ABSTRACT

The early evolution of the quasar luminosity function (QLF) and black hole mass function (BHMF) encodes key information on the physics determining the radiative and accretion processes of supermassive black holes (BHs) in high-z quasars. Although the QLF shape has been constrained by recent observations, it remains challenging to develop a theoretical model that explains its redshift evolution associated with BH growth self-consistently. In this study, based on a semi-analytical model for the BH formation and growth, we construct the QLF and BHMF of the early BH population that experiences multiple accretion bursts, in each of which a constant Eddington ratio is assigned following a Schechter distribution function. Our best-fit model to reproduce the observed QLF and BHMF at $z \approx 6$ suggests that several episodes of moderate super-Eddington accretion occur and each of them lasts for $\tau \simeq 20 - 30$ Myr. The average duty cycle in super-Eddington phases is $\simeq 15\%$ for massive BHs that reach $\geq 10^8$ M_☉ by $z \simeq 6$, which is nearly twice that of the entire population. We find that the observed Eddington-ratio distribution function is skewed to a log-normal shape owing to detection limits of quasar surveys. The predicted redshift evolution of the QLF and BHMF suggests a rapid decay of their number and mass density in a cosmic volume toward $z \geq 6$. These results will be unveiled by future deep and wide surveys with the James Webb Space Telescope, Roman Space Telescope, and Euclid.

Keywords: Supermassive black holes (1663); Quasars (1319); High-redshift galaxies (734)

1. INTRODUCTION

The growth of massive BHs in active galactic nuclei (AGN) is elegantly related to their luminous accretion phases across the cosmic time [\(Soltan](#page-23-0) [1982\)](#page-23-0). The cosmic BH accretion history and their radiative efficiency are well constrained by comparing the mass density of supermassive black holes (SMBHs) in the local universe and the mass accreted onto BHs inferred from the integration of the QLF based on multi-wavelength observations (e.g. [Cavaliere et al.](#page-20-0) [1971;](#page-20-0) [Small & Blandford](#page-23-1) [1992;](#page-23-1) [Yu & Tremaine](#page-24-0) [2002;](#page-24-0) [Marconi et al.](#page-22-0) [2004;](#page-22-0) [Mer](#page-22-1)[loni & Heinz](#page-22-1) [2008;](#page-22-1) [Shankar et al.](#page-23-2) [2004,](#page-23-2) [2009;](#page-23-3) [Delvecchio](#page-20-1)

[Corresponding author: Wenxiu Li; Kohei Inayoshi](#page-20-1) [wenxiuli@pku.edu.cn; inayoshi@pku.edu.cn](#page-20-1)

[et al.](#page-20-1) [2014;](#page-20-1) [Ueda et al.](#page-23-4) [2014;](#page-23-4) [Tucci & Volonteri](#page-23-5) [2017;](#page-23-5) [Si](#page-23-6)[cilia et al.](#page-23-6) [2022\)](#page-23-6).

Currently the $z \sim 6$ quasar population is well constrained by multiband surveys [\(Jiang et al.](#page-21-0) [2008;](#page-21-0) [Willott](#page-23-7) [et al.](#page-23-7) [2010a;](#page-23-7) [Chambers et al.](#page-20-2) [2016;](#page-20-2) [Matsuoka et al.](#page-22-2) [2018a,](#page-22-2) [2019;](#page-22-3) [Dey et al.](#page-20-3) [2019\)](#page-20-3) along with the QLF (e.g., [Kashikawa et al.](#page-21-1) [2015;](#page-21-1) [Jiang et al.](#page-21-2) [2016;](#page-21-2) [Onoue et al.](#page-22-4) [2017;](#page-22-4) [Matsuoka et al.](#page-22-5) [2018b\)](#page-22-5). Deep spectroscopic observations of high-z quasars enable us to measure the virial BH mass with the Mg II single-epoch method and bring insights of the mass distribution (e.g., [Jiang et al.](#page-21-3) [2007;](#page-21-3) [Kurk et al.](#page-21-4) [2007;](#page-21-4) [Willott et al.](#page-23-8) [2010b;](#page-23-8) Bañados et al. [2018;](#page-19-0) [Onoue et al.](#page-22-6) [2019;](#page-22-6) [Shen et al.](#page-23-9) [2019\)](#page-23-9). However, extrapolation of the Soltan-Paczyński argument toward higher redshifts of $z \geq 6$ is still limited because of the current capability of high-z quasar observations [\(Mc-](#page-22-7)[Greer et al.](#page-22-7) [2013;](#page-22-7) [Yang et al.](#page-24-1) [2016;](#page-24-1) [Wang et al.](#page-23-10) [2019;](#page-23-10) [Fan et al.](#page-20-4) [2019\)](#page-20-4). Nevertheless, in the era of the James

[∗] [Kavli Astrophysics Fellow](#page-20-1)

Webb Space Telescope (JWST) and forthcoming facilities, e.g., the Roman Space Telescope (RST) and Euclid, infrared imaging and spectroscopic observations will unveil a wealth of information on the high-z quasar properties and their environments [\(Rieke et al.](#page-22-8) [2019;](#page-22-8) [Akeson](#page-19-1) [et al.](#page-19-1) [2019;](#page-19-1) [Laureijs et al.](#page-21-5) [2011\)](#page-21-5). Deep observations of high-z quasars and their host galaxies will shed light on the early BH evolution and help answer questions regarding the existence of SMBHs in the early universe [\(Volonteri](#page-23-11) [2012;](#page-23-11) [Haiman](#page-20-5) [2013;](#page-20-5) [Inayoshi et al.](#page-21-6) [2020\)](#page-21-6), and early development of BH-galaxy coevolution (e.g., [Wang et al.](#page-23-12) [2013;](#page-23-12) [Venemans et al.](#page-23-13) [2017;](#page-23-13) [Izumi et al.](#page-21-7) [2021;](#page-21-7) [Inayoshi et al.](#page-21-8) [2022;](#page-21-8) [Habouzit et al.](#page-20-6) [2022\)](#page-20-6). Future gravitational-wave observations both via space interferometers such as LISA, Tianqin, and Taiji, and pulsar timing array experiments [\(Sesana et al.](#page-23-14) [2008;](#page-23-14) [Amaro-](#page-19-2)[Seoane et al.](#page-19-2) [2017;](#page-19-2) [Luo et al.](#page-21-9) [2016;](#page-21-9) [Smits et al.](#page-23-15) [2009\)](#page-23-15) will enable us to probe the abundance of coalescing massive BH binaries at high redshifts, setting constraints on the properties of their quasar counterparts [\(Kocsis et al.](#page-21-10) [2006;](#page-21-10) [Haiman et al.](#page-20-7) [2009;](#page-20-7) [Padmanabhan & Loeb](#page-22-9) [2022\)](#page-22-9).

