## Abstract

The spread of online misinformation is increasingly perceived as a problem for societal cohesion and democracy [1, 2]. Much attention has focused on the role of social media as a vector of misinformation [3]. The role of political leaders has attracted less research attention, even though leaders demonstrably influence media coverage [4] and public opinion [5], and even though politicians who “speak their mind” are perceived by segments of the public as authentic and honest even if their statements are unsupported by evidence or facts [6–8]. Here we show that in the last decade, U.S. politicians’ conception of truth has undergone a distinct shift, with authentic but evidence-free belief-speaking becoming more prominent and more differentiated from

evidence-based truth seeking. We analyze communications by members of the U.S. Congress on Twitter between 2011 and 2022 and show that political speech has fractured into two distinct components related to belief-speaking and evidence-based truth-seeking, respectively, and that belief-speaking—but not truth-seeking—can be associated with the sharing of untrustworthy information. We show that in tweets by conservative members of Congress, an increase in belief-speaking of 10% is associated with a decrease of 13.7 points of quality (using the NewsGuard scoring system) in the sources shared in a tweet. In addition, we find that an increase of belief-speaking language by 10% in the shared articles themselves is associated with a drop in NewsGuard score of 7.9 points for members of both parties. By contrast, increase in truth-seeking language in tweets and articles is associated with an increase in quality of sources. The results support the hypothesis that the current dissemination of misinformation in political discourse is in part driven by a new understanding of truth and honesty that has replaced reliance on evidence with the invocation of subjective belief.

## 1 Main

Numerous indicators suggest that democracy is in retreat worldwide [e.g., 9, 10]. Although symptoms and causes of this democratic backsliding are difficult to tease apart, the widespread dissemination of misinformation<sup>1</sup>—on social media, in hyperpartisan news sites, and in political discourse—is undoubtedly a challenge to democracies [1]. There is increasing evidence that exposure to misinformation can cause people to change their behavior [e.g., 11]. Exposure to misinformation has been identified as a contributing cause of voting for populist parties in Italy [12] and has been causally linked to ethnic hate crimes in Germany ([13]; for a review of causal effects, see [14]).

Misinformation has several troubling psychological attributes. First, misinformation lingers in memory even if people acknowledge, believe, and try to adhere to a correction [15]. Even though people may adjust their factual beliefs in response to corrections [e.g., 16], their political behaviors and attitudes may be largely unaffected [e.g., 6, 7]. Second, perhaps most concerning, in some circumstances people may even come to *value* overt dishonesty as a signal of “authenticity” [8]. A politician who routinely and blatantly misinforms the public is overtly violating the established societal norm of being accurate and truthful. Within a populist logic this norm violation identifies the politician

---

<sup>1</sup>We use “misinformation” as an umbrella term to refer to any information that people consume and which later on turns out to be false. Misinformation can be spread unintentionally, when communicators mistakenly believe some item of information to be true, or it can be spread intentionally, for example in pursuit of a political agenda. Intentionally disseminated misinformation is often referred to as “disinformation”. The psychological and cognitive consequences of disinformation are indistinguishable from those of unintentional misinformation, and we therefore use the latter term throughout.

as an enemy of the “establishment” and, by implication, an authentic champion of “the people”—dishonesty and misinformation thus become a sign of distinction [8]. For example, polls have shown that around 75% of Republicans considered President Trump to be “honest” at various points throughout his presidency (e.g., NBC poll, April 2018). This perception of honesty is at odds with the records of fact checkers and the media, which have identified more than 30,000 false or misleading statements by Trump during his presidency (*Washington Post* fact checker).

This discrepancy between factual accuracy and perceived honesty is, however, understandable if “speaking one’s mind” on behalf of a constituency is considered a better marker of honesty than veracity. The idea that untrue statements can be “honest”, provided they arise from authentic belief speaking, points to a distinct ontology of honesty that does not rely on the notion of evidence but on a radically constructivist appeal to an intuitive shared experience as “truth” [1]. There have been several attempts to characterize this ontology of truth and honesty and the stream of misinformation it gives rise to [e.g., 1, 17, 18]. A recent analysis of ontologies of political truth ([19]; see also [20]) proposed two distinct conceptions of truth: “belief-speaking” and “truth-seeking”. Belief-speaking relates only to the speaker’s beliefs, thoughts, and feelings, without regard to factual accuracy. Truth-seeking, by contrast, relates to the search for accurate information and an updating of one’s beliefs based on that information.

The first of these two ontologies echoes the radical constructivist “truth”, based on intuition and feelings, that characterized 1930s fascism [e.g., 21]. This conception of truth sometimes rejects the role of evidence outright. For example, Nazi ideology postulated the existence of an “organic truth” based on personal experience and intuition that can only be revealed through inner reflection but not external evidence [e.g., 21, 22]. Contemporary variants of this conception of truth can be found in critical postmodern theory [23] and right-wing populism [24, 25]. The second ontology, based on truth-seeking, aims to establish a shared evidence-based reality that is essential for the well-being of democracy [26]. This conception of truth aims to be dispassionate and does not admit appeals to emotion as a valid tool to adjudicate evidence, although it also does not preclude truth-finding from being highly contested and messy ([27] vs. [28]).

For democratic societies, a conception of truth that is based on “belief-speaking” alone can have painful consequences as democracy requires a body of common political knowledge in order to enable societal coordination [26]. For example, people in a democracy must share the knowledge that the electoral system is fair and that a defeat in one election does not prevent future wins. Without that common knowledge, democracy is at risk. The attempts by Donald Trump and his supporters to overturn the 2020 election results with baseless claims of electoral fraud have brought that risk into sharp focus [29]. To achieve a common body of knowledge, democratic discourse

must go beyond belief-speaking. Democratic politics requires truth-seeking by leaders—otherwise, they may choose to remain wilfully ignorant of embarrassing information, for example, by refusing briefings from experts that are critical of their favoured public-health policy. A corollary of this requirement is that the public considers truth-seeking by politicians as an indicator of honesty rather than (only) belief speaking.

Although truth and honesty are closely linked concepts, with honesty and truthfulness being nearly synonymous [30], in the present context they need to be disentangled for clarity. We focus here primarily on conceptions of *honesty*, which refers to a virtuous human quality and a socially recognized norm, rather than *truth*, which refers to the quality of information about the world. Thus, the two ontologies of truth just introduced describe how the world can be known—namely either through applying intuition or seeking evidence, irrespective of the virtuous qualities (or lack thereof) of the beholder. Nonetheless, this ontological dichotomy maps nearly seamlessly into the different conceptions of honesty that we characterize as belief-speaking and truth-seeking, respectively.

To date, there has been much concern but limited evidence about the increasing prevalence of belief-speaking at the expense of truth-seeking in American public and political life. We aim to explore this presumed shift in conceptions of truth and honesty by focusing on Twitter activity by members of both houses of the U.S. Congress. The U.S. is not only the world’s leading democracy but it is also a crucible of the contemporary conflict between populism and liberal democracy and the intense partisan polarization it has entailed [31]. The choice of Twitter is driven by the fact that public outreach on Twitter has become one of the most important avenues of public-facing discourse by U.S. politicians in the last decade [32] and is frequently used by politicians for agenda-setting purposes [33].

Our analysis addressed several research questions: Can we identify aspects of belief-speaking and truth-seeking in public-facing statements by members of Congress? And if so, how do these conceptions evolve over time? What partisan differences, if any, are there? Is the quality of shared information linked to the different conceptions of honesty? To answer these questions, we performed a computational analysis of an exhaustive dataset of tweets posted by U.S. politicians, detecting links to misinformation sources and analyzing text of tweets and news sources.

## 2 Identifying different conceptions of honesty in political speech

We first sought to identify the two components of truth and honesty — belief-speaking and truth-seeking — in public-facing political speech by elected U.S. officials. For our analyses, we collected a corpus of tweets from members of the U.S. Congress between January 1, 2011 and March 16, 2022. After removing

retweets and duplicates, our corpus contained a total of 1,806,073 tweets (see Methods for details). Twitter accounts were categorized by party affiliation.

To measure the conceptions of honesty in text, we created two dictionaries of words associated with each of the concepts. We followed a computational grounded theory approach [34] to incorporate both expert knowledge and computational pattern recognition. We started with a list of seed words for each conception, followed by computational expansion and iterative pruning and refinement through human input (see Methods for details). We validated the dictionaries in three steps.

First, to validate the candidate keywords (selected by the authors), we created a survey on Prolific and asked participants ( $N = 50$ ) to rate each keyword’s representativeness of the two honesty components on two separate Likert scales. We then ran paired  $t$ -tests between each word’s representativeness ratings for belief-speaking and truth-seeking, respectively. Keywords that were rated as significantly more representative for belief-speaking (truth-seeking) were included in the belief-speaking (truth-seeking) dictionaries. The final dictionaries include a total of 37 keywords for each component and are provided in Table 1 (see Methods for details). Following the distributed dictionary representation (DDR) approach [35], we converted the keywords into vector embeddings using a pretrained algorithm (GloVe). Those representations capture nuanced contextual information and are amenable to a vector-similarity approach to establish overlap between each dictionary and the text or document of interest.

The second validation step applied the dictionaries to historic articles from the *New York Times* for three text categories: “opinion”, “politics” and “science” (see Methods for details). For each article, we calculated the semantic similarity  $D_b$  and  $D_t$  between the article and the belief-speaking and truth-seeking dictionaries, respectively (see Methods for details). A semantic similarity of 1.0 means that a piece of text is perfectly similar to the words contained in a dictionary, whereas a similarity of  $-1.0$  means that it is perfectly dissimilar. We found that articles in the “science” category are more similar to truth seeking than all articles on average ( $\langle D_t \rangle_{\text{sci}} - \langle D_t \rangle = 0.049$ ), followed by articles in the opinion ( $\langle D_t \rangle_{\text{op}} - \langle D_t \rangle = 0.006$ ) and politics ( $\langle D_t \rangle_{\text{pol}} - \langle D_t \rangle = -0.007$ ) category. Articles in the opinion category show the highest similarity to the belief speaking dictionary ( $\langle D_b \rangle_{\text{op}} - \langle D_b \rangle = 0.014$ ), followed by articles in the science ( $\langle D_b \rangle_{\text{sci}} - \langle D_b \rangle = 0.008$ ) and politics ( $\langle D_b \rangle_{\text{pol}} - \langle D_b \rangle = -0.007$ ) category. The analysis of *New York Times* content thus supported the validity of our dictionaries because truth-seeking and belief-speaking predominated in science and opinion, respectively — exactly as would be expected.

Finally, to establish the uniqueness of our dictionaries and to differentiate the honesty conceptions from existing similar measures, we investigated the relationship between our two components to text features such as authenticity [36], analytic language [37] and a moral component reflecting judgemental

language [38], as well as emotion valence, each measured using LIWC 2022 [39]. We calculated scores for each of these components for every tweet in the corpus. Both belief-speaking and truth-seeking are negatively correlated with the “analytic” and “positive emotion” language components, while they are positively correlated with “authentic”, “moral” and “negative emotion”. All correlations are highly significant ( $p < 0.001$ ) but small — the correlation with the largest magnitude ( $r = -0.23$ ) is observed between belief-speaking similarity and “analytic”. Details of the comparison with LIWC scores are summarised in the online supplement (Section S3). In summary, these analyses show that belief-speaking and truth-seeking are uniquely identifiable and do not overlap greatly with existing related measures of text features.

### 3 Partisan and temporal dynamics of conceptions of honesty

Having validated our dictionaries, we first obtained a baseline similarity between all tweets contained in our corpus and our dictionaries, obtaining  $\langle D_b \rangle = 0.572$  and  $\langle D_t \rangle = 0.525$ . We next produced textual scatterplots [40] (see Methods for details).

