Abstract: This paper demonstrates a hafnium zirconium oxide (HZO)-based ferroelectric NEMS unimorph as the fundamental building block for very low-energy capacitive readout in-memory computing. The reported device consists of a 250 $\mu m \times 30 \mu m$ unimorph cantilever with 20 nm thick ferroelectric HZO on 1 μ m SiO₂. Partial ferroelectric switching in HZO achieves analog programmable control of the piezoelectric coefficient (d₃₁) which serves as the computational weight for multiply-accumulate (MAC) operations. The displacement of the piezoelectric unimorph was recorded by actuating the device with different input voltages V_{in}. The resulting displacement was measured as a function of the ferroelectric programming/poling voltage V_p. The slopes of central beam displacement (δ_{max}) vs V_{in} were measured to be between 182.9nm/V (for $-8V_p$) and – 90.5nm/V (for 8V_p), demonstrating that V_p can be used to change the direction of motion of the beam. The resultant δ_{max} from AC actuation is in the range of -18 to 36 nm and is a scaled product of the input voltage and programmed d₃₁ (governed by the V_p). The multiplication function serves as the fundamental unit for MAC operations with the ferroelectric NEMS unimorph. The displacement from many such beams can be added by summing the capacitance changes, providing a pathway to implement a multi-input and multi-weight neuron. A scaling and fabrication analysis suggests that this device can be CMOS compatible, achieving high in-memory computational throughput.

Neuromorphic computation is of great interest to computing theory and practical implementations due to the potential for low-power, high efficiency, and small form factor information processing with deep neural networks (DNNs) [1]–[3]. The building blocks of DNNs are perceptron blocks, which inherently necessitate brain-like synaptic functions achieved through arrays of MAC units. With the ever-increasing number of variables required for neuromorphic computation with high accuracy, there is an urgent need to develop highly energy-efficient device architectures [3]–[5]. The energy used per MAC unit is, therefore, a useful metric to compare technologies. Ferroelectric field-effect transistors (Fe-FET) have been used to mimic analog synaptic operation with gate-ferroelectric switching in silicon and germanium channel devices to realize multi-level conductance modulation with potentiation and depression with 50-100 ns switching pulses and 3-5 MV/cm fields[6], [7]. FET-based in-memory computation architectures are susceptible to large read and write energy consumption and high leakage currents in idle mode, particularly with gate dielectric thickness scaling down to < 5 nm [8]. NEMS switches and beams offer an alternate pathway to zero-leakage in-memory compute synaptic functionality, provided that the beam actuation has embedded programmable weights in the form of tunable capacitive or piezoelectric coupling. We have previously reported a graphene-on-HZO ferroelectric device that uses potential gradients across the graphene to achieve fractional switching, with the modulated graphene resistance also used for resistive memory readout [9]. While analog in-memory computing has been demonstrated using different architectures which use transistors or memristors, few prior works have used a NEMS-based approach that takes advantage of a released beam structure to eliminate energy leakage in an idle state [10]–[13]. In previous work, the idea of using nanomechanical electrostatic actuators to produce MAC units has been described [13]. In contrast, we present a ferroelectric/piezoelectric beam transducer to enable the multiplication that can be read out capacitively, eliminating any DC currents.

This paper presents a novel technique to store the neural net weights in the form of the programmable piezoelectric coefficient d₃₁ of HZO-driven unimorph, which changes by applying a polarization switching voltage V_p . After polarization programming, different actuation inputs (V_{in}), actuate the cantilever such that the unimorph displacement is a scaled product of V_p and V_{in} . The displacement can in turn be measured as capacitive sense current from a capacitive divider circuit, for massively parallel MAC operations from arrays of such NEMS elements. Figure 1 shows the concept of the partial polarization in a ferroelectric for analog control of beam-bending in a unimorph. In addition to the active ferroelectric film, the unimorph stack also includes metal contact layers and an insulating elastic layer. The polarization versus E-field (PE loop) for an 80 µm diameter metal-ferroelectric-metal (MFM) capacitor on a 20 nm thin HZO film is shown in figure 1a. Moving counterclockwise along the PE loop starting with all dipoles point downward (point O), the film can be in a state of net-zero polarization (points A and A') at the positive and negative coercive fields, fully down or up-switched (points C and C') or partially polarized (along the slopes of A-B and A'-B'). Each point along the PE loop achieves a specific macroscopic value of d₃₁, with the maximum and minimum values at the two extrema (at points C and C') with the appropriate choice of bias voltage $V_p = E t_{HZO}$. After programming, if a much smaller actuation voltage Vin is applied such that it produces no dipole switching, an in-plane stress is generated due to expansion or contraction of the HZO film along its length, resulting in the piezoelectric bending moment M_{Piezo} . The programming would enable weight-storage in DNNs at reduced rates compared to inference events. The beam displacement is a solution of the Euler-Bernoulli equation:

$$\frac{\partial^2 y}{\partial x^2} = -\frac{M_{Piezo}}{C} \tag{1}$$

Here, M_{piezo} is the piezoelectric moment generated due to applied V_{in} and *C* is the total flexural rigidity of the multi-layer piezoelectric stack [14]. By using zero displacements and zero slopes boundary conditions on each end of the clamped-clamped beam, the Euler–Bernoulli equation yields the beam displacement profile. The maximum beam displacement occurs at the center i.e. $y(\frac{l}{2}) = \delta_{max}$. For piezoelectric coefficient d₃₁ and in-plane stress σ_1 in HZO, the beam displacement can be expressed as:

$$\delta_{\max} \propto M_{Piezo} \propto \sigma_1 \propto d_{31} \propto P(Polarization) \propto V_p$$
⁽²⁾

For an input voltage V_{in}, the NEMS beam displacement is, hence, a scaled product of weights and inputs.

$$\delta_{\max} = SF. V_p. V_{in} \tag{3}$$

Here, the scale factor (SF) depends on ferroelectric material properties, beam geometry, Young's modulus, etc. However, we can design the multiplier to achieve linear behavior in the transfer characteristics curve along the rising and falling slopes of the PE loop to accomplish a multiplicative function for parallel MAC operations. Figure 1c represents the multiplier unit with a capacitive readout to measure the output voltage. The left and right beams are poled with the same magnitude but with opposite polarity. Thus, for the same input voltage V_{in} , the left and right beams displace such that the difference between the two represents the product of V_{in} and V_p . The differential motion causes differential capacitance between left and right capacitive parallel plates. The output voltage is given by:

$$V_{out} = 2V_{dd} \frac{C_L - C_R}{C_L + C_R} \cong -2V_{dd} \frac{\gamma(x_L - x_R)}{2g} = SF. V_p. V_{in}$$
(4)

Where γ is an constant which depends on beam geometry, and x_L and x_R are left and right parallel plate displacements with initial gap g. Several multiplier units can then be further connected in parallel with an activation unit to form a perceptron. The output voltage of the MAC unit (figure 1d) is:

FIG 1 (a) PUND loop of 20 nm-thick HZO film (b) Polarization-dependent bending moment generated in ferroelectric-on-elastic unimorph at various points along the PE loop (E_c is coercive field) (c) Conceptual multiplier unit with ferroelectric actuation and capacitive readout. The output voltage is the product of V_{in} and stored weights in the form of d_{31} coefficients. (d) Several multipliers with capacitive readout can be placed in parallel to form a MAC unit that can perform accumulation operation by summing up the capacitances from each device.

Figure 2a and 2b show the top and cross-section views respectively of the clamped-clamped ferroelectric unimorph used to demonstrate piezoelectric coefficient programming. 1 μ m thick thermal SiO₂ forms the elastic layer underneath 20 nm ferroelectric HZO. The HZO is capped by 3 nm of alumina (Al₂O₃), followed by annealing at 400°C to crystallize the HZO in its ferroelectric orthorhombic phase. 200 nm platinum (Pt) and 100 nm aluminum (Al) were deposited to form the bottom and top metal contacts for the HZO respectively. The beam was released by isotropic etching of the silicon substrate using Xactix *XeF*₂ etcher. Details of the fabrication process and challenges encountered are included in the supplementary material. A scanning electron microscope image of the fabricated device is shown in Figure 2c. After release, the beams were observed to be buckled due to residual film-stress generated during microfabrication. A 3D optical profilometer (ZygoTM system) was used to measure the beam buckling profile (figure 2d). The maximum displacement for a 250 $\mu m \times 30 \mu m$ was 4.98 μm .

FIG 2 (a),(b) Schematic top and cross-section view of the ferroelectric beam (c) SEM image of the beam showing released structure (d) 3D profile of the released beam measured using $Zygo^{TM}$ profilometer showing beam curvature due to residual stresses in the stack. For $250 \times 30 \mu m$ beam, the measured maximum displacement at the center was $4.98 \mu m$.