The shapes of the QLF and BHMF contain key information on the physics characterizing the radiative and accretion processes of high-z SMBHs, as well as their seeding mechanisms in principle. Two approaches have been utilized to model those distribution functions. The first is semi-analytical modeling, in which BH seed formation, gas accretion, and BH mergers associated with the hierarchical growth of the parent dark matter (DM) halos are taken into account in a simplified way. This is an effective way of examining the statistical properties of the early BH population and making predictions that can be directly compared with the observed QLF and BHMF (e.g., [Haiman & Loeb](#page-20-8) [1998;](#page-20-8) [Shankar et al.](#page-23-16) [2010;](#page-23-16) [Ricarte & Natarajan](#page-22-10) [2018a](#page-22-10)[,b;](#page-22-11) [Dayal et al.](#page-20-9) [2019;](#page-20-9) [Piana et al.](#page-22-12) [2021;](#page-22-12) [Yung et al.](#page-24-2) [2021;](#page-24-2) [Kim & Im](#page-21-11) [2021;](#page-21-11) [Trinca et al.](#page-23-17) [2022;](#page-23-17) [Oogi et al.](#page-22-13) [2022\)](#page-22-13). However, due to the limitation of capturing the detailed properties of the relevant physics, a large number of model parameters need to be calibrated based on the observed distribution functions of lower-z quasar populations (e.g., [Hop](#page-21-12)[kins et al.](#page-21-12) [2007\)](#page-21-12) and empirical correlations between the SMBH mass and their host galaxy properties seen in the local universe [\(Kormendy & Ho](#page-21-13) [2013\)](#page-21-13). The second approach is more phenomenological, using extrapolation of the low-z QLF evolution with fitting function forms (e.g., [Kulkarni et al.](#page-21-14) [2019;](#page-21-14) [Shen et al.](#page-23-18) [2020;](#page-23-18) [Finkelstein](#page-20-10) [& Bagley](#page-20-10) [2022\)](#page-20-10). This method also allows us to forecast the higher-z QLF and bring insights for future surveys. Nevertheless, those semi-analytical and phenomenological approaches introduce numerous physical parameters and make the essential mechanisms reproducing the observed results elusive. Therefore, it is required to construct a theoretical model characterized by a minimum number of parameters but capable of dealing with the essential physical processes.

To determine the initial conditions of the early BH assembly, the formation pathway of seed BHs has been extensively investigated by numerical simulations and semi-analytical studies [\(Begelman et al.](#page-19-3) [2006;](#page-19-3) [Regan](#page-22-14) [& Haehnelt](#page-22-14) [2009;](#page-22-14) [Tanaka & Haiman](#page-23-19) [2009;](#page-23-19) [Natarajan](#page-22-15) [& Volonteri](#page-22-15) [2012;](#page-22-15) [Hirano et al.](#page-21-15) [2014,](#page-21-15) [2015;](#page-21-16) [Valiante](#page-23-20) [et al.](#page-23-20) [2018;](#page-23-20) [Sassano et al.](#page-22-16) [2021;](#page-22-16) [Toyouchi et al.](#page-23-21) [2023;](#page-23-21) [Bhowmick et al.](#page-19-4) [2022\)](#page-19-4). Massive star formation episodes in the early universe is substantially modulated by external environmental effects such as (i) H₂ photodissociating irradiation from nearby galaxies [\(Omukai](#page-22-17) [2001;](#page-22-17) [Oh & Haiman](#page-22-18) [2002;](#page-22-18) [Bromm & Loeb](#page-20-11) [2003;](#page-20-11) [Shang](#page-23-22) [et al.](#page-23-22) [2010;](#page-23-22) [Sugimura et al.](#page-23-23) [2014;](#page-23-23) [Visbal et al.](#page-23-24) [2014;](#page-23-24) [Chon et al.](#page-20-12) [2016\)](#page-20-12), (ii) supersonic baryonic streaming motion that delays gas collapse in halos [\(Fialkov et al.](#page-20-13) [2012;](#page-20-13) [Tanaka & Li](#page-23-25) [2014;](#page-23-25) [Hirano et al.](#page-21-17) [2018;](#page-21-17) [Schauer](#page-22-19) [et al.](#page-22-19) [2017;](#page-22-19) [Inayoshi et al.](#page-21-18) [2018\)](#page-21-18), and (iii) dynamical heating caused by frequent halo mergers and turbulence injection led by cold accretion flows [\(Yoshida](#page-24-3) [et al.](#page-24-3) [2003;](#page-24-3) [Mayer et al.](#page-22-20) [2010,](#page-22-20) [2015;](#page-22-21) [Wise et al.](#page-23-26) [2019;](#page-23-26) [Latif et al.](#page-21-19) [2022\)](#page-21-19). Those effects keep isothermal collapse ($T \sim 8000$ K) of massive gas at high accretion rates of ≥ 0.1 M_☉ yr⁻¹ without vigorous fragmentation [\(Inayoshi et al.](#page-21-20) [2014;](#page-21-20) [Becerra et al.](#page-19-5) [2015;](#page-19-5) [Latif](#page-21-21) $&$ Ferrara [2016\)](#page-21-21), and allow supermassive stars with $\sim 10^5$ M_☉ (presumably seed BHs) to form at the halo centers [\(Hosokawa et al.](#page-21-22) [2013;](#page-21-22) [Schleicher et al.](#page-23-27) [2013;](#page-23-27) [Woods et al.](#page-24-4) [2019;](#page-24-4) [Toyouchi et al.](#page-23-21) [2023\)](#page-23-21). Although the conditions required for heavy seed formation are thought to be too stringent to be realized in the typical regions of the early universe [\(Dijkstra et al.](#page-20-14) [2008;](#page-20-14) [Ahn et al.](#page-19-6) [2009;](#page-19-6) [Inayoshi & Tanaka](#page-21-23) [2015\)](#page-21-23), recent studies by [Lupi et al.](#page-21-24) [\(2021\)](#page-21-24) and [Li et al.](#page-21-25) [\(2021\)](#page-21-25) found that the formation of heavy seeds accelerates in rare, overdense regions of the universe, where non-linear galaxy clustering boosts the irradiation intensity and frequency of halo mergers. In such massive halos, intense cold streams through cosmic webs and supersonic turbulent motion promote the formation of massive gas clouds that collapse into supermassive stars and seed BHs [\(Dekel et al.](#page-20-15) [2009;](#page-20-15) [In](#page-21-26)[ayoshi & Omukai](#page-21-26) [2012;](#page-21-26) [Latif et al.](#page-21-19) [2022\)](#page-21-19). The mass distribution of seed BHs is expected to be substantially top-heavy, extending the upper mass to $\gtrsim 10^{4-5}$ M_{\odot} [\(Li et al.](#page-21-25) [2021;](#page-21-25) [Toyouchi et al.](#page-23-21) [2023\)](#page-23-21). Metal enrichment of the progenitor halos due to internal and external star formation activity would regulate the formation of seed BHs and alter the characteristic of the mass distribution function (see also a quantitative argument on the low efficiency of enrichment in [Li et al.](#page-21-25) [2021\)](#page-21-25). Further studies with hydrodynamic simulations are required to improve our understanding of the efficiency of metal enrichment in quasar progenitor halos (e.g., [Chiaki et al.](#page-20-16) [2018\)](#page-20-16).