Figure 1 shows diagnostic words in a two-dimensional plot, with the x- and y-axes representing party and honesty conception respectively. Each dot is a unigram from the corpus, and its colour is associated with party keyness. The closer to a corner a word is, the more it characterizes that particular conception of honesty and party dimension. We see that Republican belief-speaking keywords, situated in the top-left corner, often refer to political opponents (“joe”, “biden”, “pelosi”, “democrats”) or conservative values (“freedom”, “america”, “god”). On the other hand, truth-seeking keywords by the same party are linked to economic (“energy”, “taxpayer”, “tax”, “business”) or health aspects (“medical”, “vaccine”). On the right hand side of the figure, we find that Democrat belief-speaking tweets often regard people (“woman”, “friend”, “family”), feelings (“happy”, “love”, “grateful”) or social justice (“equal”, “black”, “justice”), whereas truth-seeking texts particularly concern scientific topics (“climate”, “testing”, “pandemic”), as well as assisting measures (“affordable”, “protection”). It is also interesting to note how ideological positions are represented across the parties. As an example, Republicans use truth-seeking texts as a medium to convey concepts such as “control”, “enforcement”, “secure”, “individual”, “rural” and “farmer”. By contrast, Democrats use the same honesty component to frame ideas such as “safety”, “resource”, “essential”, “care”, “condition”, “public” and “worker”.

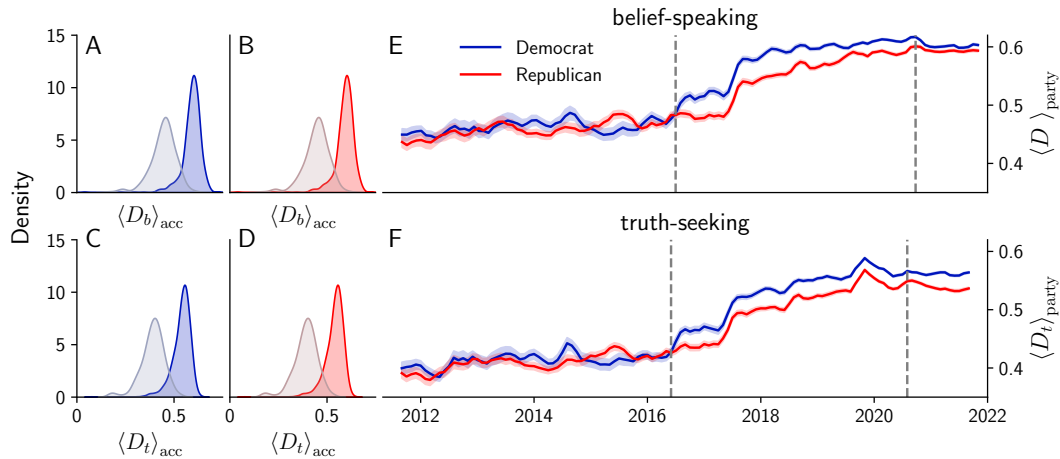

The online supplement explores the topics of politicians’ communications further. The analysis revealed that controversial topics invoked more belief-speaking or truth-seeking than the average tweet, with only a few exceptions. For example, vaccine related discourse involved far less belief-speaking than

between the first (2011-2013, 128 Democrats, 166 Republicans) and last (2019-2022, 515 Democrats, 469 Republicans) four years of tweets contained in the corpus.

For both parties, the mean belief-speaking similarity  $\langle D_b \rangle_{\text{party}}$  considerably increased from 0.45 to 0.60 for Democrats (unpaired t-test  $t = -27.57$ ,  $p < 0.001$ , Cohen’s  $d = 2.98$ ) and from 0.44 to 0.58 for Republicans ( $t = -23.46$ ,  $p < 0.001$ , Cohen’s  $d = 2.48$ ). Similarly, we see an increase in the similarity to truth-seeking  $\langle D_t \rangle_{\text{party}}$  from 0.40 to 0.55 for Democrats ( $t = -29.35$ ,  $p < 0.001$ , Cohen’s  $d = 3.21$ ) and from 0.39 to 0.52 for Republicans ( $t = -25.10$ ,  $p < 0.001$ , Cohen’s  $d = 2.56$ ). This overall increase in both belief-speaking and truth-seeking similarity also becomes apparent in Figure 2 **E** and **F**, and is especially pronounced after the presidential election in late 2016.

This parallel increase for both belief-speaking and truth-seeking could reflect the fact that in recent years, topics concerning fake news have become increasingly central to political discourse [41], resulting in opposing claims and counterclaims (e.g., Donald Trump routinely accused mainstream media such as the *New York Times* of spreading “fake news”, [4]). Whereas those claims represented mainly belief speaking, they were accompanied by increasing attempts by the media, and other actors, to correct misinformation through truth-seeking discourse.

**Figure 2** Belief-speaking and truth-seeking similarity in tweets by members of the U.S. Congress for the period 2011 to 2021 shown separately for members of each party. **A** and **B** distributions of the average within-politician belief-speaking similarity  $\langle D_b \rangle_{\text{acc}}$  in tweets of members of the Democratic and Republican parties for the years 2011 to 2013 (grey) and 2019 to 2022, respectively. **C** and **D** distributions of the average within-politician truth-seeking similarity  $\langle D_t \rangle_{\text{acc}}$ . **E** and **F** average belief-speaking and truth-seeking similarity  $\langle D_b \rangle_{\text{party}}$  and  $\langle D_t \rangle_{\text{party}}$  over time. Timelines have been smoothed with a rolling average of three months. The 95% confidence intervals were computed with bootstrap sampling over 1,000 iterations. Dashed vertical lines indicate dates of presidential elections in 2016 and 2020.

## 4 Relation of honesty components to information trustworthiness

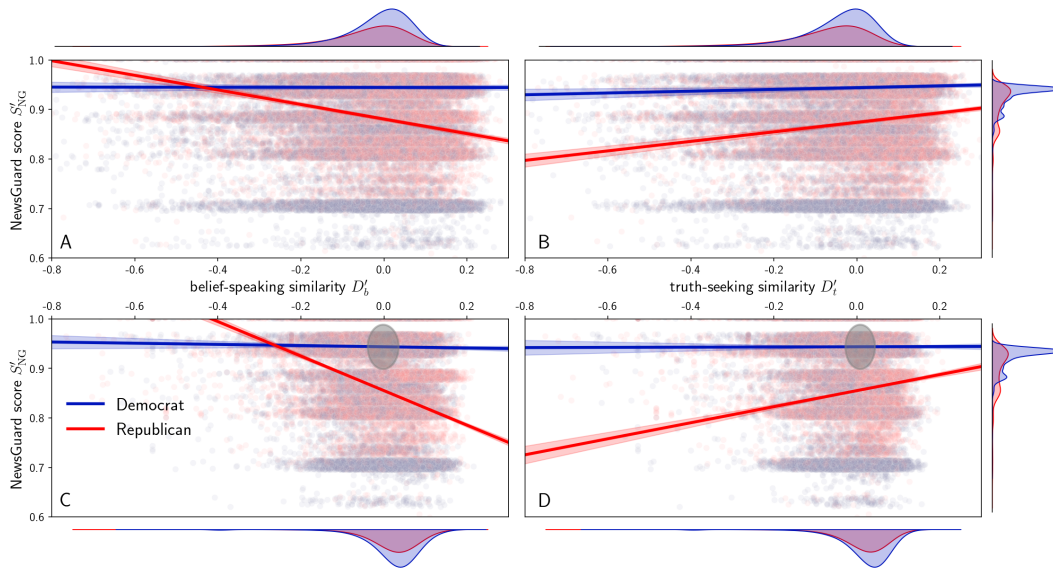

To test our hypothesis that belief-speaking is preferentially associated with dissemination of misinformation, we analyzed the association between belief-speaking and truth-seeking, respectively, to the quality of the information that is being relayed. To assess information quality, we examined links to websites external to Twitter that were shared by the accounts. We followed an approach employed by similar research in this domain [42, 43] and used a trustworthiness assessment by professional fact checkers of the *domain* a link points to. We used the NewsGuard information nutrition data base [44] as well as an independently compiled data base of domain trustworthiness labels [45] (see Methods and Section S6 in the online supplement for details).

The NewsGuard data base as of the beginning of March 2022 indexed 6,860 English language domains. Each domain is scored on a total of 9 criteria, ranging from “doesn’t label advertising” to “repeatedly publishes false information”. Each category awards a varying number of points for a total of 100. Domains with less than 60 points are considered “not trustworthy”. The majority of indexed domains (63%) are considered trustworthy. After excluding links to other social media platforms (e.g., twitter.com, facebook.com, youtube.com and instagram.com) as well as links to search services (google.com, yahoo.com), the database covered between 20% and 60% of the links posted by members of the U.S. Congress, with a steadily increasing share of links covered over time and no difference in coverage between the parties — see also Extended Data Figure 3.

For each tweet, we calculated the belief-speaking and truth-seeking similarity  $D_b$  and  $D_t$ . Figure 3 A and B shows  $S'_{NG}$ , the NewsGuard score rescaled to [0; 1] over the centered belief-speaking and truth-seeking similarity  $D'_b = D_b - \langle D_b \rangle$  and  $D'_t = D_t - \langle D_t \rangle$ , respectively, for each tweet posted by a member of Congress.

To investigate the relationship between  $D'_b$ ,  $D'_t$  and  $S'_{NG}$ , we fitted a linear mixed effects model with random slopes and intercepts for every Congress Member following Equation (1). The lines shown in Figure 3 A and B show  $S'_{NG}$  predicted by the model depending on  $D'_b$ ,  $D'_t$ , party  $P$  and their interaction terms (see Methods for details).

The analysis conducted with  $P = \text{Democrat}$  as baseline yielded a significant fixed effect for  $D'_t$  (coefficient 0.017 [0.004; 0.029],  $p = 0.0101$ ,  $t = 2.6$ ),  $P = \text{Republican}$  (coefficient -0.065 [-0.069; -0.060],  $p < 0.001$ ,  $t = -27.3$ ) the interaction between Republican and  $D'_b$  (coefficient -0.137 [-0.156; -0.118],  $p < 0.001$ ,  $t = -14.0$ ), the interaction between Republican and  $D'_t$  (coefficient 0.079 [0.060; 0.099],  $p < 0.001$ ,  $t = 8.1$ ), and the three-way interaction between  $D'_b$ ,  $D'_t$  and Republican (coefficient -0.173 [-0.212; -0.134],  $p < 0.001$ ,  $t = -8.7$ ). See Extended Data Table 2 for the full regression statistics and

**Figure 3** Relation of information quality with belief-speaking and truth-seeking. **A** and **B** show the rescaled NewsGuard score  $S'_{NG}$  of links posted by individual U.S. Congress members over centered belief-speaking ( $D'_b$ ) and truth-seeking ( $D'_t$ ) similarity measured in tweet texts, respectively. The lines and shaded areas indicate NewsGuard score predictions and 95% confidence intervals from a linear mixed effects model (see Eq. (1)). **C** and **D** show the rescaled NewsGuard score  $S'_{NG}$  over centered belief-speaking and truth-seeking similarity measured in article texts scraped from the links posted by U.S. Congress members. The lines and shaded areas indicate NewsGuard score predictions and 95% confidence intervals from a linear regression model (see Eq. (2)). The grey ellipses indicate the mean and standard deviation of the honesty component similarity and  $S_{NG}$  for articles shared by members of both parties. These articles were excluded in the regression analysis. The scatter plots show only  $10^5$  data points per panel and vertical jitter was applied to visually separate data points. Note that we truncated the y-axis at 0.6. The full data is shown in Extended Data Figure 4. Marginal distributions on the sides show the kernel density estimation over the full data on the respective axes, separated by party.

Extended Data Figure 1 for a visualization of the fixed effect of the three-way interaction.

