

The Sky Distribution and Magnitudes of Starlink Satellites by the Year 2027

Anthony Mallama

anthony.mallama@gmail.com

2022 September 1

Abstract

Visual magnitudes and sky coordinates are projected for the full constellation of Starlink satellites. The results are presented in the form of sky maps and numerical tables. Observer latitudes from the equator to 60° are considered. The solar elevations include -12° (the end of nautical twilight), -18° (the end of astronomical twilight) and -30° .

1. Introduction

The largest group of spacecraft currently in orbit is the constellation of Starlink satellites. They presently number over 2,000 and are projected to total nearly 12,000 by year 2027. Professional astronomers are already experiencing interference from Starlink spacecraft when making celestial observations (Mroz et al., 2022) and amateur stargazers are concerned as well for both scientific and aesthetic reasons (Mallama and Young, 2021). The International Astronomical Union has established a Centre for the Protection of Dark and Quiet Skies from Satellite Constellation Interference to address this problem. A reading list of papers on satellite constellations and their impact is provided in Appendix A.

This paper forecasts the distribution and brightness of Starlink satellites in the sky after the entire constellation is in place. The method is to compute the azimuth, elevation and range for each satellite visible at ground locations from the equator to latitude 60°. These coordinates are based on spacecraft orbital elements and they allow for computation of the apparent magnitude. Brightness is calculated from a phase curve equation derived from visual magnitudes.

Section 2 lists the spacecraft orbital elements and describes the method of computing satellite topocentric coordinates. The method of determining whether a satellite is in sunlight or in the Earth's shadow is also explained. Section 3 describes the phase functions for three Starlink satellite designs. These curves characterize brightness versus the phase angle which is measured at the satellite between the Sun and the Earth. Then the equation for computing apparent magnitudes is presented. More details about the Starlink phase functions can be found in Appendix B. Section 4 gives examples of resulting sky maps which plot satellite locations by azimuth, elevation and magnitude. Sample tables of numerical results are also provided. Comprehensive sets of map and numerical results for a wide range of observer latitude and solar distances below the horizon are given in Appendix C. Section 5 considers the limitations and uncertainties in this study. Section 6 presents the conclusions and compares the satellite number density to an earlier forecast made by McDowell (2020).

2. Satellite orbits and celestial coordinates

Starlink satellites will occupy in 8 'shells' at altitudes ranging from 336 to 570 km as listed in Table 1. There are several orbital planes for each shell and a number of satellites in each plane. For this study the ascending nodes of the planes for each shell are distributed evenly over 2π radians. Likewise, the orbital

anomaly for each satellite in a plane is 2π divided by the number of satellites in that plane. The geocentric coordinates of satellites are determined from the elements including the anomalies. Examples of these coordinates for the satellites in medium inclination and high inclination shells are shown in Figures 1 and 2, respectively.

Figure 1 (left). The distribution of satellites in shell 1 with orbital inclination 53.0 degrees is shown as a polar plot with the radial axis extending from 0 degrees in the direction of the north pole of the Earth's axis to 180 in the opposite direction. Satellite positions are concentrated toward the equator and away from the poles.

Figure 2 (right). The distribution of satellites in shell 4 with orbital inclination 97.6 degrees is illustrated. Satellite positions are more concentrated toward polar latitudes than in Figure 1.

Table 1. Orbital information

Shell	1	2	3	4	5	6	7	8
Altitudes	550.	540.	570.	560.	560.	336.	341.	346.
Inclinations	53.0	53.2	70.0	97.6	97.6	42.0	48.0	53.0
Planes	72	72	36	6	4	50	50	50
Sats_per_plane	22	22	20	58	43	50	50	50

The information in Table 1 is taken from <https://en.wikipedia.org/wiki/Starlink> as retrieved on 2022 July 15. 'Planes' here is 'count' in the source document, and 'sats_per_plane' here is 'sat_per' in the source. The number of planes and satellites per plane for shells 6 through 8 was not listed in the source document, so each is taken to be approximately the square root of 'satellites' there.