In this paper, we propose a theoretical model for the redshift-dependent QLF and BHMF at $z \geq 6$, applying the semi-analytic seed formation model from [Li](#page-21-25) [et al.](#page-21-25) [\(2021\)](#page-21-25) to study the BH growth in the early universe. We assume that the early BH population experiences multiple accretion bursts, in each of which a constant Eddington ratio is assigned following a Schechter distribution function. We conduct the Markov Chain Monte Carlo (MCMC) fitting procedure to optimize the BH growth parameters so that the observed QLF and BHMF at $z \approx 6$ are simultaneously reproduced. Our best-fit model suggests several episodes of modest super-Eddington accretion and requires individual burst durations of $\simeq 20-30$ Myr to avoid over(under)-production of BHs at the high-mass end. We also find that the observed Eddington-ratio distribution function is skewed to a log-normal shape from the intrinsic Schechter-like function owing to detection limits of quasar observations. We further discuss the redshift evolution of the QLF and BHMF at $z \geq 6$, and give implications for future observations. Those results will be tested by future deep and wide-field surveys with JWST, RST, and Euclid, by conducting spectroscopic measurements of individual BH masses and constructing high-z QLFs.

This paper is organized as follows. In Section [2,](#page-2-0) we describe the semi-analytical model for BH seeding and subsequent growth via accretion, and explain the MCMC fitting procedure to constrain the theoretical model by the high-z quasar observations. In Section [3,](#page-8-0) we present the fitting result for the model parameters reproducing the observational data, and discuss the physics determining the BH growth. In Section [4,](#page-11-0) we discuss the cosmological evolution of the BHMF and QLF suggested by our best-fit model, as well as the detection number of those BHs at $z \sim 6$ –10 with Euclid and RST. In Section [5,](#page-15-0) we present the evolutionary tracks of individual BHs and their statistical properties at $z \gtrsim 6$, based on the growth model calibrated above. We finally summarize our findings in Section [6.](#page-17-0) Throughout this work, we apply the cosmological parameters from [Planck Collabo](#page-22-22)[ration et al.](#page-22-22) [\(2016\)](#page-22-22), i.e., $\Omega_{\rm m} = 0.307, \ \Omega_{\Lambda} = 0.693, \ \Omega_{\rm b} =$ 0.0486, and $H_0 = 67.7 \text{ km s}^{-1} \text{Mpc}^{-1}$. All magnitudes quoted in this paper are in the AB system.

2. METHODOLOGY

2.1. Seed BH formation

The QLFs at high redshifts are determined by the BH seeding mechanism and subsequent growth. We first describe our model regarding the formation of BH seeds in progenitor DM halos that end up in high- z quasar host galaxies with halo mass of $M_h \gtrsim 10^{11} M_{\odot}$. The mass range of those DM halos for $z \sim 6$ quasars is motivated by the halo mass measurement, where the rotation velocity of gas based on the [C II] 158 μ m line width is assumed to be the circular velocity of the halo [\(Ferrarese](#page-20-17) [2002;](#page-20-17) [Wang et al.](#page-23-12) [2013;](#page-23-12) [Shimasaku & Izumi](#page-23-28) [2019\)](#page-23-28). In our model, we consider three parent halos with $M_h = 10^{11}$, 10^{12} , and 10^{13} M_{\odot} at $z = 6$ and generate $N_{\text{tot}}(=10^4)$ merger trees for each parent halo mass backward in time using the GALFORM semi-analytic algorithm based on the extended Press-Schechter formalism [\(Press & Schechter](#page-22-23) [1974;](#page-22-23) [Cole et al.](#page-20-18) [2000;](#page-20-18) [Parkinson](#page-22-24) [et al.](#page-22-24) [2008\)](#page-22-24). For each tree, we adopt a minimum DM halo mass of $M_{h,\text{min}} = 10^5 M_{\odot}$, which is small enough to capture the earliest star formation episodes via H_2 line cooling at the high-z universe [\(Haiman et al.](#page-20-19) [1996;](#page-20-19) [Tegmark et al.](#page-23-29) [1997\)](#page-23-29).

We consider seed BH formation in the main progenitors of quasar host galaxies, following a semianalytical model established by [Li et al.](#page-21-25) [\(2021\)](#page-21-25). In the highly-biased, overdense regions of the universe, those progenitor halos are likely irradiated by intense H_2 photodissociating radiation from nearby star-forming galaxies and heat the interior gas by successive mergers. The two effects counteracting H_2 formation and cooling prevent gas collapse and delay prior star formation (e.g., [Visbal et al.](#page-23-24) [2014;](#page-23-24) [Wise et al.](#page-23-26) [2019\)](#page-23-26). Under such peculiar circumstances, massive clouds collapse to the halo centers at high accretion rates and leave massive stars (presumably seed BHs) behind. Our model takes into account various key physical processes on star formation such as halo merger heating, radiative cooling, and (photo-)chemical reaction networks. The time evolution of the gas dynamics and thermal states is calculated in a self-consistent way with the halo assembly history. We calculate the time-dependent H_2 photo-dissociating radiation flux $(H_2 + \gamma \rightarrow 2 H)$ following [Dijkstra et al.](#page-20-20) [\(2014\)](#page-20-20). The flux is measured at one free-fall time, $t_{\rm ff} \simeq 32[(1+z)/21]^{-3/2}$ Myr, of the individual source halos after their single star bursts. The value of $t_{\rm ff}$ is typically longer than the lifetime of massive stars that dominate the production of UV radiation. Therefore, this treatment underestimates the photodissociating flux since the assumption of an old stellar population provides less UV radiation than smoothlyproceeding star formation [\(Lupi et al.](#page-21-24) [2021\)](#page-21-24). In this sense, our model gives a conservative estimate of the formation efficiency of heavy seed BHs. In addition, we take account of H⁻ photo-detachment $(H^-+\gamma \rightarrow H+e^-)$ caused by irradiation from nearby galaxies. This effect suppresses H_2 formation through electron-catalysed reactions $(H+e^- \rightarrow H^-+\gamma; H^-+H \rightarrow H_2+e^-)$, and thus delays gravitational collapse of gas clouds at the halo centers [\(Omukai](#page-22-17) [2001;](#page-22-17) [Shang et al.](#page-23-22) [2010\)](#page-23-22). In this paper, we approximate the galaxy spectrum to be a black-body spectrum with $T_{\text{rad}} = 2 \times 10^4$ K [\(Sugimura et al.](#page-23-23) [2014;](#page-23-23) [Inayoshi & Tanaka](#page-21-23) [2015\)](#page-21-23).