Therefore an increase in  $D'_b$  of 10% predicted a decrease in  $S_{NG}$  of 13.7, but only for members of the Republican party. An increase in  $D'_t$  of 10% predicted an increase in  $S_{NG}$  of 1.7 for Democrats and of 9.6 for Republicans. For Democrats, we find no significant relationship between  $S_{NG}$  and belief-speaking or truth-seeking similarity. Predictions of the NewsGuard score depending on belief-speaking and truth-seeking similarity based on the two-way interactions between honesty components and party are shown as lines in panels **A** and **B** of Figure 3, respectively.

In the online supplement, we explore this pattern further by considering NewsGuard scores and honesty components broken down by state and party (Section S8). We find that the quality of information being shared by Republicans tends to be lower in southern states (e.g., AL, TN, TX, OK, KY) than in the north (e.g., NH, AK, ME), although there are also striking exceptions

(e.g., NY). For Democrats, no clearly discernible pattern across states emerges. We also find that the voting patterns during the 2020 presidential election in their home state did not affect the quality of news being shared by members of Congress.

To exclude a dependence of these results on use of the NewsGuard data base, we validated this analysis with an independently collected list of news outlet reliability from academic and fact-checking sources. Results are reported in the online supplement (Section S6) and are consistent with results reported in the main text. In addition, using the different outlet reliability information data base, we also find a significant yet smaller effect of belief-speaking similarity on the quality of shared information for Democrats that goes in the same direction as the effect for Republicans.

Finally, we wanted to know whether the content of belief-speaking and truth-seeking words in the texts found at the websites the tweets linked to was also indicative of low information quality. To this end, we attempted to scrape the text of all linked websites (see Methods). We successfully collected text from about 78% of links, with no difference in coverage for links with a low or high NewsGuard score. We excluded texts with less than 100 words and only retained one copy of the text in the case when multiple tweets contained links to the same website. In addition, we excluded all links that were posted by members of both parties (1454), such that every link had a unique party designation. This resulted in a total of 153,910 unique news texts.

We investigated the dependence of the NewsGuard score associated with the domain the text was scraped from on the belief-speaking similarity and the truth-seeking similarity of the article text (rather than in the original tweet). We fitted a linear regression model to predict the rescaled NewsGuard score  $S'_{\text{NG}}$  depending on party, the centered belief-speaking and truth-seeking similarities  $D'_b$  and  $D'_t$ , and the two-way interaction terms (see Equation (2) and Methods for details).

We show both the data for individual links and the model predictions for  $D'_b$  and  $D'_t$  in Figure 3 C and D, respectively. Again, we found a significant inverse relationship between  $P = \text{Republican}$  and  $S'_{\text{NG}}$  (coefficient  $-0.094 [-0.095; -0.093]$ ,  $p < 0.001$ ,  $t = -138.9$ ) as well as the interaction term between Republican and  $D'_b$  (coefficient  $-0.339 [-0.363; -0.316]$ ,  $p < 0.001$ ,  $t = -28.1$ ). We also confirmed the positive relationship between  $S'_{\text{NG}}$  and the interaction term between Republican and  $D'_t$  (coefficient  $0.172 [0.146; 0.198]$ ,  $p < 0.001$ ,  $t = 13.0$ ). For Democrats, we find no significant relationship between  $D'_b$  or  $D'_t$  and  $S'_{\text{NG}}$ . The three-way interaction between  $D_b$ ,  $D_t$  and party is also not significant. See Extended Data Table 3 for the full regression statistics. Our analysis of article texts therefore reproduces the main results from our analysis of tweet texts.

## 5 Discussion

We curated two dictionaries that captured the distinction between an evidence-based conception of honesty (truth-seeking) and a conception based on intuition, subjective impressions, and feelings (belief-speaking). We confirmed the validity and diagnosticity of the dictionaries by soliciting ratings from human participants and by showing that belief-speaking prevailed in opinion pieces in the *New York Times* but not in their science section, whereas the reverse occurred for truth-seeking. Applying those dictionaries to public political discourse by members of the U.S. Congress, represented by their tweets, we find a bipartisan increase of the use of both truth-seeking and belief-speaking language over time, in particular from late 2016 onward. The use of truth-seeking and belief-speaking language is particularly intense for controversial topics, and this is also a bipartisan phenomenon. The parties differ considerably, however, when the quality of information being shared is considered. Overall, Republicans tend to share information of lower quality than Democrats (see also [46]), and this difference is in large part driven by belief-speaking: the more Republicans engage in belief-speaking, the more likely they are to share low-quality information. This relationship is absent (or attenuated; see Section S5 in online supplement) for Democrats. Our results have several theoretical and practical implications that deserve to be explored.

First, our data cast a new light on several recent analyses of the American public’s information diet that have shown that conservatives are more likely to encounter and share untrustworthy information than their counterparts on the political left [42, 46–48]. Several reasons have been put forward for this apparent asymmetry, for example that partisans are motivated to share derogatory content towards the political outgroup [49]. Because greater negativity towards Democrats is mostly found in lower-quality outlets, conservatives may disproportionately share untrustworthy information because it is satisfying a need for outgroup derogation [50]. Our analysis offers another explanation, namely that the public is sensitive to cues provided by the political elites which, as we have shown here, also differ considerably in the accuracy of content that they share on social media. Specifically, Republican politicians frequently, though not always, share low-quality information and are thus providing a cue to their partisan followers of the legitimacy of those outlets. Similar evidence for the sensitivity of the public to leadership cues have been observed in the climate change arena, where the growing polarization of the public along party lines mainly resulted from the Republican leadership gradually assuming a more hostile stance towards the science of climate change [51].

Our analysis furthermore identified belief-speaking as a “gateway” rhetorical technique for the sharing of low-quality information. The more Republican politicians appeal to beliefs and intuitions, rather than evidence, the more likely they are to share low-quality information. For Democrats, this association was absent in the main analysis using NewsGuard scores, and it was much attenuated if an independent source of domain quality was used (see online

supplement). This pattern gives rise to the question why, if belief-speaking gives licence to the sharing of misinformation, is it only Republicans (or mainly Republicans) who avail themselves of that option?

A possible answer can be found in the finding that belief-speaking is associated with greater negative emotion (see online supplement). Belief-speaking may therefore result from Republican politicians’ desire to derogate Democrats, as suggested by [50]. In support, most Republican belief-speaking words identified in Figure 1 pertain to their political opponents. Few if any such words appear for belief-speaking by Democrats. On that view, negative emotional content should be a mediator of the association between belief-speaking and low quality of shared content. Conversely, if belief-speaking were instrumental in the sharing of low-quality content for other reasons, then it should mediate the association involving negative emotionality. We report two competing mediation models in the online supplement (Section S7). While the models cannot definitively adjudicate between the two possibilities, the analyses suggest the former hypothesis is in a better position to explain the mediating effect on the spread of low-quality news among Republicans. Within this framework, and concordant with [50], negative emotion associated with derogation of the opponent is the driving force behind the association between belief speaking and the spread of low-quality content among Republicans. Further indirect support for this possibility is provided by the fact that Republican members of Congress do not exclusively share misinformation. When they engage in truth-seeking, Republicans’ accuracy of shared information rises nearly to the same level as that of Democrats.

Finally, we return to the argument advanced at the outset, namely that belief-speaking can be a marker of “authenticity” which allows partisan followers to consider a politician to be honest despite them promulgating low-quality or false information. We cannot directly test this argument based on the present data because we have no way of ascertaining the perceived honesty of the politicians in our sample. We do, however, have state-level electoral data from the 2020 presidential election, which show that Republicans did not suffer an electoral penalty for their use of belief-speaking and the associated sharing of low-quality information (online supplement, Section S8). There is no association between the accuracy of Republicans’ shared information and the vote share for Trump, suggesting that voters were not deterred by belief-speaking based dissemination of misinformation.

## 6 Outlook

Our analysis was limited to communications by the “political class” in the United States, and although the U.S. is the world’s leading democracy, the trends uncovered here should not be considered in isolation but deserve to be contrasted to observations in other countries and cultures. A recent comparison of the overall accuracy of information shared by U.S. members of Congress

found that their accuracy was lower—even among Democrats—than the information shared by parliamentarians from mainstream parties in the U.K. and Germany [46]. Although there were differences between parties in those two countries as well, they were small in magnitude and European conservatives were more accurate than U.S. Republicans, underscoring that conservatism is not, per se, necessarily associated with reliance on low-quality information. Another international comparison of populist leaders (Trump in the U.S., Modi in India, Farage in the U.K. and Wilder in the Netherlands) found some commonalities among those politicians, such as the use of insults against political opponents, but also identified Trump as an outlier in the use of critical language [52]. Further examinations of belief-speaking and truth-seeking outside the U.S. context are therefore urgently needed to explore the generality of our findings and to redress the existing global imbalance in research activity [14].

Future research should also address the particular role played by social media in our analysis. We de-emphasized this angle because our analysis extended to mainstream news articles shared by the members of Congress and found very similar results compared to the tweets. However, there may be other situations in which social media play a uniquely different role from conventional mainstream media, and those situations remain to be identified and examined.

## 7 Methods

### 7.1 U.S. Congress Member tweet corpus

A corpus of contemporary political communication in English was created by scraping tweets by members of both houses of the U.S. Congress on March 15 and March 16 2022. To build the corpus, lists of Twitter handles of members of congress were collected for the 114<sup>th</sup> (from [www.socialseer.com](http://www.socialseer.com)), 115<sup>th</sup> (from [www.socialseer.com](http://www.socialseer.com)), 116<sup>th</sup> (from <https://doi.org/10.7910/DVN/MBOJNS>), and 117<sup>th</sup> (from <https://trriagecancer.org/congressional-social-media>) Congress. For the 114<sup>th</sup> and 115<sup>th</sup> Congress, only handles of senators were available. For the 116<sup>th</sup> and 117<sup>th</sup> Congress, Twitter handles were available for both houses of Congress. This resulted in a total of 1,143 unique Twitter handles, which includes Congress member staff and Congress member campaign accounts. If a politician had multiple accounts, all were included in the dataset.

For each of the Twitter handles, metadata were collected on March 16, 2022 via the Twitter API v2 using the Python package `twarc` [53]. Metadata included the account’s handle, user name, creation date, location, user description, number of followers, number of accounts followed, and tweet count. Out of the 1,143 accounts, 108 were not accessible because they had been deleted, suspended, or set to “private”.

To build the text corpus, all tweets posted by the collected Twitter accounts starting from November 6, 2010 and up to March 16, 2022 were collected,

using academic access to the Twitter API. Earlier tweets all the way back to 2006 could be retrieved, but we chose 2010 as the earliest date due to changes in the design of retweeting in the Twitter platform at that time. The retweet button was introduced in November 2009 (previously retweeting was done by hand), and it took approximately a year for users to start using it consistently. Furthermore, the prominence of Twitter in U.S. politics emerged later, especially since 2012. The language estimate facility of the Twitter API was used to remove non-English posts (58,326 tweets). The resulting corpus consisted of a total of 2,588,559 tweets, of which 1,523,050 were original tweets, 266,737 were quote tweets, 248,511 were replies and 552,892 were retweets. Note that quoting, replying and retweeting are not exclusive categories. We removed retweets from the corpus because they do not constitute original content. The number of tweets was low ( $< 200,000$ ) in the years 2010 to 2017 and increased sharply in the later years until it exceeded 700,000 tweets in 2021. We removed exact matches (i.e., duplicates) and included only tweets with more than 10 words. Furthermore, we excluded tweets from the year 2010 from subsequent analyses because their number was relatively small (772 tweets). The final corpus contained 1,806,073 tweets. Next to the tweet text, the corpus contained the tweet creation date as well as a unique identifier of the account that posted the tweet. The identifier permitted linkage to the metadata collected about the user accounts, such as party affiliation.