The satellite azimuth and elevation at a selected ground location are determined by transforming its geocentric coordinates to topocentric values at the latitude and longitude on the ground. Examples of the satellite azimuths and elevations shown in Figures 3 and 4 illustrate how the distribution changes with observer latitude.

Figure 3 (left). The distribution of satellites above the horizon as seen from the equator is plotted. Density increases with distance from zenith but the azimuthal distribution is practically uniform.

Figure 4 (right). The satellite distribution as seen from latitude 60° north is heavily concentrated toward the south (azimuth 180°) because most orbital inclinations are less than that latitude.

Satellites may be hidden from sunlight by the Earth's shadow in which case they do not interfere with optical astronomy. The shadow limit at a shell's orbital altitude corresponds to an angular radius measured at center of the Earth relative to a line extending from the Sun through that geocenter location. The radius values are given by the arc-cosine of the Earth's radius divided by the distance of a satellite from the geocenter. These shadow radii range from about 67° for the highest altitude satellites to 72° for the lowest. Figures 7 and 8 in Section 4 illustrate how the Earth's shadow eclipses satellites over a larger area of sky as the Sun's distance below the horizon grows.

3. Phase function and satellite brightness

Phase curves describe spacecraft brightness as a function of the angle measured at the satellite between the Sun and the observer. The chassis of a Starlink spacecraft is shaped like a flat panel and its

orientation is nominally perpendicular to the nadir-z zenith direction. Additionally, there is a large solar array attached at a right angle to the zenith-facing side of the panel and it projects upward. These components are shown schematically in Figure 5 along with their orientation in space.

Sunlight scatters from Starlink spacecraft in a manner that differs sharply from that of round bodies like the Moon and planets. Those celestial bodies preferentially reflect light back in the direction from which it originated. Starlink spacecraft, on the other hand, reflect sunlight both backwards and forwards. The forward scattering is likely due to a near-specular reflection from the flat nadir side.

Figure 5. This schematic of the Starlink spacecraft illustrates its shape and orientation relative to the Sun and Earth.

There have been two changes to the detailed design of Starlink satellites, so far. The Original Design was the brightest and about 400 spacecraft (<https://planet4589.org/space/stats/star/starstats.html>, derived from data retrieved 2022 June 15) were launched before it was modified in response to the concerns of astronomers. The manufacturer, SpaceX, added a sunshade to help reduce luminosity and about 1,100 of this new model, called VisorSat, were launched (ibid). VisorSats were typically 1.3 magnitudes fainter than the Original Design (Mallama, 2021a) at operational altitudes. However, when SpaceX upgraded the communication system for Starlink from radio to laser in 2021 the sunshades had to be dropped from the design (Witze, 2022). In order to compensate for removing the shades SpaceX began development of reflective materials for the nadir side of the flat panel to direct sunlight away from observers beneath the spacecraft. The new design occurred at about serial number 3000 and so this latest model is referred to as Series-3000 herein. This latest design of Starlink is typically about 0.5 magnitudes brighter than VisorSats although it is still approximately 0.8 magnitudes fainter than the Original Design (Mallama, 2022).

Besides their different characteristic luminosities each Starlink design has its own distinct phase function. Figure 6 shows that the response for the Original Design is relatively flat, while that of VisorSat

is strongly curved and that for Series-3000 is intermediate between the two. Since the phase function for Series-3000 lies between the two others and because this model represents the current Starlink design, the magnitudes in this paper rely on its phase function as indicated by Eq. 1,

$$v = 3.817 + 0.06970 \phi - 0.0003999 \phi^2 + 5 \log(d / 1000)$$

Eq. 1

where v is the apparent visual magnitude, ϕ is the phase angle in degrees, and d is the distance from the satellite to the observer in km. The distance term accounts for the inverse square law of light.

Figure 6. Phase functions corresponding to the three Starlink designs for spacecraft at their operational altitudes. The visual magnitudes used to derive these functions are close to the V-band of the Johnson-Cousins photometric system of electronic measurements. Dashed lines are extrapolations beyond the observed range; satellites are rarely seen at these extreme phase angles.