In addition, we consider baryonic streaming motion relative to DM produced in the epoch of cosmic recombination at $z_{\text{rec}} \simeq 1100$. This effect also delays gas collapse and star formation in protogalaxies through injection of kinetic energy into gas (e.g., [Fialkov et al.](#page-20-13) [2012;](#page-20-13) [Tanaka & Li](#page-23-25) [2014;](#page-23-25) [Hirano et al.](#page-21-27) [2017;](#page-21-27) [Schauer et al.](#page-22-25) [2019;](#page-22-25) [Li et al.](#page-21-25) [2021\)](#page-21-25). The amplitude of the streaming velocity is set to $v_{\text{bsm}} = 0$ and $v_{\text{bsm}} = 1 \sigma_{\text{bsm}}$, where $\sigma_{\rm bsm} = 30 \text{ km s}^{-1} (1+z)/(1+z_{\rm rec})$ is the root-meansquare speed at a redshift of z [\(Tseliakhovich & Hirata](#page-23-30) [2010\)](#page-23-30). We calculate the effective sound speed of gas as $c_{\text{eff}} = \{c_{\text{s}}^2 + v_{\text{tur}}^2/3 + (\alpha_0 v_{\text{bsm}})^2\}^{1/2}$ at the center of each progenitor halo, where c_s is the thermal sound speed, v_{tur} is the turbulent velocity of gas (i.e., the specific kinetic energy accumulated through halo mergers), and the coefficient is set to $\alpha_0 = 1^{-1}$ $\alpha_0 = 1^{-1}$ $\alpha_0 = 1^{-1}$. When the gas core becomes gravitationally unstable, the evolution of the gas density profile is well described by the Penston-Larson self-similar solution [\(Penston](#page-22-26) [1969;](#page-22-26) [Larson](#page-21-28) [1969\)](#page-21-28). The mass accretion rate from the envelope can be written as $\dot{M} = c_{\text{eff}}^3/G$, where G is the gravitational constant.

At the vicinity of an accreting protostar, an accretion disk forms due to angular momentum of the inflowing material from large scales [\(Stacy et al.](#page-23-31) [2010;](#page-23-31) [Clark et al.](#page-20-21) [2011;](#page-20-21) [Greif et al.](#page-20-22) [2011\)](#page-20-22). The episodic nature of disk accretion decreases the time-averaged accretion rate onto the protostar as $\dot{M}_{\star} = \eta \dot{M}$, where we adopt $\eta = 0.3$ as the conversion efficiency owing to angular momentum of the accreting flow [\(Sakurai et al.](#page-22-27) [2016;](#page-22-27) [Toyouchi](#page-23-21) [et al.](#page-23-21) [2023\)](#page-23-21). The size evolution of an accreting protostar and the radiative feedback strength depend sensitively on whether the accretion rate becomes higher than a critical value of $\dot{M}_{\text{crit}} = 0.04 M_{\odot} \text{ yr}^{-1}$ [\(Omukai](#page-22-28) [& Palla](#page-22-28) [2001;](#page-22-28) [Hosokawa et al.](#page-21-22) [2013;](#page-21-22) [Schleicher et al.](#page-23-27) [2013;](#page-23-27) [Sakurai et al.](#page-22-29) [2015;](#page-22-29) Haemmerlé et al. [2018\)](#page-20-23). For $\dot{M}_{\star} > \dot{M}_{\text{crit}}$, the stellar envelope inflates owing to rapid entropy injection through accreting matter, keeping its surface temperature as low as $T_{\text{eff}} \simeq 5000 \text{ K}$. Since stellar UV radiation is hardly emitted from the cold surface, the accretion flow efficiently feeds the central star without being impeded by radiative feedback. As a result, the stellar mass reaches $\sim 10^5 M_{\odot}$ but is limited by the general-relativistic instability to

$$
M_{\star,\text{GR}} \simeq \left[0.83 \log \left(\frac{\dot{M}_{\star}}{M_{\odot} \text{ yr}^{-1}} \right) + 2.48 \right] \times 10^5 \ M_{\odot}, \tag{1}
$$

in the range of $\dot{M}_{\star} \geq 0.1 M_{\odot} \text{ yr}^{-1}$ [\(Shibata et al.](#page-23-32) [2016;](#page-23-32) [Woods et al.](#page-24-5) [2017,](#page-24-5) [2019\)](#page-24-4). On the other hand, for $\dot{M}_{\star} \leq \dot{M}_{\rm crit}$, the protostar begins to contract by loosing its thermal energy via radiative diffusion and increases its surface temperature to $T_{\text{eff}} \sim 10^5$ K. Hence, intense stellar UV radiation heats the disk surface and launches mass outflows, preventing mass supply from the disk to the star [\(McKee & Tan](#page-22-30) [2008;](#page-22-30) [Hosokawa et al.](#page-21-29) [2011\)](#page-21-29). In this case, the stellar mass is determined by the balance between mass accretion and mass loss via photoevaporation [\(Tanaka et al.](#page-23-33) [2013\)](#page-23-33). The feedback-regulated mass can be approximated as [2](#page-0-1)

$$
M_{\star, \text{fb}} \simeq 2.9 \times 10^3 M_{\odot} \left(\frac{\dot{M}_{\star}}{0.01 M_{\odot} \text{yr}^{-1}} \right), \qquad (2)
$$

see more details in [Li et al.](#page-21-25) [\(2021\)](#page-21-25). For an intermediate accretion rate between \dot{M}_{crit} and 0.1 M_{\odot} yr⁻¹, we perform logarithmic interpolation in the $\dot{M}_{\star} - M_{\star}$ plane to smoothly connect $M_{\star,fb}$ and $M_{\star,GR}$ at the boundaries. At the end of the stellar lifetime, those massive primordial stars result in BHs without significant mass loss via stellar winds [\(Heger et al.](#page-21-30) [2003;](#page-21-30) [Spera et al.](#page-23-34) [2015\)](#page-23-34). One important caveat is the effect of stellar rotation on the structure evolution. Namely, the mass loss rate of a rotating massive star via winds would be enhanced by the centrifugal force on the surface or suppressed by efficient mixing of the interior structure by meridional circulation (see Ekström et al. [2008;](#page-20-24) [Yoon](#page-24-6) [et al.](#page-24-6) [2012,](#page-24-6) references therein). Although those effects in the high mass regime are poorly understood yet, full general-relativistic simulations of the gravitational collapse of a rotating supermassive star show that most of the stellar mass is eventually swallowed by the newly born BH, ejecting only ∼ 10% of the mass [\(Shibata &](#page-23-35) [Shapiro](#page-23-35) [2002;](#page-23-35) [Shibata et al.](#page-23-32) [2016\)](#page-23-32). Therefore, we assume that the mass of a remnant BH is equal to that of its stellar progenitor.