In addition to the perspective of individual tweets taken in the analysis presented in Section 3, we also considered the perspective of individual links taken in the analysis presented in Section 4. For this analysis, we only considered tweets that contained at least one link (1,328,411 tweets). Because a single tweet can contain more than one link, we expanded the dataset such that every entry referred to a single link, transferring the tweet-level honesty-component labels to the individual links. This resulted in a total of 1,425,813 links. From each link, we extracted the domain the link pointed to. If the link was shortened using a link-shortening service such as bit.ly, we followed the link to retrieve the full domain name. The domains were then matched against the NewsGuard domain trustworthiness data base as well as the independently compiled list of trustworthiness labels (described in Section 7.6 and Section S6 in the online supplement).

## 7.2 Honesty component keywords and validation

We relied on keywords to identify the relevant subsets of tweets that involved the presumed distinct conceptions of honesty. Initially, two lists of keywords, one for each honesty component, were generated by the researchers involved in this article. The aim was to capture linguistic cues whose presence might signal that one of the components has been enacted by the speaker. To illustrate, initial keywords for truth-seeking included terms such as “reality”,

“assess” “examine”, “evidence”, “fact”, “truth”, “proof”, and so on. For belief-speaking, initial keywords were terms such as “believe”, “opinion”, “consider”, “feel”, “intuition”, or “common sense”.

The lists were expanded computationally using a combination of the *fasttext* library [54] and colexification networks [55, 56]. Colexification networks connect words in a language based on their common translations to other languages, thus signalling words that can be used to express multiple concepts. For example, the words “air” and “breath” are considered to be colexifications because they both translate into the same word in multiple languages (“sukdun” in Manchu, “vu:jnas” in Kildin Sami, “jind” in Nenets; [57]). Colexification networks have been used recently to study emotion structures in language [58] and are predictors of word meaning ratings [55]. Including colexification networks in lexicon expansion gives word lists with a better trade-off between precision and recall [56] than previous approaches using *wordnet* or word embeddings, such as *empath*. We subsequently filtered the expanded lists to remove duplicates, overlapping terms appearing in more than one list, and lemma inflections (i.e., “convey”, “conveys”, “conveyed”). The keywords were then used to identify texts relevant to the presumed conceptions of honesty.

To validate the keyword lists, we asked participants in an online survey to score each term on two scales reflecting the honesty components. Data were acquired on September 20, 2022, from 50 individuals (male = 15, female = 34, unlisted = 1; age  $M = 39.46$ ,  $SD = 15.84$ ) using the Prolific survey platform [59]. Participants were asked to score each term on two distinct Likert scales ranging from 1 to 5, which respectively indicated low and high representativeness of the word for that honesty component. The instructions provided to participants can be found in the online supplement (Section S1). The distributions of ratings collected for each keyword are shown in the online supplement, Figures S1 and S2.

We next performed paired *t*-tests to see how participants sorted the terms into the two conceptions. The results of the *t*-tests are shown in the online supplement (Table S1). Out of 98 keywords, 61 were judged to belong in the category we previously assigned them to, 24 did not reach the significance threshold ( $p < 0.05$ ) and were therefore removed, and 13 were classified by participants as belonging to the opposite category. We followed the raters’ indications and moved the keywords that were classified as belonging to the opposite category from their original dictionary to the the other dictionary. The final list of keywords for both dictionaries is given in Table 1.

### 7.3 Identification of honesty components in text

As a first preparatory step, we removed URLs and replaced user handles on Twitter with the word *user*. We then split the tweet texts into individual tokens (words). We then created embeddings of each word contained in the honesty component dictionaries (see Table 1) with GloVe [60] trained on 840B tokens

from the Common Crawl corpus, following the distributed dictionary representation (DDR) approach [35]. We then averaged the single-word embeddings within every honesty component to create an embedded representation of the entire dictionary. Similarly, we embedded every token contained in a given tweet and calculated an average of all token embeddings to create an embedded representation of the tweet. For every tweet and both components we then calculated the cosine similarity between the embedded tweet representation and the embedded dictionary representations to arrive at a belief-speaking similarity score  $D_b$  and a truth-seeking similarity score  $D_t$  for the given tweet. Similarity scores range from -1 (not similar at all) to 1 (perfectly similar). We followed the same approach to measure belief-speaking and truth-seeking similarity in the text of the articles collected from links posted by Congress Members on Twitter (see Section 7.8 below).

To test the robustness of our results to perturbations of the dictionaries, we recalculated belief-speaking and truth-seeking similarities using versions of the dictionaries where 7 words (20%) were removed from the dictionary at random before embedding the words and calculating dictionary representations. We then re-ran the regression of  $S'_{NG}$  on  $D'_b$ ,  $D'_t$ , party and the interaction terms (see Equation (1)), where  $D'_b$  and  $D'_t$  are the centered belief-speaking and truth-seeking similarities, calculated using the representations of the perturbed dictionaries. The distribution of estimates for the fixed effects of the two-way interaction between party and  $D'_b$ , and party and  $D'_t$  over 100 perturbations are shown in Extended Data Figure 2. While the estimates for the effect of  $D'_b$  and  $D'_t$  on NewsGuard score vary by about 20% between different perturbed dictionary versions, the effects never change direction and always stay significant ( $p < 0.001$ ) for Republicans, as reported in the main text.

Lastly, in addition to GloVe [60] embeddings, we also calculated  $D'_b$  and  $D'_t$  using word2vec [61] and fasttext [54] embeddings to exclude a dependence of our results on the choice of embedding, with similar results.

## 7.4 New York Times corpus

We retrieved data from the *New York Times* (NYT) through their archive API (<https://developer.nytimes.com/docs/archive-product/1/overview>). By iterating over the months since the founding of the newspaper in the 19<sup>th</sup> century, we retrieved information on every article in the archive. The information returned by the API included the article title and an abstract that summarizes the article content, as well as additional metadata such as publication date and section of the paper. This approach is different to earlier research that used the NYT API to obtain a number of articles over time that contain certain terms, which does not yield any further text or ways to filter the data [62]. Because we needed text to identify honesty components in articles, the archive endpoint was more suitable than the term search function of the NYT API, despite not giving us the full text of all articles but only returning a summary.

We extracted three distinct categories of content from the NYT corpus based on the sections identified in the metadata: (i) An *opinion* category which comprises opinion pieces such as “OpEds”; (ii) a *politics* category consisting of articles in the sections U.S., Washington, and World; and (iii) a *science* category which includes health, science, education, and climate articles. We chose these three clusters because we expected opinion articles to contain more belief-speaking, whereas we expected science articles to contain more truth-seeking. We expected articles in the politics cluster to fall in between. We retrieved a total of 809,271 articles consisting of 240,567 opinion articles, 518,123 politics articles, and 50,581 science articles.

## 7.5 Word and topic keyness analysis

The scatterplot in panel **A** of Figure 1 was produced following the same approach used in Scattertext [40], a Python package designed to illustrate words and phrases that are more characteristic of a category than others. Starting from raw frequencies, we calculated for each word both the relative frequency across categories (i.e., parties) as well as the relative frequency within a category. These values are defined by the package author as precision and recall, respectively. The former represents the discriminative power of a word regardless of its frequency in a certain category. The latter is the percentage frequency with which a word appears in a certain category. We then transformed these two values using a normal cumulative distribution function (CDF) to scale and standardize the scores. Next, we calculated the harmonic mean of the normal CDF-transformed scores, obtaining a Scaled F-Score (SFS), which ultimately is the term scoring metric used to identify distinguishing words. Because we were comparing different categories (i.e., Democrats vs. Republicans), we calculated SFS of words for both of them, obtaining two values,  $SFS^d$  and  $SFS^r$ . Lastly, we extracted a final SFS that ranges from -1 (more Republican) to 1 (more Democratic) using the following formula:

$$SFS = 2 \cdot \left( -0.5 + \begin{cases} SFS^x & \text{if } SFS^x > SFS^y, \\ 1 - SFS^y & \text{if } SFS^x < SFS^y, \\ 0 & \text{otherwise} \end{cases} \right).$$

We repeated the same operation on word frequencies across honesty components. We divided the tweets using four quantiles and categorized those appearing in the 5th group (top 20%) of a component as belief-speaking or truth-seeking. When a tweet was part of the upper quantile for both components, then the highest among the two average scores was used to categorize the tweet. As a result, each term had two SFS: one for party distribution and one for component distribution. These two values were used as coordinates for the scatterplot shown in panel **A** of Figure 1.

## 7.6 NewsGuard nutrition labels

Following precedent [42, 43], we use source trustworthiness as an estimator for the trustworthiness of an individual piece of shared information. We use nutrition labels provided by NewsGuard, a company that offers professional fact checking as a service and curates a large data base of domains. The trustworthiness of a domain is assessed in nine categories, each of which awards a number of points: Does not repeatedly publish false content (up to 22 points), gathers and presents information responsibly (18), regularly corrects or clarifies errors (12.5), handles the difference between news and opinion responsibly (12.5), avoids deceptive headlines (10), website discloses ownership and financing (7.5), clearly labels advertising (7.5), reveals who is in charge, including any possible conflicts of interest (5), the site provides names of content creators, along with either contact or biographical information (5).

NewsGuard categorizes domains with a score of 60 or higher as “generally adheres to basic standards of credibility and transparency” [44]. Similar to [63], we use this value as a threshold below which we categorize a domain and the link pointing to it as “not trustworthy”.

After excluding links to other social media platforms (e.g., twitter.com, facebook.com, youtube.com, and instagram.com) as well as links to search services (google.com, yahoo.com), the NewsGuard database covers between 20% and 60% of the links posted by members of the U.S. Congress, with a steadily increasing share of links covered over time — see Extended Data Figure 3 A.

## 7.7 Regression

We performed a range of regression analyses to quantify the relationship between various manifestations of honesty components and information quality. For the predictions shown in Figure 3 A and B we fitted the following linear mixed effects model for tweets from members of the U.S. Congress:

$$S'_{\text{NG}} \sim 1 + D'_b \times D'_t + D'_b \times D'_t \times P + (1 + D'_b \times D'_t \mid \text{userID}) \quad (1)$$

Here,  $S'_{\text{NG}}$  is the NewsGuard nutrition score of a domain a Congress member linked to in a post on Twitter, rescaled to [0; 1].  $D'_b = D_b - \langle D_b \rangle$  and  $D'_t = D_t - \langle D_t \rangle$  are the centered belief-speaking and truth-seeking similarity of the text in the tweet with the link, respectively.  $P$  is the party designation of the account that posted the tweet which can be “Republican” or “Democrat”. We include random slopes and intercepts for every account (userID). We fitted the model using the `lmer` function from the R library `lme4` [64]. Regression results are reported in Extended Data Table 2.

For the predictions shown in Figure 3 C and D, we fitted the following model for articles that were linked to by the U.S. Congress members:

$$S'_{\text{NG}} \sim D'_b + D'_t + P \times D'_b + P \times D'_t. \quad (2)$$

Here,  $D'_b$  and  $D'_t$  are the belief-speaking and truth-seeking similarity, respectively, of the article text retrieved from the link. We fitted the model using an ordinary least squares fitting approach from the Python package statsmodels [65]. Regression results are reported in Extended Data Table 3.

## 7.8 News article collection

Our corpus of tweets contained 219,787 unique links to news articles that were shared by members of Congress. We scraped the text using Newspaper3k [66], a python package for scraping and curating news articles. Some links were broken, restricted, or could not be scraped by the package, resulting in 78% of total scraping coverage. In addition, 1,914 links did not contain a valid NewsGuard score. We removed from the main analysis articles that were shared by members of more than one political party (i.e., a link was shared either by Republicans or Democrats, but not both). This resulted in the removal of 1,454 links (0.85% of all remaining links), which were analyzed separately (see ellipses in Figure 3). When broken down by trustworthiness (NewsGuard score  $< 60$ ), the coverage for trustworthy links ( $N = 212,983$ ) was 82%, and 79% for untrustworthy links ( $N = 4,892$ ). A test of independence between the share of articles scraped for trustworthy and untrustworthy links did not reach statistical significance  $\chi^2(1) = 2.81$ ,  $p = 0.094$ . The distribution of NewsGuard scores as well as the belief-speaking and truth-seeking similarity in each article is shown in Extended Data Figure 4 C and D.