The phase function accounts for some of the apparent brightness of Starlink satellites. However, their complex shapes make the luminosity sensitive to spacecraft attitude (yaw, pitch and roll) in a way that is not yet generally understood. Brightness variations due to attitude appear as scatter in an empirically derived phase function diagram. A study of Starlink magnitudes (Mallama, 2021b) indicated that this scatter was about 0.4 magnitudes after observational uncertainties were removed. Therefore, the apparent magnitudes computed in this paper have that amount of scatter applied. The Box-Muller algorithm for normal statistical distributions as implemented here:

https://masuday.github.io/fortran_tutorial/random.html is employed. More details about the Starlink phase function and the scatter are provided in Appendix B.

4. Distribution in the sky and apparent magnitudes

The geometric and photometric aspects of Starlink satellites discussed in the previous two sections allow for simulation of their appearance in the sky. Examples of sky maps showing distributions and magnitudes as well as numerical output are presented in this section. The statistical results include satellite counts by magnitude, by elevation and by quadrant of the sky, as well as the number of satellites in sunlight and in shadow.

Maps for an observer at the terrestrial equator and with the Sun on the celestial equator are shown as Figures 7 and 8, while corresponding numerical data is given in Tables 2 and 3. At the end of astronomical twilight when the Sun is 18° below the horizon (Figure 7 and Table 2) satellites are visible in all quadrants of the sky; 89 of them are brighter than magnitude 7, and 21 of those are above 30° elevation. When the Sun has descended to 30° below the horizon (Figure 8 and Table 3) there no satellites visible in the quadrants opposite the solar azimuth; only 19 satellites are brighter than magnitude 7 and none of those are above 30° elevation.

Similar maps and tables for observer latitudes from the equator to 60° are presented in Appendix C. Results are given for the dates of solstice and equinox, and for solar distances of 12° , 18° and 30° below the horizon. The distribution and magnitudes of satellites is discussed in the Section 6.

Figure 7 (left). The distribution and brightness of Starlink satellites for an observer at the equator on a date of equinox with the Sun 18° below the horizon at azimuth 270° is plotted.

Figure 8 (right). The Sun is 30° below azimuth 270° . This plot along with Figure 7 illustrates how the Earth's shadow progressively hides more satellites as the Sun descends further below the horizon. They also demonstrate how the forward-scattering phase curve enhances the brightness of satellites that are aligned with the solar azimuth.

5. Limitations of this study

Several factors place limits on the results presented here. Most importantly, the future of the Starlink constellation is uncertain. The source of the orbital data listed in Table 1 does not give complete Keplerian elements and some assumptions had to be made as stated there. Furthermore, since only a fraction of the satellites have actually been launched the actual configuration and number of the Starlink satellites in space may turn out to be different. Also, the projected completion date for launching all of the nearly 12,000 satellites may not be met.

Another issue is the phase curve. The magnitudes in this study are computed from the curve for Series-3000 satellites. However, there have already been three Starlink designs and each has had its own distinctive reflection characteristics and phase curve. Future design modifications would likely result in new phase functions.

Besides changes to the shape of Starlink satellites, SpaceX CEO Elon Musk has stated in this video https://youtu.be/XP5k3ZzPf_0?t=561 that the future Starlink 2.0 will be a larger spacecraft with a length of 7 meters. This increased size may reflect more light and appear brighter in the sky.

Finally, SpaceX has requested approval to launch 30,000 satellites in addition to the 12,000 already approved. So, the sky could become much more crowded with bright satellites than this study projects.

6. Conclusions

The sky maps and numerical results in Section 4 and in Appendix C indicate the impact of Starlink satellites on celestial observation by the year 2027. During astronomical twilight hundreds of spacecraft brighter than magnitude 7 will be visible from any one location. However, most of those will be within 30° of the horizon and only tens of satellites will be seen at higher elevations. The number of visible satellite diminishes rapidly after astronomical twilight ends.