Let us consider that a seed BH with a mass of $M_{\bullet,i}$ formed in the i-th halo merger tree at the cosmic age

¹ The value of $\alpha_0 = 1.0$ is motivated by cosmological simulations of massive primordial stars under fast streaming velocities [\(Hirano](#page-21-27) [et al.](#page-21-27) [2017;](#page-21-27) [Schauer et al.](#page-22-25) [2019\)](#page-22-25). Note that our previous study in [Li et al.](#page-21-25) [\(2021\)](#page-21-25) adopted $\alpha_0 = 4.7$ [\(Hirano et al.](#page-21-17) [2018\)](#page-21-17).

² A recent study by [Toyouchi et al.](#page-23-21) [\(2023\)](#page-23-21) provides a more sophisticated prescription of the feedback-regulated stellar mass based on their radiation hydrodynamical simulations.

Figure 1. Mass distribution of seed BHs formed in quasar host galaxies at different redshifts ($10 \le z \le 50$). In each panel, the contribution from newly-born BHs in the redshift interval is highlighted in magenta, and the cumulative number distribution of BHs formed by prior episodes is shown in green. The majority of seed BHs form in the epoch of $20 \leq z \leq 40$, and the distribution is extended to $M_{\bullet} \gtrsim 10^5 M_{\odot}$, reflecting the halo assembly and environmental effects discussed in Section [2.1.](#page-2-1)

 t_i ($1 \leq i \leq N_{\text{tot}} = 10^4$), and each of them contributes to the probability distribution function (PDF) of seed mass at a time t as

$$
p_i^{\text{seed}}(M_{\bullet}, t) \equiv \frac{\mathrm{d}^2 P_i^{\text{seed}}}{\mathrm{d}M_{\bullet} \,\mathrm{d}t} = \frac{\delta(M_{\bullet} - M_{\bullet,i}) \,\,\delta(t - t_i)}{N_{\text{tot}}}.\tag{3}
$$

Based on the cumulative seed-mass distribution of $dP_i^{\text{seed}}/dM_{\bullet}$ (i.e., the integral of p_i^{seed} over time), we construct the mass function from all $N_{\rm tot}$ seeds formed in one parent halo with a mass of M_h , where gas has a coherent streaming velocity of v_{bsm} as a function of time (and redshift). The absolute abundance of those seed BHs is calculated with the number density of the parent halo in a comoving volume at $z = 6$ from the Sheth-Tormen mass function [\(Sheth et al.](#page-23-36) [2001\)](#page-23-36),

$$
n_{M_{\rm h}} = \int_{M_{\rm h}}^{10M_{\rm h}} \frac{dn_{\rm ST}}{dM_{\rm h}'} dM_{\rm h}',\tag{4}
$$

where we adopt $M_h = 10^{11}$, 10^{12} , and 10^{13} M_{\odot} , with number densities of $n_{M_h} = 9.9 \times 10^{-4}$, 6.2 × 10⁻⁶, and 8.9×10^{-10} Mpc⁻³, respectively. Combining the PDF and number density normalization, we obtain the seed

BH mass function cumulative at time t as

$$
\Phi_{M_{\bullet}}^{\text{seed}}(t) \equiv \sum_{M_{\rm h}, v_{\rm bsm}} n_{M_{\rm h}} f_{v_{\rm bsm}} \cdot \sum_{i}^{N_{\rm tot}} \frac{\mathrm{d}P_{i}^{\text{seed}}}{\mathrm{d}\log M_{\bullet}}(t) \Big|_{M_{\rm h}, v_{\rm bsm}},\tag{5}
$$

_N_r

where $f_{v_{\text{bsm}}}$ is the volume fraction of the universe with a streaming velocity. The value is calculated as $f_{v_{\text{bsm}}} =$ 0.6 and 0.4 for $v_{\text{bsm}} = 0$ and $v_{\text{bsm}} = 1 \sigma_{\text{bsm}}$, respectively.

Fig. [1](#page-4-0) presents how the seed mass function is developed in each redshift interval. The majority of seed BHs form in the epoch of $20 \le z \le 40$, and the distribution function is extended to $M_{\bullet} \gtrsim 10^5$ M_{\odot} , reflecting the halo assembly and environmental effects. Note that in this study, we consider massive seed BHs formed in lowmetallicity environments, but neglect a potential contribution from BHs left behind the second-generation star formation in metal-enriched environments. The latter ones would dominate in number at the low-mass end of the BHMF at $z \sim 6$, but have little impact on the bulk properties of the observed QLF and BHMF (see [Trinca](#page-23-17) [et al.](#page-23-17) [2022\)](#page-23-17).

2.2. BH mass growth

With BH seeds planted, we study the evolution of the BH mass distribution until $z = 6$. The growth model of each BH is characterized by a minimal number of free parameters, giving the accretion rate by

$$
\dot{M}_{\bullet} = \lambda f(M_{\bullet}) \dot{M}_{\text{Edd}},\tag{6}
$$

where λ is the ratio of the quasar bolometric luminosity to its Eddington luminosity L_{Edd} , and $\dot{M}_{\text{Edd}} \equiv$ $L_{\rm Edd}/\eta_0 c^2$ is the Eddington accretion rate with a radiative efficiency of $\eta_0 = 0.1$ [\(Shakura & Sunyaev](#page-23-37) [1973\)](#page-23-37), which is consistent with the value obtained from the Soltan-Paczyński argument (e.g., [Yu & Tremaine](#page-24-0) [2002;](#page-24-0) [Cao](#page-20-25) [2010\)](#page-20-25). Based on studies on the mass dependence of the radiative efficiency for AGNs at $z \leq 3$ [\(Cao & Li](#page-20-26) [2008;](#page-20-26) [Li et al.](#page-21-31) [2012;](#page-21-31) [Ueda et al.](#page-23-4) [2014\)](#page-23-4), we introduce a similar functional form of