## 8 Data availability

The tweet IDs of the tweet texts and URLs of the articles analysed in this study are deposited in OSF under accession code <https://doi.org/10.17605/OSF.IO/VNY8K>. We provide code to download tweets from tweet IDs and article texts from article URLs and process the data in the code repository that accompanies this article <https://doi.org/10.5281/zenodo.6826515>.

Dictionaries of keywords associated with the different conceptions of honesty are deposited in OSF under accession code <https://doi.org/10.17605/OSF.IO/VNY8K>.

The independently compiled list of domain accuracy and transparency scores is deposited on GitHub under accession code <https://doi.org/10.5281/zenodo.6536692>.

The NewsGuard data base used to assess domain trustworthiness is commercially available from NewsGuard and cannot be shared publicly.

Aggregated values for information trustworthiness and honesty components for tweets and articles used to produce all figures in this article are deposited in OSF under accession code <https://doi.org/10.17605/OSF.IO/VNY8K>.

## 9 Code availability

Python 3.8.5 and R 4.2 were used to collect the data and perform the data analysis presented in this study. Data collection and analysis code is available under MIT license in a GitHub repository under accession code <https://doi.org/10.5281/zenodo.6826515>.

## 10 Acknowledgments

We acknowledge Travis Coan for helpful feedback on the manuscript.

## 11 Funding

This report was funded by the Templeton Foundation through a grant awarded to Wake Forest University. SL was also supported by funding from the Humboldt Foundation in Germany, and SL and DG are beneficiaries of the ERC Advanced Grant PRODEMINFO (101020961). JL was supported by the Marie Skłodowska-Curie grant No. 101026507.

## 12 Author information

## 13 Ethics declarations

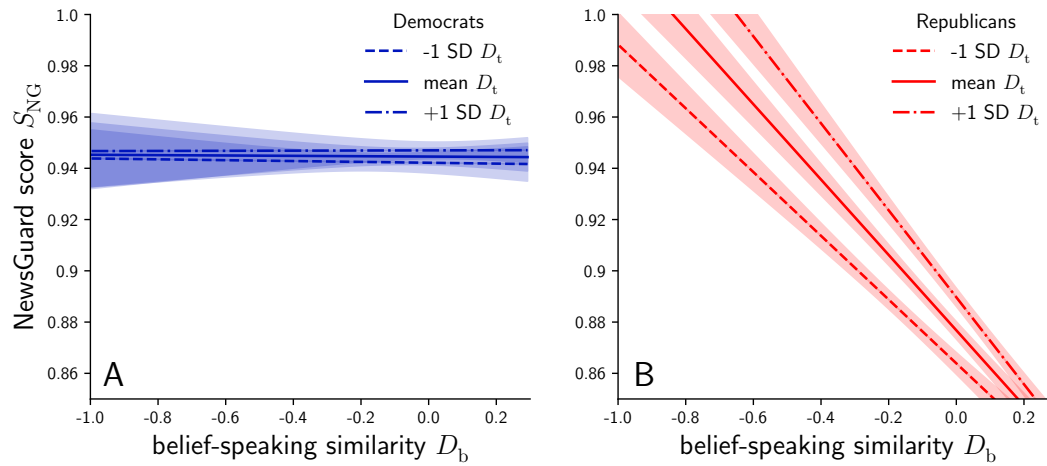

### 13.1 Inclusion and ethics

This study is based on publicly available archival Twitter data on U.S. Members of Congress and their official staff and campaign accounts. Only public figures are analyzed and only content that was not deleted by the time of data retrieval was considered. All U.S. Members of Congress in curated Twitter account lists are included as long as their Twitter accounts were public by the retrieval data. We focused on the two major parties to have sufficient evidence for statistical analysis and our results cannot be extended to independent members of congress or members of other parties besides the Democratic and the Republican party.

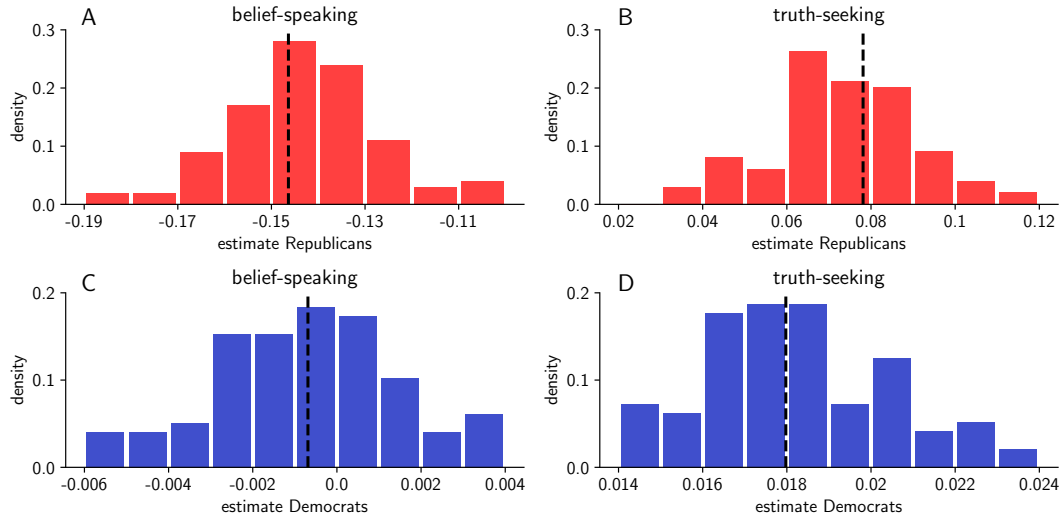

### 13.2 Competing interests

The authors declare no competing interests.

## 14 Extended data figures and tables

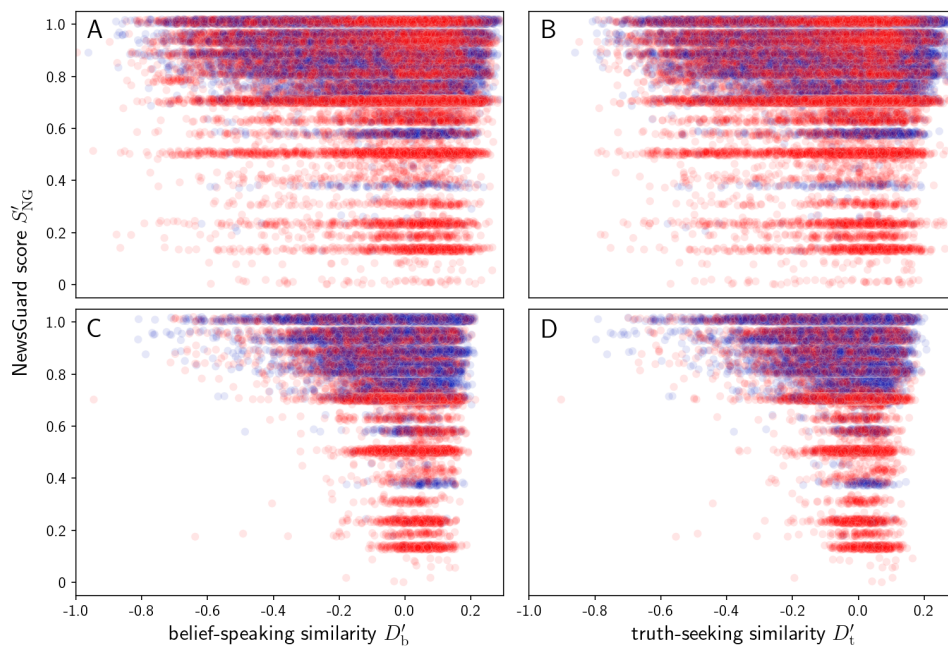

**Extended Data Figure 1** Prediction of rescaled NewsGuard score  $S_{NG}$  for different values of centered belief-speaking similarity  $D'_b$  and different levels (-1 SD, mean, +1 SD) of centered truth-seeking similarity  $D'_t$  based on the fixed effect estimate of the three-way interaction  $P \times D'_b \times D'_t$  (see linear mixed effects model in Eq. (1)) for tweets from **A** Democrat and **B** Republican members of the U.S. Congress.

**Extended Data Figure 2** Dictionary robustness tests. **A** and **B** show the distribution of estimates of the effect of belief-speaking and truth-seeking similarity  $D_b$  and truth-seeking similarity  $D_t$  for Republicans from the linear mixed model (see Eq.(1)), where  $D_b$  and  $D_t$  were calculated with a perturbed dictionary for every tweet, respectively. **C** and **D** show the distribution of estimates of the effect of  $D_b$  and  $D_t$  for Democrats, respectively. Distributions were calculated from 100 dictionary perturbation iterations.

**Extended Data Figure 3** Share of links posted by accounts belonging to members of the U.S. Congress pointing to domains indexed in **A** the NewsGuard data base and **B** the independently compiled list.

**Extended Data Figure 4** **A** and **B** rescaled NewsGuard score  $S'_{NG}$  of links shared in tweets by members of the U.S. congress over centered belief-speaking similarity  $D'_b$ . Red and blue dots denote tweets by Democrats and Republicans, respectively. **B** shows  $S'_{NG}$  over centered truth-seeking similarity  $D'_t$  in tweets. **C** and **D** show the same information but with  $D'_b$  and  $D'_t$  calculated using the text of the articles that were linked instead of the tweet texts.

**Extended Data Table 1** Keyword lists for the two honesty components belief-speaking and truth-seeking.

Belief-speaking	Truth-seeking
basically	actually
believe	analyze
claim	assess
confide	correct
consider	correction
contemplate	determine
contention	evaluate
envisage	evidence
feel	examine
frankly	exploration
genuinely	fact
guess	information
hint	inspect
judge	investigate
look	observe
obvious	proof
obviously	prove
of course	question
opinion	quiz
plainly	real
ponder	reality
position	rectify
presume	research
probably	revise
seem	sample
sensation	science
sentiment	scrutinize
signal	search
suggest	specify
suggestion	supervise
suppose	test
surely	trace
think	track
trust	trial
try	truth
view	validate
virtually	verify

**Extended Data Table 2** Results of a linear mixed effects model for the dependence of the rescaled NewsGuard score of each link  $S'_{\text{NG}}$  on centered belief-speaking similarity  $D'_b$  and truth-seeking similarity  $D'_t$  in tweets, with party  $P$  as fixed variable following Eq.(1). The table reports results for the fixed effects. 247,947 observations were included. Regression was performed with the function `lmer` from the R library `lme4` [64].

	coef.	std. err.	$t$	$P >  t $	[0.025	0.975]

## **S1 Instructions to participants during keyword validation**

What follows is a verbatim copy of the instructions provided to the participants who rated the keywords.

*People can have different ideas about what it means to be "honest".*

*We are focusing on two ideas of honesty.*

*One is based on intuition, "gut feeling" and authenticity. According to this idea, people speak the truth and are honest when they "say what they felt to be true in the moment". Whether or not claims are correct reflections of reality is not as important. We call this idea of honesty and truth "belief speaking".*

*The other idea is based on evidence, analysis, and veracity. According to this idea, people speak the truth and are honest when their claims align with the evidence. Whether or not claims are authentic reflections of a person's feelings is not as important. We call this idea of honesty and truth "truth seeking".*

*Your task is to judge, for each of the words below, which idea of honesty it is most closely related to. If someone uses that word, does it likely reflect belief speaking? Or does the word likely reflect truth seeking?*

*Please indicate which idea of honesty each word is closest to by selecting, for each column, a value from 1 to 5, where 1 means that the word is the least representative of that category, and 5 means that the word is highly representative of that category. There are no right or wrong answers, we are interested in your analysis of the meaning of those words.*

## S2 Dictionary keyword validation results

To validate the keywords contained in the belief-speaking and truth-seeking dictionaries we asked raters on the survey platform Prolific [?] to score each term on two scales reflecting their representativeness for belief-speaking and truth-seeking, respectively. The collected data contains responses from 50 participants and ratings from 1 to 5 for each keyword. Data were acquired September 20, 2022, the instructions provided to participants are reported in section “Prolific Questionnaire Instructions”. The distributions of ratings collected for each keyword are shown in Figures S1 and S2.