HZO ferroelectric characterization was performed using a Sawyer-Tower circuit configuration on a custom probe station with continuous wave (CW) positive-up-negative-down (PUND) input waveforms to extract the coercive field (E_c) and remnant polarization (P_r). In prior work, we have used electrical breakdown under a large top metal pad to contact the bottom electrode with 5-10 Ω resistance [15]. The PUND input signal has 83 µs rise, fall, and wait times (corresponding to 1kHz PUND frequency), and a peak-to-peak amplitude of 15V. Figure 3a shows time-domain input voltage and output sense current measured with an 11.8 k Ω sense resistor. The P and N pulses show a switching current peak below the peak voltage, indicative of polarization switching, whereas the U and D pulses show capacitive displacement current and low leakage. This confirms ferroelectricity in the released HZO films without any degradation, consistent over 10,000 cycles of switching with CW operation. Figure 3b plots the switching current density (J) vs E-field. The PUND measurement was performed on multiple such released NEMS beams with a range of lengths from 100-400 µm and widths spanning 15-39 µm. The overlay from these measurements is shown with multiple dotted lines in figure 3c. For comparison, the PUND loop for an unreleased 80 µm diameter circular electrode is also shown on the same plot (solid black line). This shows that there is little/no degradation of ferroelectric properties of the HZO before and after release. Multiple release devices with different electrode sizes had overlapping loops suggesting high repeatability. PUND measurements yield an extracted $E_c \approx 1.5 MV/cm$ and $P_r \approx$ $10\mu C/cm^2$, consistent with previously reported values[16]–[18]. The devices were also tested for DC breakdown as shown in figure 3d. The device's current density exceeds 10µA/cm² at 3.15MV/cm.

FIG 3 (a) Input voltage and output current vs time plot of the device showing much larger switching currents as compared to leakage currents. Inset- Setup for poling the NEMS beam (b) Switching current density vs electric field plot showing ferroelectric switching peaks. (c) Measured Polarization vs E-field characteristics of released beam devices with different lengths and widths showing repeatability. The Measured PE loop of the standard unreleased circular electrode is shown with a solid black (d) DC I-V of the device showing high current density above 3.15 MV/cm indicating leakage.

The central device concept of this work is to use analog weight storage in the bending motion of the NEMS beam for in-memory computation, which relies on the programming of the d_{31} coefficient of the device by using different poling voltages. The test methodology used for this experiment is as follows:

Step 1: Device poling with CW single-sided pulses at 3 kHz. The configuration used for poling is depicted in figure 3a (inset). The test signal is applied to the top electrode, and the ground connection is made to the bottom electrode by breaking down the HZO under a large top metal pad to short it to the bottom electrode.

Step 2: Beam actuation with small V_{in} to measure the displacement amplitude, without additional polarization switching.

Step 3: Increase poling voltage by 0.5V and repeat steps 1-2, while tracing the PE loop counterclockwise from $0V \rightarrow 8V \rightarrow 0V \rightarrow -8V \rightarrow 0V$.

This voltage sweep for V_p is similar to the PUND loop with one key difference. In this technique, we stepped the V_p by 0.5V and then measured the beam displacement with a fixed V_{in} amplitude, unlike the PUND measurements in CW operation with increasing voltages.

FIG 4 (a) Central beam displacement δ_{max} and resonant frequency f_0 vs poling voltage V_p plot for the 250 µm × 30 µm ferroelectric clamped-clamped beam. Devices were poled at different V_p with 0.5V increment along the loop $(0V \rightarrow 8V \rightarrow 0V \rightarrow 8V \rightarrow 0V)$ and the beam displacement profile was measured using the Polytec LDV at $V_{in} = 0.1$ V in the frequency range of 450-460kHz. The δ_{max} (red line) changes for different values of V_p and traces a hysteresis loop similar to PUND measurements. The polarization in the beam, induced due to V_p , changes the internal stress resulting in the frequency f_0 tuning (black line) which could be exploited for memory storage. (b) The resonance vibration magnitude and phase plots of the same beam at different points on plot (a).

A Polytec MSA-400 laser doppler vibrometer (LDV) was used to measure the beam motion. For a 250 $\mu m \times 30 \mu m$ beam, a 0.1V amplitude frequency chirp from 1kHz to 1 MHz was applied. A resonance at f₀=455.23 kHz was identified with a quality factor of 305. AC voltage V_{in}=0.1V was used to measure peak amplitudes. Figure 4a shows the peak beam displacement δ_{max} and resonant frequency f_0 vs poling voltage V_p plot for the nominal 250 $\mu m \times 30 \mu m$ ferroelectric clamped-clamped beam. δ_{max} (red line) is modulated for different values of V_p and traces a hysteresis loop, similar to the PE loop from PUND measurements. The net effect of the number of upward and downward pointing dipoles that control the macroscopic polarization in the beam (induced due to V_p) also changes the beam stiffness resulting in resonance frequency modulation (black line), which presents a separate modality of weight storage in the beam. The two dips in f_0 correspond to the positive and negative coercive fields of the HZO film, where the net polarization is almost zero. As illustrated in figure 1b, domain randomization is a potential cause for likely film relaxation at these points causing f_0 to drop.