$$
f(M_{\bullet}) = \frac{2}{1 + (M_{\bullet}/M_{\bullet,c})^{\delta}},\tag{7}
$$

where $M_{\bullet,c} = 10^8$ M_{\odot} is adopted ^{[3](#page-0-1)}. With a positive value of δ , the BH growth at the high mass end is suppressed, while the growth speed for less massive BHs is accelerated. In the limit of $\delta \ll 1$, where $f(M_{\bullet}) \simeq 1$ is nearly independent of $M_{\bullet,c}$, the model in Eq. [\(7\)](#page-5-0) reproduces an exponential growth with an e -folding timescale of $t_{\rm S} = M_{\bullet}/\dot{M}_{\rm Edd} \approx 45$ Myr (the so-called Salpeter timescale; [Salpeter](#page-22-31) [1964\)](#page-22-31). Note that we do not explicitly consider the energy loss with radiation in Eq. [\(6\)](#page-5-1), neglecting a factor of $1 - \eta_0 = 0.9$. This small deviation from unity can be absorbed by the uncertainty due to the functional form of $f(M_{\bullet})$ and does not bring a significant impact on the results discussed below.

Quasar activity is thought to take place episodically with accretion bursts triggered by gas inflows to the galactic nuclei [\(Di Matteo et al.](#page-20-27) [2005;](#page-20-27) [Hopkins](#page-21-32) [et al.](#page-21-32) [2005\)](#page-21-32), and the BH feeding rate declines by selfregulating feedback processes (e.g., [Younger et al.](#page-24-7) [2008;](#page-24-7) [Novak et al.](#page-22-32) [2011\)](#page-22-32) or gas consumption [\(Pringle](#page-22-33) [1991;](#page-22-33) [Yu et al.](#page-24-8) [2005;](#page-24-8) [King & Pringle](#page-21-33) [2007\)](#page-21-33). This "flickering" pattern of individual quasar luminosity evolution can be directly translated into the diversity in the Eddington ratios of quasar samples. We here suppose that the Eddington ratio distribution function $dP/d \ln \lambda$ (ERDF) is characterized with a Schechter function and the distribution function is independent of redshift [\(Hopkins](#page-21-34) [et al.](#page-21-34) [2006;](#page-21-34) [Hopkins & Hernquist](#page-21-35) [2009\)](#page-21-35). For unobscured AGNs at low redshifts, the ERDF is characterized with a Schechter function [\(Schulze et al.](#page-23-39) [2015;](#page-23-39) [Jones et al.](#page-21-36) [2016;](#page-21-36) [Aird et al.](#page-19-7) [2018\)](#page-19-7). Motivated by those facts, we give the ERDF by a Schechter function with two free parameters λ_0 and α as

$$
\frac{\mathrm{d}P}{\mathrm{d}\ln\lambda} \propto \left(\frac{\lambda}{\lambda_0}\right)^\alpha \exp\left(-\frac{\lambda}{\lambda_0}\right). \tag{8}
$$

The normalization is set so that the integral of this function over $\lambda_{\min} (= 0.01) \leq \lambda < \infty$ is unity. The minimum Eddington ratio λ_{\min} is adopted from the simulated evolution of quasar luminosities that decrease mildly toward $\lambda \sim 0.1 - 0.01$ with ≤ 100 Myr after the peak activity [\(Novak et al.](#page-22-32) [2011\)](#page-22-32). Moreover, a turnover in the ERDF at the lowest value of $\lambda \leq 0.01 - 0.001$ is suggested by observations of X-ray selected AGNs [\(Aird et al.](#page-19-7) [2018\)](#page-19-7).

To characterize the episodic accretion patterns of individual BHs, we introduce a time duration of τ , during which a single value of λ is assigned to an accreting BH following the ERDF of Eq. [\(8\)](#page-5-2). In this way, we give a different growth speed of a BH in every period with a duration of τ until $z = 6$ (the corresponding cosmic age is $t_{\rm H} \simeq 913$ Myr). This treatment enables us to capture the nature of accretion bursts and prohibit an unrealistically long-lasting rapid growth phase of a BH. This phenomenological method avoids numerous uncertainties in modeling of the galaxy assembly, gas feeding, and BH feedback processes in the quasar progenitor halos, which are implemented as sub-grid models in previous cosmological simulations [\(Di Matteo et al.](#page-20-28) [2017;](#page-20-28) [Barai et al.](#page-19-8) [2018;](#page-19-8) [Lupi et al.](#page-21-37) [2019\)](#page-21-37). These studies found that the growth of massive BH seeds toward SMBHs is characterized by the intermittent patterns with quiescent and accretion phases. Instead of treating these ingredients explicitly in our semi-analytical model, we extract an averaged but fundamental timescale that governs mutual correlation between the QLF and BHMF, based on direct comparison to those distribution functions for the observed high-z quasar population.

Thus far, we assume that all the seed BHs formed in parent halos participate in the assembly of SMBHs and end up in quasar host galaxies by $z \approx 6$. To relax this stringent assumption, we introduce the seeding fraction of $f_{\rm seed}(\leq 1)$. As discussed in [Tanaka & Haiman](#page-23-19) [\(2009\)](#page-23-19), a small value of $f_{\text{seed}} < 1$ is required to avoid overproduction of SMBHs at $z \sim 6$, depending on BH seeding and growth mechanisms in semi-analytical models. Since the value has been poorly constrained both by theoretical and observational studies, we treat it as a free parameter. We take three different values of $f_{\text{seed}} = 1$, 0.1, and 0.01, and explore its effect on shaping the QLF

³ A series of radiation hydrodynamical simulations for BH accretion suggest that the gas supplying rate from galactic scales into the nuclear scale is not high enough to sustain super-Eddington accretion when the BH mass is higher than the characteristic value [\(Toyouchi et al.](#page-23-38) [2021\)](#page-23-38).

Figure 2. Schematic illustration of the numerical procedure for calculating the BH mass function between a time interval with a duration of τ . The time evolution of the distribution is calculated by adding newly-forming seed BHs and taking into account growth of existing BHs via mass accretion. For a given BH population at a checkpoint at $t = T_0$, their growth is calculated with Eqs. [\(9\)](#page-6-0) and (10), where the ERDF is assumed to follow Eq. (8). For a newly formed seed BH with M_k during the interval (i.e., $T_0 \le t_k < T_0 + \tau$, we evolve the BH mass in $\Delta t = T_0 + \tau - t_k$ and add it to the mass distribution of the existing BHs.

and BHMF. Note that the seed mass function shown in Fig. [1](#page-4-0) is given with $f_{\text{seed}} = 1$.