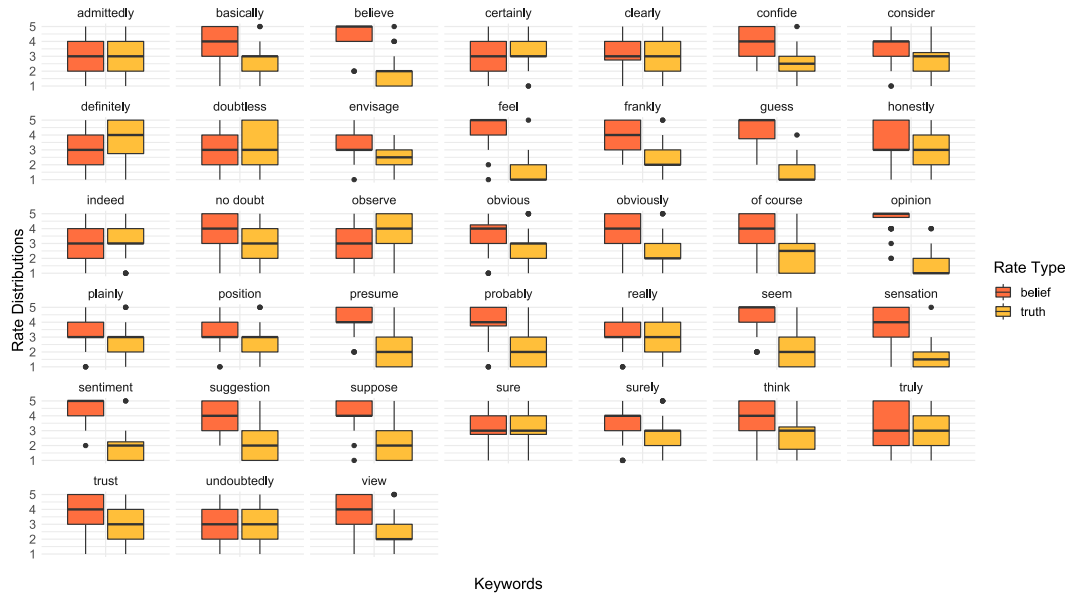

To determine the validity of each keyword, we conducted t-tests between the distribution of representativeness ratings for belief-speaking and the distribution of representativeness ratings for truth-seeking for every keyword. If the difference between the distributions was significant ( $\alpha = 0.05$ ), the keyword was included in the belief-speaking dictionary if the t-value was positive, and in the truth-seeking dictionary if the t-value was negative. Results of the t-tests for each keyword are reported in Table S1.

**Table S1:** Results of the t-tests of the keyword ratings performed by 50 raters. “component” indicates the honesty component a given keyword was initially assigned to. The column “valid” is a binary variable indicating whether our initial component assignment for the keyword was confirmed by the raters, based on the t-value direction (positive for belief-speaking, negative for truth-seeking) and a significance level of  $\alpha = 0.05$ . The column “opposite” indicates whether a keyword was shifted to the opposite honesty component dictionary. This happened when the t-value was significant ( $\alpha = 0.05$ ) but in the opposite direction than initially assumed. Rating distributions are shown in Figure S1 for the keywords that were initially categorised as “belief-speaking” and in Figure S2 for the keywords that were initially categorised as “truth-seeking”.

**Figure S1** Boxplots of rates distributions for keywords we originally categorized as ‘belief-speaking’. Clear cases where our categorizations were confirmed are, for example, ‘opinion’, ‘feel’, ‘believe’. Examples of discarded keywords are ‘clearly’, ‘undoubtedly’, ‘sure’. The only reversed case is ‘observe’, categorized as ‘truth-seeking’ by the raters.

**Figure S2** Boxplots of rates distributions for keywords we originally categorized as ‘truth-seeking’. Clear cases where our categorizations were confirmed are, for example, ‘verify’, ‘fact’, ‘evidence’. Examples of discarded keywords are ‘witness’, ‘testimony’, ‘overhaul’. Instances of reversed keywords are ‘suggest’, ‘ponder’, ‘judge’, categorized as ‘belief-speaking’ by the raters.

**Table S2** Pearson correlation between belief-speaking and truth-seeking similarity and LIWC scores measuring the prevalence of “analytic”, “authentic” and “moral” language, as well as positive and negative emotions in tweets.

Honesty component	Analytic	Authentic	Moral	Pos. emotion	Neg. emotion
Belief-speaking	-0.23	0.09	0.07	-0.07	0.11
Truth-seeking	-0.12	0.04	0.01	-0.19	0.04

### S3 LIWC text analysis

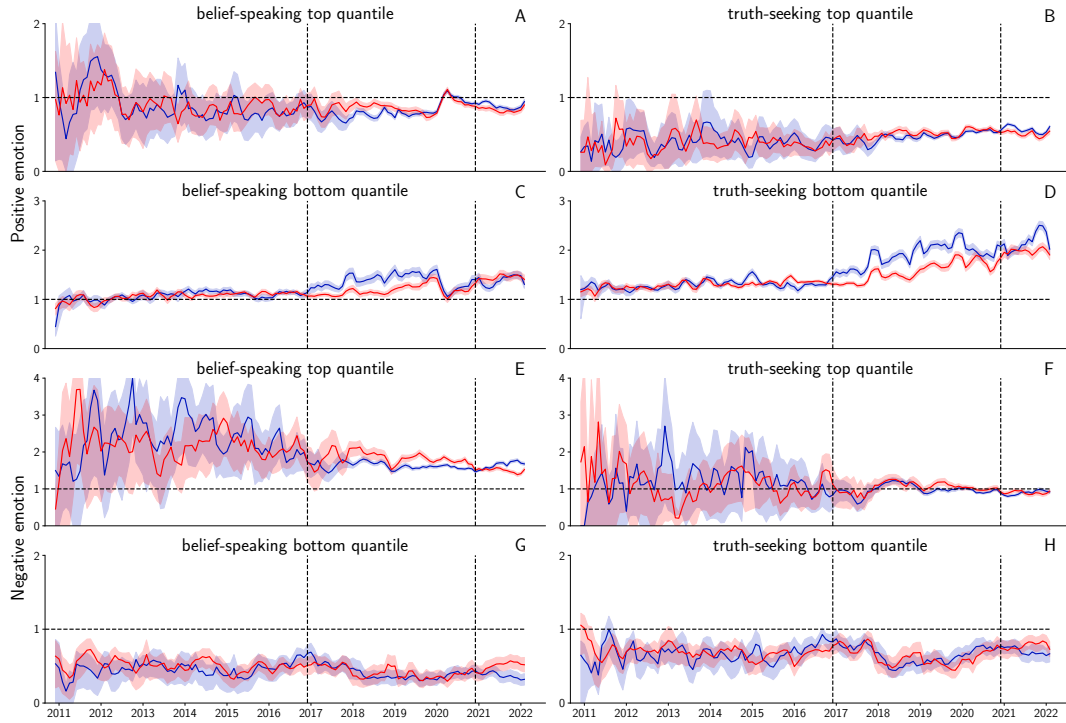

We explored the content of the tweet texts within the two honesty components using the Linguistic Inquiry and Word Count (LIWC) program [?]. LIWC is a text processing software that has been continuously developed for more than two decades and computes several indicator variables from text based on word lists generated by psychologists and validated in various experiments — similar to our approach in generating the word lists for the belief-speaking and truth-seeking word lists.

With the Beta version of LIWC-2022 software (<https://www.liwc.app/>), we computed the scores for each tweet text for the following LIWC categories: emotion (divided into positive and negative), authenticity, analytic, and moral. Positive and negative emotion scores are related to the sentiment polarity of a text. Authenticity indicates to what extent the language used is perceived as honest and genuine [?]. Analytic is linked to logical and formal thinking [?]. Finally, moral reflects the judgmental language expressed by positive or negative evaluation of someone’s behavior or character [?]. The scores provide an efficient summary of those attributes in each text.

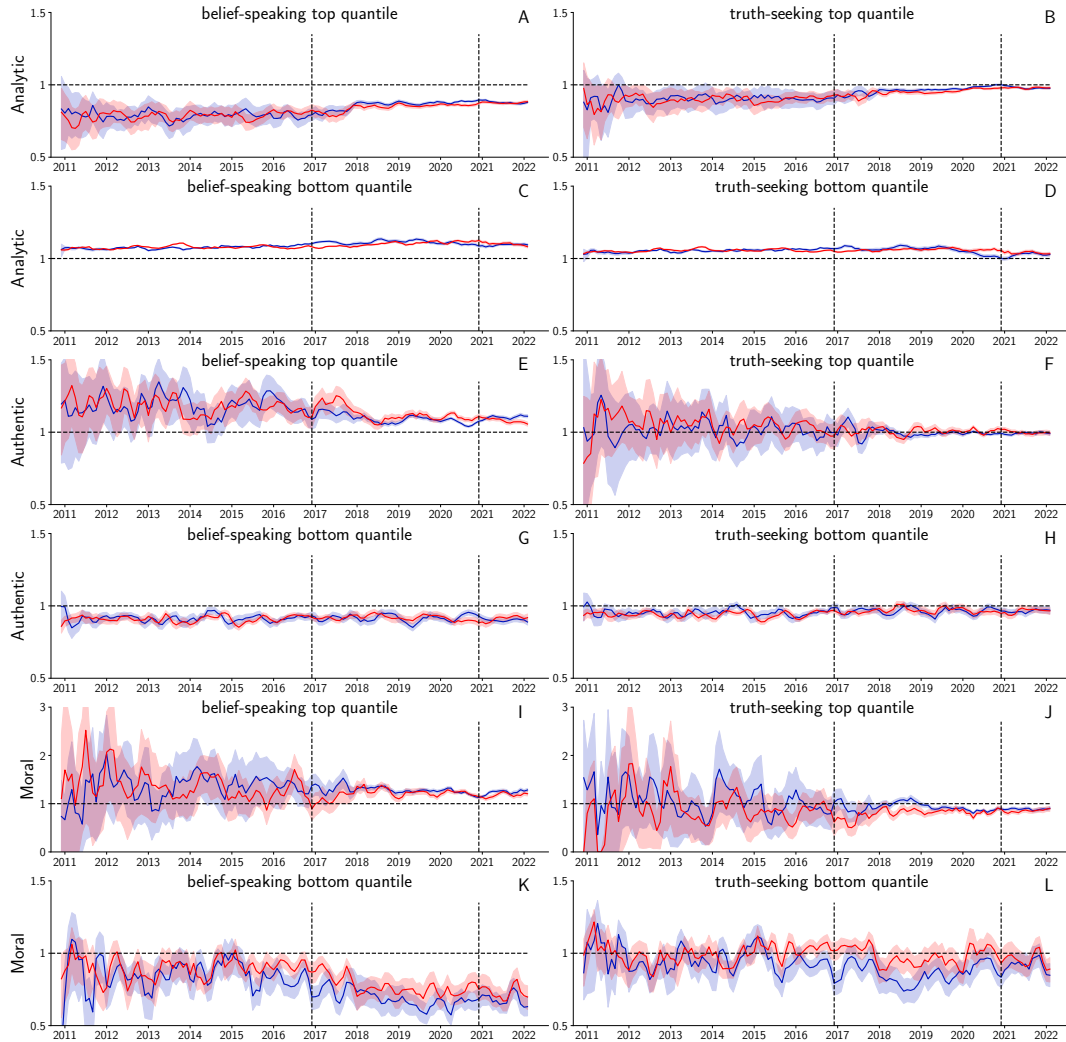

Correlations between LIWC scores and belief-speaking and truth-seeking similarity are given in Table S2. In addition, we show the time-development of the scores broken for the top and bottom quantiles of belief-speaking and truth-seeking similarity for positive and negative emotions in Figure S3 and for the “analytic”, “authentic” and “moral” components in Figure S4.