Additionally, spacecraft that are aligned with the solar azimuth and those opposite that azimuth tend to be brighter because of forward and backward scattering of light. Finally, the density of satellites is greater toward celestial south for an observer north of the terrestrial equator and vice-versa due to the geocentric distribution of satellites.

Finally, the results obtained here are compared with two previous studies. First, McDowell (2020) forecast “a latitude-dependent areal number density of between 0.005 and 0.01 objects per square degree at airmass <2”. The corresponding numbers from this study range from 0.003 at the equator to 0.006 at 50° latitude. These smaller densities are due lower orbital altitudes for satellites in shells 2 through 5. At the time of McDowell’s study these heights were expected to range from 1110 to 1325 km but now they are from 540 to 560. Second, Lawler et al. (2022) predict that latitudes near 50° will experience the worst satellite interference. This analysis finds that the number density increases to that latitude as noted above, and then it falls off sharply by latitude 60°. So, these findings agree.

Appendix A. Reading list of papers on satellite constellation interference

These papers are grouped by subject matter as follows: impacts on observations, working group reports and conference material, satellite brightness, mitigation strategies and general. Titles are given here to indicate content while full citations are provided in the Reference section.

Appendix B. Phase functions

The material in this appendix supplements the discussion of phase functions in Section 3. The empirically derived phase functions for Original Design, VisorSat and Series-3000 spacecraft plotted in Figure X are shown along with the observations in Figures B-1, B-2 and B-3.

Figures B-1, B-2 and B-3 (left to right). The observed and modeled phase curves for Original Design, VisorSat and Series-3000 Starlink satellites are compared. The scatter is mostly due to variations in spacecraft attitude (yaw, pitch and roll).

A study of Starlink magnitudes measured electronically (Mallama 2021b) revealed that phase functions can change with time as illustrated in Figure B-4. This variation may have resulted from systematic changes to spacecraft attitude.

Figure B-4. Two markedly different VisorSat phase functions separated by several months are illustrated.

The plots in Figures B-5 and B-6 demonstrate moderate sensitivity of magnitudes in the sky to phase function by comparing Series-3000 to VisorSat. The magnitudes for Series-3000 are somewhat brighter at high elevations. This result is consistent with the phase curves in B-2 and B-3 where VisorSats are fainter around phase angle 90°. At low elevations the magnitudes are more nearly equal.

Figures B-5 (left) and B-6 are for an observer at 30° latitude with the Sun 18° below the horizon at azimuth 281° . B-5 is for the Series-3000 phase function and B-6 is for VisorSat.

The phase curves were derived from visual magnitudes observed by Jay Respler at latitude 40.330 and longitude 74.445 west, and by the author at 38.982 and 76.763. They are reported at <http://www.satobs.org/seesat/index.html>.

Appendix C. Sky maps and numerical tables for latitudes from 10° to 60°

Results for observer latitudes 0° through 60° are presented in appendix sections C-0 through C-6. Each section is divided into subsections α , β and γ for the Sun at declinations -23.4° (winter solstice), 0.0° (equinox) and $+23.4^\circ$ (summer solstice). The subsections contain sky maps and numerical results for the Sun's distance below the horizon of 12° (end of nautical twilight), 18° (end of astronomical twilight) and 30° , respectively. For example, in Appendix C-0- α the number '0' is for latitude 0° , the ' α ' is for solar declination -23.4° , and the results include solar zenith angles of 102° , 108° and 120° . The maps and numerical results for southern observer latitudes are the same as their northern counterparts with two trivial exceptions; the sky quadrants on each side of the east-west line are reversed and the solar declinations are switched on the solstice dates.

Appendix C-0- α . Latitude 0°, solar declination -23.4°

Figure C-0- α . The distribution and brightness of Starlink satellites is illustrated for an observer at the equator on a date when the Sun is at declination -23.4°. From left to right the Sun's distance below the western horizon is 12° (end of nautical twilight), 18° (end of astronomical twilight) and 30°.
