guarantees band features hosting hourglass fermions[18] along $S - R$ in TaCo_2Te_2 . But the splitting between adjacent Dirac crossing is too small to be resolved in the ARPES spectra (Fig. 3(f)). Increasing the effect of SOC, e.g., via substituting Co with Rh or Ir, would increase the adjacent Dirac crossing splitting and promote the practical observation of hourglass fermion features by ARPES. This expectation is indeed true as proved by our DFT calculation on the isostructural $\text{Ta}T_2\text{Te}_2$, where T represents Co, Rh, and Ir [62]. As shown in Fig. 3(g-i), in the considered energy-momentum region always exists an hourglass fermion feature for all the three materials. With increasing SOC, the energy splitting between adjacent Dirac points increases from $\sim 3 \text{ meV}$ in TaCo_2Te_2 to $\sim 15 \text{ meV}$ in TaIr_2Te_2 . The latter energy scale is comparable to the breadth of observed bands here, thus making the ARPES observation of hourglass fermions in TaIr_2Te_2 very promising. Our observation thus calls for further efforts to explore exotic states of matter and emergent phenomena intertwining correlation, symmetry, and band topology based on the TaCo_2Te_2 family of materials.

Materials and Methods

Sample growth and Characterizations

High quality TaCo_2Te_2 single crystals were synthesized by using a chemical vapor transport method with I_2 as a transport agent. The mixture of Ta powder (purity 99.9%), Co pieces (99.99%), and Te shot (99.99%) were prepared with a molar ratio of $\text{Ta} : \text{Co} : \text{Te} = 1 : 1 : 2$, and sealed in a quartz tube under high vacuum. Then it was placed in a horizon two-zone tube furnace and maintained under a temperature gradient of 950 - 850 °C. After two weeks, shiny single crystals

with a typical size of about $1 \times 2 \times 0.1$ mm³ were obtained. The structure of the crystals was characterized by x-ray diffraction with Cu $K\alpha$ radiation at room temperature using a Rigaku Miniex diffractometer. The diffraction pattern can be well indexed by the $(00l)$ reflections. Magnetic measurements were performed using the QD Magnetic Property Measurement System (MPMS) with the Vibrating Sample Magnetometer (VSM) mode. Temperature dependent magnetic susceptibility and the field-dependent magnetization results were collected with an external magnetic field of 0.2 T, which is parallel to the c axis.

ARPES measurement

ARPES measurements were performed at the beamline 13U of the National Synchrotron Radiation Laboratory (NSRL) and the beamline 1 of the Hiroshima Synchrotron Radiation Center (HSRC), Hiroshima, Japan. The energy resolution was set at 25 meV for Fermi surface mapping and 12.5meV for band structure measurements, respectively. The angular resolution was set at 0.1°. Samples were cleaved *in situ* along the (001) crystal plane under ultra-high vacuum with pressure better than 5×10^{-11} mbar and temperatures around 20 K.

First-principles calculations

The first-principles calculations are performed using the Vienna ab initio simulation package [63,64] within the projector augmented wave method [65]. The exchange correlation functional was treated within the generalized gradient approximation in the Perdew-Burke-Ernzerhof formalism [66]. The plane-wave basis with an energy cutoff of 500 eV. The BZ was sampled by using the Γ -centered $5 \times 5 \times 2$ Monkhorst-Pack grid [67] in the self-consistent calculation. The spin polarized calculations are calculated to give a nonmagnetic ground state. In addition, a tight-binding (TB) Hamiltonian based on the maximally localized Wannier functions (MLWF) [68] is constructed by using the Wannier90 package [69]. Through the TB Hamiltonian, the Fermi surface is further plotted by using the WannierTools package [70].