Figure S3 shows the timelines of LIWC scores for positive and negative emotions for the top and bottom quantile for belief-speaking and truth-seeking similarity. We performed the same analysis for “authentic”, “analytic” and “moral” language, using LIWC dictionaries as described in the Methods Section “LIWC text analysis”. The time development of “analytic” language broken down by honesty component is shown in Figure S4, panels **A** to **D**, the time development of “authentic” language is shown in Figure S4 panels **E** to **H** and the time development of “moral” language is shown in Figure S4 panels **I** to **L**.

**Figure S3** Time-development of LIWC scores of positive and negative emotions in tweets of members of the U.S. Congress. Panels **A** and **B** show the score for positive emotions for tweets that belong to the top belief-speaking and truth-seeking similarity quantile, while panels **C** and **D** show the positive emotion score for the bottom similarity quantiles. Timelines are normalized by the overall emotion score (baseline) for positive emotions measured in the full corpus. The dashed horizontal line at 1.0 corresponds to prevalence equal to baseline. Red and blue lines correspond to tweets by Republicans and Democrats, respectively. Panels **E**, **F**, **G** and **H** show the same information as panels **A**, **B**, **C** and **D**, but for the negative emotion score instead of the positive emotion score. The 95% confidence intervals (indicated by shading) were computed with bootstrap sampling over 1,000 iterations. Dashed vertical lines indicate dates of presidential elections in 2016 and 2020. Timelines are smoothed, using a rolling average over three months.

**Figure S4** Time-development of LIWC scores of “analytic”, “authentic” and “moral” language in tweets of members of the U.S. Congress. Panels **A** and **B** show the “analytic” score for tweets that belong to the top belief-speaking and truth-seeking similarity quantile, while panels **C** and **D** show the “analytic” score for the bottom similarity quantiles. Timelines are normalized by the overall emotion score (baseline) for positive emotions measured in the full corpus. Red and blue lines correspond to tweets by Republicans and Democrats, respectively. Panels **E** to **H** show the same information as panels **A** to **D**, but for “authentic” language. Panels **I** to **L** show the same information but for “moral” language. The 95% confidence intervals (indicated by shading) were computed with bootstrap sampling over 1,000 iterations. Dashed vertical lines indicate dates of presidential elections in 2016 and 2020. Timelines are smoothed, using a rolling average over three months.

## S4 Topic analysis

To investigate the prevalence of belief-speaking and truth-seeking, we performed topic modelling using the Python package BERTopic [? ]. Following a three-step approach, the package uses the Sentence-BERT (SBERT) framework to create the embeddings for each document, then uses the Uniform Manifold Approximation and Projection (UMAP) technique [? ] to decrease the dimensionality of embeddings and identify clusters through HDBSCAN [? ]. Finally, it creates topic representations using class-based term-frequency inverse-document-frequency (TF-IDF). We opted for BERTopic rather than more established techniques such as Latent Dirichlet Allocation (LDA) because the former performs better when modelling short and unstructured texts as in the case of Twitter data when compared to the latter [? ? ]. Since BERTopic relies on an embedding approach, data was only minimally preprocessed to keep the original sentence structure. This means we lemmatized the entire dataset to produce cleaner topic representations, and only removed URLs from the texts.

Considering that the dataset contains more than 1.5 million tweets, we also applied thresholds to the topic modelling. The document minimum frequency was set to 200 in order to reduce the number of small topics. The number of neighboring sample points used when making the manifold approximation was set to 100 to produce a more global view of the embedding structure. Finally, the minimum document frequency for the c-TF-IDF was set to 50 to reduce the topic-term matrix size and decrease memory-related issues during the computation. With these settings, the model was able to identify 363 topics.

To check whether this was an optimal number of topics, we used *ldatuning* [? ], an R package that trains multiple models and calculates validation metrics. Despite the fact that *ldatuning* does not employ embeddings but Latent Dirichlet allocation and that the data it modelled was preprocessed by removing stopwords and irrelevant text (numbers, unknown characters, URLs, Twitter handles), it indicated 300 as an optimal number of topics for the dataset, thus converging towards the BERTopic results.

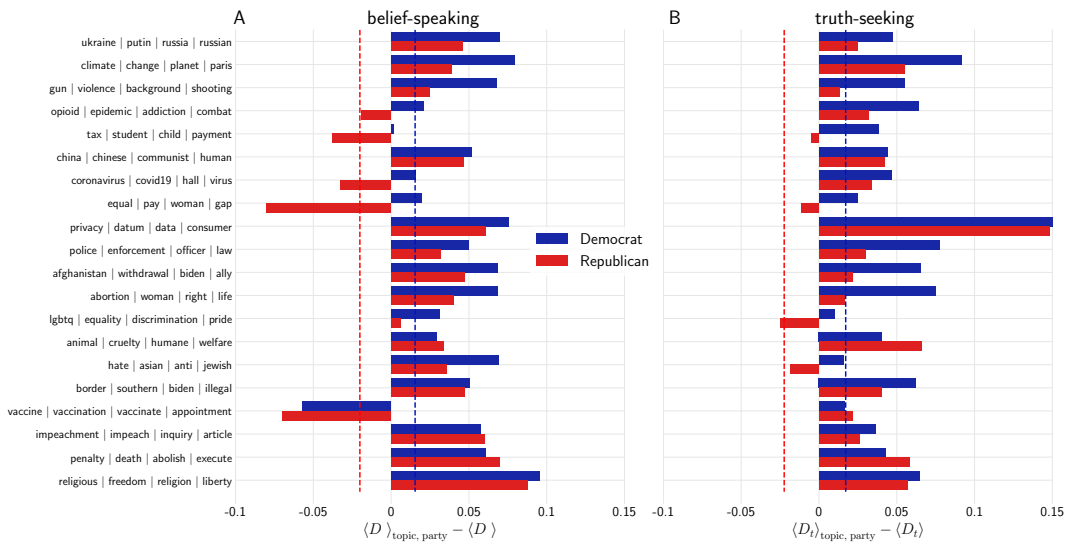

Building on the topic modelling, we investigated the difference between belief-speaking and truth-seeking in communication about controversial topics in U.S. politics, such as foreign policy, climate change, or the death penalty, and how this differs by party. The selection of controversial topics presented here is inspired by other research in the same area, e.g. [? ] and current research topics of non-partisan think-tanks, e.g. [? ]. By default, BERTopic assigns each document to a single topic. Therefore, we used this information to calculate how particular controversial topics were distributed across parties and components, as shown in Figure S5. To do this, we grouped the tweets by the topic they were assigned to as well as by the parties that created them and averaged their belief and truth scores. We repeated this procedure for all 20 topics

of interest. We also calculated the average belief and truth scores for all 363 topics found by BERTopic. Finally, we subtracted the specific component averages of a topic  $t$  from the full corpus component averages to highlight how parties differ in honesty-speech when talking about controversial matters.

In Figure S5 **A** and **B** we show the average belief-speaking and truth-seeking similarity within a given topic  $\langle D_b \rangle_{\text{topic, party}}$  and  $\langle D_t \rangle_{\text{topic, party}}$ , minus the average belief-speaking and truth-seeking similarity calculated over the full corpus  $\langle D_b \rangle$  and  $\langle D_t \rangle$  for members of the Democratic and Republican parties, respectively. Each horizontal bar in the figure thus represents the deviation from the average score across the entire corpus. A value greater than zero implies that a topic involved more belief-speaking or truth-seeking than expected on average, and a value less than zero implies below-average invocation of belief-speaking or truth-seeking. It is immediately apparent that most of these controversial topics invoked more belief-speaking or truth-seeking than the average tweet, with only a few exceptions. For example, vaccine related discourse involved far less belief-speaking than any other topic for both parties.

There is, however, also considerable heterogeneity in the amount of belief-speaking and truth-seeking used between the topics: Topics such as impeachment, religious freedom and Putin/Ukraine show a large amount of belief-speaking in both parties, whereas topics such as vaccines show little. Similarly, for truth-seeking the topics climate change, impeachment and religious freedom show a large share of this honesty component for both parties whereas the LGBTQ topic shows little.

There are also marked differences in the balance of belief-speaking and truth-seeking within a topic and between the parties. The topics of climate change, gun violence, COVID-19 and the gender pay gap have the largest difference in belief-speaking, with tweets by Democrats containing more belief-speaking than those by Republicans. The topics of climate change, police, Afghanistan and abortion have the largest difference in truth-seeking with tweets by Democrats containing more truth-seeking while for the topic of animal cruelty, tweets by Republicans contain more truth-seeking.

**Figure S5** Panels **A** and **B** show the difference between within-topic within-party belief-speaking and truth-seeking similarity  $\langle D_b \rangle_{\text{topic, party}}$  and  $\langle D_t \rangle_{\text{topic, party}}$  and mean corpus belief-speaking and truth-seeking similarity  $\langle D_b \rangle$  and  $\langle D_t \rangle$ , respectively for a range of hand-picked controversial topics. Values for Democrats and Republicans correspond to blue and red bars, respectively. Dashed lines indicate the mean belief-speaking and truth-seeking similarity for each party in the full corpus  $\langle D_b \rangle_{\text{party}} - \langle D_b \rangle$  and  $\langle D_t \rangle_{\text{party}} - \langle D_t \rangle$ , respectively.

## S5 Validation using an independently compiled list of unreliable news sources

To exclude a dependence of the main results reported in Section “Relation of honesty components to information trustworthiness” on use of the NewsGuard data base, we validated this analysis with an independently collected list of news outlet reliability from academic and fact-checking sources. Details on how this list was compiled are reported in Section “Independent list of untrustworthy sources” below. Using this list, we can assign an accuracy score  $S_a$  ranging from 1 to 5 as well as a transparency score  $S_t$ , ranging from 1 to 3 to each domain. In addition, a domain with an accuracy score of  $\leq 2$  and/or a transparency score of 1 will be labelled as “unreliable”. Similar to the analysis above, we analyse the dependency of the accuracy score  $S'_a$  rescaled to  $[0; 1]$  and the transparency score  $S'_t$  rescaled to  $[0; 1]$  on the centered belief-speaking and truth-seeking similarity measured in tweet texts  $D'_b = D_b - \langle D_b \rangle$  and  $D'_t = D_t - \langle D_t \rangle$ , respectively. We fit a linear mixed effects model with party as fixed variable and random slopes and intercepts for every Congress Member for each of the two scores:

$$S'_a \sim 1 + D'_b \times D'_t + D'_b \times D'_t \times P + (1 + D'_b \times D'_t \mid \text{userID}) \quad (1)$$

$$S'_t \sim 1 + D'_b \times D'_t + D'_b \times D'_t \times P + (1 + D'_b \times D'_t \mid \text{userID}) \quad (2)$$

Again, we found a significant positive fixed effect of  $D'_t$  (coefficient 0.095 [0.076; 0.114],  $p < 0.001$ ,  $t = 9.7$ ) and accuracy  $S'_a$  as well as for party  $P = \text{Republican}$  (coefficient -0.0640 [-0.071; -0.057],  $p < 0.001$ ,  $t = -17.2$ ). We reproduce the negative effect of the interaction term between  $D'_b$  and Republican (coefficient -0.103 [-0.133; -0.073],  $p < 0.001$ ,  $t = -6.8$ ), and a positive effect for the interaction term between  $D'_t$  and Republican (coefficient 0.066 [0.036; 0.095],  $p < 0.001$ ,  $t = 4.4$ ). Similarly, the three-way interaction between  $D_b$ ,  $D'_t$  and Republican is significant and negative (coefficient -0.273 [-0.338; -0.208],  $p < 0.001$ ,  $t = -8.3$ ).