From figure 4a, the positive linear dependence of δ_{max} can be seen in the voltage interval $2.5V \rightarrow 8V$. Similarly, negative linear dependence in the interval $-2.5V \rightarrow -8V$. Here, the slope of δ_{max} vs. V_p is SF×V_{in} as defined in Eq. 3. The effect of V_{in} on δ_{max} is explained in the next section. Two points were selected on the positive slope to show the resonance vibration magnitude and phase plots of the vibrating beam (figure 4b). Points 1 and 2 have almost the same displacement magnitude but exactly opposite phases. This 180° phase difference is a signature of polarization inversion corresponding to a sign change for δ_{max} . To show the effect of V_{in} on δ_{max} , V_{in} was swept from 0.02V to 0.20V for different values of the V_p (figure 5).

FIG 5 The displacement vs V_{in} for different values of V_p . The black and red traces correspond to the positive V_p (5.5 \rightarrow 8V) red negative V_p (-5.5 \rightarrow -8V) poling voltages respectively, showing the multiplication functionality.

Figure 5 plots δ_{max} vs V_{in} at different values of V_p which emulates the transfer characteristics of the analog multiplier. For a fixed poling voltage, an input voltage sweep yields a linear increase in displacement value. Similarly, for constant inputs, different poling voltages outputs different displacement values. We can calculate the scale factor from previous plots as follows:

$$SF = \frac{\delta_{\max}}{V_p V_{in}} \tag{6}$$

Eq. 6 demonstrates that δ_{max} is the product of inputs (V_{in}) and weights (V_p). As shown in figure 4a and figure 5, Eq. 6 behaves linearly in the range of V_p from $\pm 2.5V$ to $\pm 8V$ and V_{in} from 0 to 0.2V for the device tested here (250 µm×30 µm beam). The beam displacement can be measured using a capacitive divider circuit to measure V_{out}. The slope of the plot in figure 5 is the experimental SF×V_p. For $V_p = \pm 8V$, the measured slopes were182.9nm/V and -90.5nm/V respectively. The asymmetry in the negative and positive V_p slopes is likely due to the non-symmetric device stack. Above HZO, there is a very thin top electrode (Al) but below it, we have a thick SiO₂ and electrode (Pt) stack. Thus, for the same V_p, actuation with opposite polarity will have an unequal effect on the partial polarization resulting in different δ_{max} values.

In conclusion, we have demonstrated the successful working of an HZO-based NEMS multiplier with weight storage functionality. The device was fabricated and characterized showing the dependence of beam displacement on the poling voltage of the ferroelectric film. Polarization-dependent frequency-tuning was also observed, which can be further explored to achieve an electrically reconfigurable filter. For a 250 $\mu m \times 30 \mu m$ beam poled at 8V, δ_{max} of 18 nm and f_0 of 455.23 kHz with Q=305 was measured. The δ_{max} vs V_{in} plot at different values of V_p demonstrate the successful operation of an analog NEMS multiplier. While in this paper AC drive was used to obtain observable displacements, in the future DC input voltages are anticipated for DNN applications. A capacitive readout of the beam motion can be used instead of a topical readout for much higher resolution.

The dimensional and voltage scaling of the prototype device demonstrated is important for CMOS-integrated adoption while maximizing computational throughput. For CMOS compatibility, <1V operation is necessary. This sets an upper bound for HZO film thickness of < 7 nm for $E_c = 1.5 \ MV/cm$. Non-resonant actuation of the devices would require a settling time of ~2 QT_0 . Assuming two operations per device, multiplication and addition, the computation speed (FLOPS per device) and power consumption can be estimated as $\frac{f_0}{Q}$ and $E\frac{f_0}{Q}$ respectively. Where E is the energy consumption per operation for individual device given by $\frac{1}{2}C_{HZO}$. V_{in}^2 . For example, unimorph device of size 5 × 0.5 µm and thickness 28nm (~4×HZO thickness) with a Q=10, which can be realized by high-pressure gas damping, yields $f_0 \sim 20$ MHz and computation speed of 2MFLOPS/device. Considering driving electrodes of size 1×0.3 µm with 7nm thick HZO between V_{in} (0.1V) and GND electrodes, the energy consumption per operation can be calculated as ~500 aJ ($E = \frac{1}{2}C_{HZO}$. V_{in}^2). Combining both values result in 2 PFLOPS/watt computational performance. This computation speed with ultra-low energy consumption and zero leakage current will pave the path toward brain-level computation efficiency.