2.3. BH mass function

We describe how to calculate the time evolution of the BH mass function, combining the semi-analytical growth model and ERDF (see Eqs. [6](#page-5-1) and [8\)](#page-5-2). The schematic illustration of our numerical procedure is shown in Fig. [2.](#page-6-2) We first set a series of checkpoints with an interval of τ , tracing back from $t_H(z = 6)$ to just prior to the first seed formation time t_1 , where t_i is the *i*-th seed forming time as defined in Section [2.1](#page-2-1) ($1 \leq i \leq N_{\text{tot}}$). Note that the number of the checkpoints is given by $\lceil (t_H - t_1)/\tau \rceil + 1$, where $[x] \equiv \min\{n \in \mathbb{Z} \mid x \leq n\}.$

The time evolution of the BH mass distribution is calculated from the first checkpoint to $t_H(z = 6)$ by adding newly-forming seed BHs and taking into account growth of existing BHs via mass accretion. For a given mass distribution function $dP/dM_{\bullet,0}$ at a checkpoint of $t = T_0$, we give its evolution at $t = T_0 + \Delta t$ as

$$
\frac{\mathrm{d}P}{\mathrm{d}M_{\bullet}} = \int \frac{\mathrm{d}P}{\mathrm{d}\ln\lambda}\Big|_{\lambda_*} \cdot \frac{\mathrm{d}\ln\lambda_*}{\mathrm{d}M_{\bullet}}\Big|_{\Delta t, M_{\bullet,0}} \cdot \frac{\mathrm{d}P}{\mathrm{d}M_{\bullet,0}} \mathrm{d}M_{\bullet,0}, (9)
$$

where λ_* is the Eddington ratio required for a BH with $M_{\bullet,0}$ to grow up to M_{\bullet} in Δt , and is calculated analytically from Eq. [\(6\)](#page-5-1) by

$$
\frac{2\lambda_{*}\Delta t}{t_{\rm S}} = \ln\left(\frac{M_{\bullet}}{M_{\bullet,i}}\right) + \frac{1}{\delta} \left[\left(\frac{M_{\bullet}}{M_{\bullet,c}}\right)^{\delta} - \left(\frac{M_{\bullet,0}}{M_{\bullet,c}}\right)^{\delta} \right],\tag{10}
$$

and the derivative of $(d \ln \lambda_*/dM_{\bullet})|_{\Delta t, M_{\bullet,0}}$ is also determined. For existing BHs, we calculate the evolution of the mass distribution by setting $\Delta t = \tau$. For a seed BH formed during this cycle (i.e., $T_0 \le t_k < T_0 + \tau$), we evolve $dP_k^{\text{seed}}/dM_{\bullet}$ by setting $\Delta t = T_0 + \tau - t_k$ and add it to the mass distribution of the existing BHs at $t = T_0 + \tau$. Combining the PDF and number density normalization, the BHMF is given by

$$
\Phi_{M_{\bullet}} = \sum_{M_{\rm h}, v_{\rm bsm}} n_{M_{\rm h}} f_{v_{\rm bsm}} f_{\rm seed} \cdot \frac{\mathrm{d}P}{\mathrm{d}\log M_{\bullet}} \Big|_{M_{\rm h}, v_{\rm bsm}}. (11)
$$

To follow the time evolution of the mass function, we set up logarithmically spaced mass grids at $10^2 \leq$ $M_{\bullet}/M_{\odot} \leq 10^{12}$. The number of the grid points is set to $N_{\text{bin}} = 800$, so that the convergence of the numerical result is ensured. Our result of $\Phi_{M_{\bullet}}$ is consistent with that obtained from the direct sampling method, where we consider the growth of $10⁷$ individual BHs rather than the evolution of smooth analytical mass distribution functions. Our method reduces the statistical errors seen in the direct sampling method and thus allows us to extend the BHMF and QLF to the higher mass and brighter end in a reasonable computational time.

2.4. Obscuration-corrected QLF

Using the BHMF and its evolution, we construct the QLF, which can be directly probed by high-z quasar observations. For an accreting BH with a bolometric luminosity of $L_{\text{bol}} = \lambda L_{\text{Edd}}$, its rest-frame ultraviolet (UV) absolute magnitude of M_{1450} at 1450 Å is estimated as

$$
M_{1450} = -21.0 - 2.5 \log \left(\frac{L_{\text{bol}}}{10^{45} \text{ erg s}^{-1}} \right) \text{ [mag]}, (12)
$$

where a bolometric correction factor of $f_{1450}^{bol} = 4.4$ for the monochromatic UV band is adopted [\(Richards et al.](#page-22-34) [2006a\)](#page-22-34). We construct the QLF from the BHMF, combining this conversion factor and ERDF. However, we note that the shape and normalization of the intrinsic QLF is not necessarily identical to the observed QLF because quasar surveys with rest-frame UV-to-optical bands are not sensitive to the obscured quasar population, i.e., the observed number of fainter quasars is largely reduced by the obscuration effect [\(Ueda et al.](#page-23-40) [2003;](#page-23-40) [Gilli et al.](#page-20-29) [2007;](#page-20-29) [Hasinger](#page-21-38) [2008;](#page-21-38) [Ueda et al.](#page-23-4) [2014;](#page-23-4) [Merloni et al.](#page-22-35) [2014\)](#page-22-35).

A widely-accepted mechanism causing quasar obscuration is extinction by dusty tori and dense gas clouds in the circumnuclear region, hence tightly related to gas fueling and feedback processes from accreting BHs (see [Hickox & Alexander](#page-21-39) [2018,](#page-21-39) for a review). In addition, dense gas clouds at larger galactic scales may have a significant contribution to quasar obscuration at higher redshifts [\(Ni et al.](#page-22-36) [2020\)](#page-22-36). However, the physical origin and conditions for high-z quasar obscuration have been poorly understood yet. Observationally, the obscured fraction of AGNs with hydrogen column density of $N_{\rm H} > 10^{22}$ cm⁻² can be estimated from spectral analyses in the X-ray band (e.g., [Ueda et al.](#page-23-40) [2003;](#page-23-40) [Gilli](#page-20-29) [et al.](#page-20-29) [2007;](#page-20-29) [Hasinger](#page-21-38) [2008\)](#page-21-38). The obscured fraction is nearly $\geq 80\%$ at $L_X < 10^{43}$ erg s⁻¹ and decreases with the X-ray luminosity [\(Ueda et al.](#page-23-4) [2014;](#page-23-4) [Merloni et al.](#page-22-35) [2014\)](#page-22-35). The exact function shape still remains under debate, but the overall dependence on the X-ray luminosity holds. Moreover, the obscured fraction is found to increase gradually toward higher redshifts and is saturated at $z \geq 2-3$ [\(Hasinger](#page-21-38) [2008;](#page-21-38) [Ueda et al.](#page-23-4) [2014;](#page-23-4) [Merloni et al.](#page-22-35) [2014;](#page-22-35) [Vito et al.](#page-23-41) [2018;](#page-23-41) [Gilli et al.](#page-20-30) [2022\)](#page-20-30).