Different from the main analysis, we also find a significant negative effect for  $D'_b$  (coefficient -0.123 [-0.143; -0.104],  $p < 0.001$ ,  $t = -12.4$ ).

We see the same pattern for the transparency score  $S'_t$ , where we see a significant negative relation with  $D'_b$  and a significant positive relation with  $D'_t$  for both parties.

Full regression statistics are reported in Tables [S3](#) and [S4](#). We note that there is extensive agreement between the trustworthiness labels in the NewsGuard data base and the alternative data base: An account that is labelled “untrustworthy” in the NewsGuard data base has a high chance of being labelled “unreliable” in the alternative database as well (Krippendorff’s  $\alpha$  of 0.84).

**Table S3** Results of a linear mixed effects model for the dependence of the rescaled accuracy score of each link  $S'_a$  on centered belief-speaking similarity  $D'_b$  and centered truth-seeking similarity  $D'_t$  in tweet texts, with party  $P$  as fixed variable following Eq.(1). The table reports results for the fixed effects. 218,045 observations were included. Regression was performed with the function `lmer` from the R library `lme4` [? ].

	coef.	std. err.	$t$	$P >  t $	[0.025	0.975]

**Table S5** Description of accuracy scores.

Score	Label	Description
1	False Information	No or very little accuracy (e.g. fake news, conspiracy, satire)
2	Clickbait	Might contain smatterings of facts but is mostly misleading or clickbait
3	Biased	Mixed accuracy, half-truths, left/right bias
4	Mainstream	Low bias, mainstream media
5	Scientific	No reporting bias, scientific information

**Table S6** Description of transparency scores.

Score	Label	Description
1	No Transparency	Intentionally misleading or no information about editorial process (e.g. fake news, conspiracy)
2	Mixed Transparency	Sites with (partially) transparent intention, but can still be misunderstood because of the way articles are written (e.g. bias, clickbait, satire)
3	Transparent	Sites with a transparent editorial process and legal notice (e.g. mainstream, scientific news)

## S6 Independent list of untrustworthy sources

We compiled a list of trustworthiness ratings from a range of academic sources and fact-checking sites. Most of these sources were also used by [?]. The list includes Bufale [?], Bufalopedia [?], Butac [?], BuzzFeed News [?], Columbia Journalism Review [?], Fake News Watch [?], Media Bias Fact Check [?], Politifact [?], and Melissa Zimdars [?]. After removing duplicates, our list contained 4,767 domains, 1,677 of which were also contained in the NewsGuard data base, as of March 1, 2022.

The main challenge in combining lists from different fact checkers lies in unifying the labels the fact checkers assign to the domains. To address this, we devised a scheme where we rated each domain on two dimension that we consider to be important to assess reliability and trustworthiness of information: “accuracy” and “transparency”. We devise an accuracy score  $S_a$  that varies from 1 (false information) to 5 (scientific) and a transparency score  $S_t$  that varies from 1 (no transparency) to 3 (transparent). We provide a more detailed description of the five accuracy and three transparency levels in Tables S5 and S6. Mappings of the labels of individual fact checking sites to accuracy and transparency scores as well as the full list of domains are provided at [?].

After mapping all individual lists to the accuracy and transparency dimensions, we label every domain that has an accuracy score of 1 (False Information) or 2 (Clickbait) and/or a transparency score of 1 (No Transparency) as “unreliable”. This results in a total of 2,170 domains being labelled as “unreliable” and 2,597 as “reliable”. For the 1,677 domains that are contained in both data

bases, the Krippendorff's  $\alpha$  between “untrustworthy” (score < 60 in NewsGuard) and “unreliable” in the independently compiled data base is 0.84, which shows a very high agreement between the two databases. The independently compiled domain list including the unified labels is openly accessible at <https://doi.org/10.5281/zenodo.6536692>.

After excluding links to other social media platforms (e.g., twitter.com, facebook.com, youtube.com, and instagram.com) as well as links to search services (google.com, yahoo.com), the database covers a very similar share of links as the NewsGuard data base (between 20% and 60%) — see also Extended Data Figure 3 **B** in the main article.

## S7 Mediation analysis

Why is it the case that belief speaking is the preferred means to spread low-quality information? One possibility is that belief-speaking is the result of Republican politicians' desire to disparage Democrats, as suggested by [? ], given that belief speaking was found to be associated with greater negative emotion (see Section "LIWC text analysis"), and given that lower-quality information tends to be biased towards negativity [? ]. According to this theory, the relationship between belief-speaking and low-quality shared information should be mediated by negative emotional content. On the other hand, if believe speaking were involved in the dissemination of poor quality content for other reasons, it should mediate the association involving unpleasant emotions.

To test these opposing predictions, we examined separately for Democrats and Republicans whether (1) negative emotion mediated the effects of belief speaking on sharing low-quality information, or (2) belief speaking mediated the effects of negative emotion on sharing low-quality information. For each user, we computed mean scores of negative emotion (measured via LIWC), belief speaking, and prevalence of sharing low-quality news (average NewsGuard score of the shared articles ). We conducted a causal mediation analysis using the 'mediation' R package [? ] and a bootstrap method with 10,000 iterations. Among Republicans, when considering negative emotion as a mediator, the effect of the direct path was not statistically significant (mean direct effect = -7.74, 95% CI of bootstrapped samples = [-18.11, 2.06],  $p = .119$ ). The mediation, however, was significant (average causal mediation effect = 0.-9.46, 95% CI = [-15.18, -4.06],  $p < .001$ ), accounting for 55% of the total effect. When considering belief speaking as a mediator, the opposite pattern emerged: the direct effect was statistically significant (mean direct effect = -8.12 95% CI of bootstrapped samples = [-12.99, -3.40],  $p = .001$ ), but the average causal mediation effect did not reach statistical significance, (average causal mediation effect = -1.61, 95% CI = [-3.76, 0.46],  $p = .13$ ). See tables S7 and S8 for the full details. These results align with the findings of [? ], suggesting that the relationship between belief-speaking and low-quality shared information is indeed driven by negative emotion.

**Table S7** Mediation analysis with belief speaking as mediator. ACME = average causal mediation effect; ADE = average direct effect. 492 observations were included for Republicans and 525 for Democrats. Mediation was performed using the function `mediate` from the R package `mediation`, version 4.5.0.

		Estimate	<i>P</i>	[0.025	0.975]
Republicans	ACME	-1.609	0.129	-3.757	0.461
	ADE	-8.120	0.001	-12.989	-3.399
	Total Effect	-9.729	<.001	-14.069	-5.522
	Prop. Mediated	0.1654	0.129	-0.046	0.467
Democrats	ACME	1.598	<.001	0.872	2.411
	ADE	0.186	0.760	-1.067	1.417
	Total Effect	1.784	0.002	0.670	2.950
	Prop. Mediated	0.896	0.002	0.442	2.327

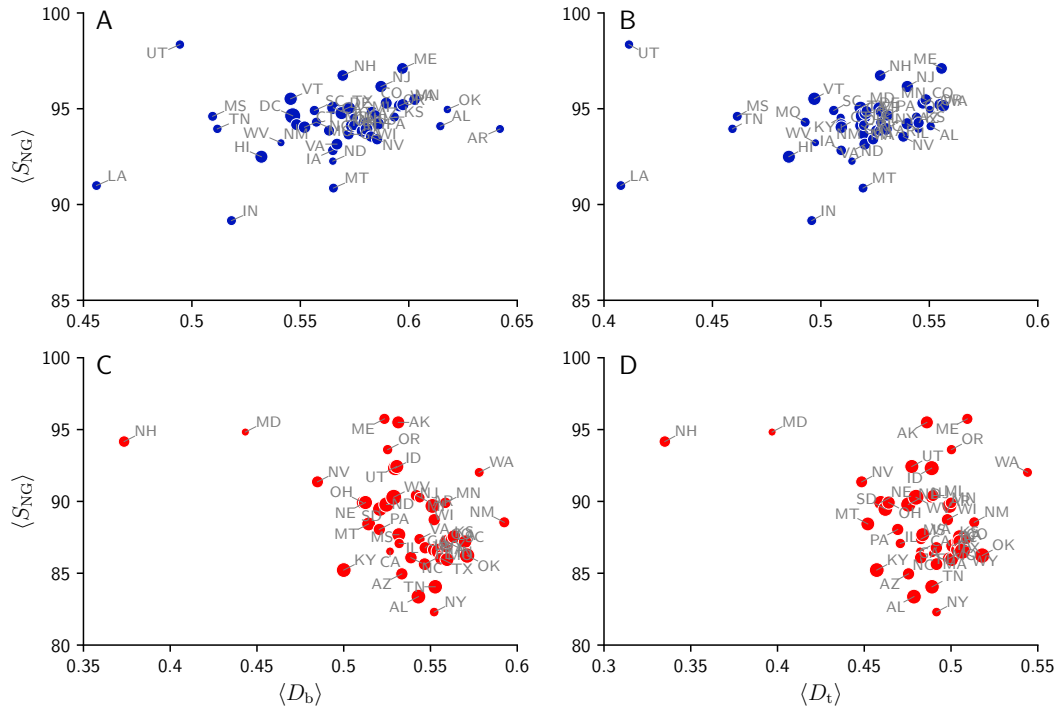

**Table S8** Mediation analysis with negative emotion as mediator. ACME = average causal mediation effect; ADE = average direct effect. 492 observations were included for Republicans and 525 for Democrats. Mediation was performed using the function `mediate` from the R package `mediation`, version 4.5.0.

		Estimate	<i>P</i>	[0.025	0.975]
Republicans	ACME	-9.458	<.001	-15.181	-4.061
	ADE	-7.743	0.119	-18.108	2.060
	Total Effect	-17.201	<.001	-26.763	-8.135
	Prop. Mediated	0.550	0.001	0.225	1.212
Democrats	ACME	0.225	0.769	-1.339	1.767
	ADE	9.188	<.001	5.232	13.067
	Total Effect	9.413	<.001	5.772	12.962
	Prop. Mediated	0.024	0.769	-0.147	0.205

## S8 Honesty components by state

To examine geographical heterogeneity, we averaged NewsGuard scores across representatives and senators within each state, broken down by party. The results are shown in Figure S6, plotting each state's NewsGuard score against average belief-speaking (left panels) and truth-seeking (right), respectively. The size of plotting symbols additionally represents the vote share for Trump (in the bottom panels) and for Biden (top) during the 2020 presidential election. It can be seen that quality of information being shared by Republicans tends to be lower in southern states (e.g., AL, TN, TX, OK, KY) than in the north (e.g., NH, AK, ME), although there are also striking exceptions (e.g., NY). For democrats, no clearly discernible pattern emerges.

We also considered the outcome of the 2020 presidential election and compared the states that were called for Trump and Biden, respectively. In states that were called for Biden, Democrat members of Congress on average have a NewsGuard score of 94.6 whereas Republicans have 89.3. In states that were called for Trump, the NewsGuard scores were 93.7 (Democrats) and 88.0 (Republicans), respectively. These differences were small, suggesting that the electoral pattern in their home states did not affect the quality of information shared by members of Congress.

**Figure S6** Honesty components by state. Panels **A** and **C** show the NewsGuard score  $S_{NG}$  over belief-speaking similarity  $D_b$  averaged by state for Democratic and Republican members of the U.S. Congress, respectively. Panels **B** and **D** show the NewsGuard score  $S_{NG}$  over truth-seeking similarity  $D_t$  averaged by state for Democratic and Republican members of the U.S. Congress, respectively. Marker sizes are scaled with the percentage of votes for Biden in the 2020 presidential election for the panels showing Democratic Congress members, and with the percentage of votes for Trump in the panels showing Republican Congress members. Note that the axes are scaled separately for each panel to reduce visual density of the point cloud.