In this study, we adopt the obscuration fraction f_{obsc} based on X-ray observations [\(Ueda et al.](#page-23-4) [2014\)](#page-23-4):

$$
f_{\text{obsc}} = \min \left[\psi_{\text{max}}, \psi \right],\tag{13}
$$

$$
\psi = \max \left[\psi_0 - \beta \log(L_X/L_{X,0}), \psi_{\min} \right], \quad (14)
$$

where the parameters are written as $\psi_{\text{max}} = 0.84$, $\psi_{\rm min}$ = 0.2, ψ_0 = 0.73, β = 0.24, and $L_{\rm X,0}$ = $10^{43.75}$ erg s⁻¹. Here, we use the bolometric correction factor of the hard X-ray band:

$$
f_X^{\text{bol}} \equiv \frac{L_{\text{bol}}}{L_X} = a \left[1 + \left(\frac{\log \left(L_{\text{bol}} / L_{\odot} \right)}{b} \right)^c \right],\qquad(15)
$$

where $a = 10.96, b = 11.93, and c = 17.79$ (see Eq. 2) in [Duras et al.](#page-20-31) [2020\)](#page-20-31). It is worth noting that the functional form of the obscuration fraction is calibrated with X-ray selected AGNs at $z \lesssim 5$, and the value for high-z quasars is still under investigation. We leave more comprehensive arguments about this effect for future work.

After taking into account the obscuration effect, the observed QLF for a given BHMF and ERDF is calculated as

$$
\Phi_{M_{1450}} = (1 - f_{\text{obsc}}) \int \frac{\text{d}P}{\text{d}\ln\lambda} \Big|_{\tilde{\lambda}} \cdot \frac{\text{d}\ln\tilde{\lambda}}{\text{d}M_{1450}} \cdot \Phi_{M_{\bullet}} \text{d}\log M_{\bullet},\tag{16}
$$

where the values of $\tilde{\lambda} = \lambda(M_{1450}, M_{\bullet})$ and d $\ln \tilde{\lambda}/dM_{1450}$ are calculated analytically from Eq. [\(12\)](#page-7-0). Hence, the observed QLF can be produced simultaneously with the BHMF from a set of model parameters.

2.5. MCMC fitting

In this section, we describe the MCMC fitting procedure used to optimize the BH growth parameters so that the observed BHMF and QLF are consistently reproduced. As discussed in Section [2.3,](#page-6-3) we consider five parameters of τ , δ , α , λ_0 , and f_{seed} . We calculate the best-fit values of the first four parameters using the emcee Python package for the MCMC sampling [\(Foreman-Mackey et al.](#page-20-32) [2013\)](#page-20-32), fixing $f_{\rm seed}$ to a single value. We vary four parameters instead of five in the fitting to guarantee that the Markov chain can be stabilized. The fitting is carried out by sampling 100 walkers with 5000 steps. We verify the convergence of the posterior distribution results by doubling the chain length.

In this analysis, we constrain those four parameters to be within certain physically acceptable ranges, assuming a prior probability function P_a^{prior} for each quantity $a = \tau$, δ , λ_0 , and α . We use a uniform prior on τ with a limit of 10 Myr $\leq \tau \leq 200$ Myr, motivated by the constraints on the quasar lifetime based on various observations (e.g., [Martini](#page-22-37) [2004\)](#page-22-37). The parameter of δ that characterizes a non-exponential BH growth is constrained at $-4 \le \log \delta \le -0.3$ $-4 \le \log \delta \le -0.3$ $-4 \le \log \delta \le -0.3$ ⁴. The prior function is uniform at $\log \delta \ge -3$ and is imposed to decay with an exponential cutoff at $\log \delta < -3$, which is small enough for the model to be approximately mass independent,

⁴ We first set a uniform prior at $0 \le \delta \le 1$, and find the posterior distribution assembles to $\delta \lesssim 0.1$. We then switch to impose the log δ prior to improve the fitting performance at small δ values.

i.e., $f(M_{\bullet}) \simeq 1$. For the characteristic Eddington ratio λ_0 in the Schechter-type ERDF, we impose a Gaussian prior function with a mean value of $\mu_{\lambda_0} = 0.6$ and a dispersion of $\sigma_{\lambda_0} = 0.4$. The choice is motivated by the brightest quasar samples at $z = 6$, whose ERDF is peaked around $\lambda \sim 0.6$ after luminosity bias correction (e.g., [Willott et al.](#page-23-8) [2010b\)](#page-23-8). For the low- λ slope of α in the ERDF, we assign a Gaussian prior function with a mean value $\mu_{\alpha} = 0$ and a dispersion of $\sigma_{\alpha} = 0.3$. Note that the value of α remains poorly constrained by the current high-z quasar observations, but the low-z quasar samples support $-0.3 \le \alpha \le 0.3$ (e.g., see the mass-integrated ERDF for comparison; the right panel of Figure 21 in [Schulze et al.](#page-23-39) [2015\)](#page-23-39).

The observed BHMF data is taken from [Willott et al.](#page-23-8) [\(2010b\)](#page-23-8) (hereafter, [W10\)](#page-23-8), where the virial BH mass measurements for 17 bright quasars at $z \approx 6$ are used. Although the BHMF spans over $10^7 < M_{\bullet}/M_{\odot} < 10^{10}$, the best constraint is given around $M_{\bullet} \simeq 10^{8.5} M_{\odot}$ and thus the statistical error size becomes larger both at the lower and higher mass range. We set up 10 logarithmically spaced mass bins and adopt errors with sizes increasing quadratically as $\Phi_{M_{\bullet}}^{\text{err}} = \pm \{0.2 +$ $[\log(M_{\bullet}/10^{8.5} M_{\odot})]^2/3$ dex, covering the same mass range as in their bootstrap resamples (see Figure 8 of [W10\)](#page-23-8). The observed (unobscured) QLF is taken from [Matsuoka et al.](#page-22-5) [\(2018b\)](#page-22-5) (hereafter [M18\)](#page-22-5) over a wide range of UV magnitude at $-30 < M_{1450} < -22$ mag (see their Table 4 and Figure 13). The magnitude bins and the error sizes are given consistently with [M18.](#page-22-5)

In the MCMC fitting, the four parameters are sampled to generate the synthetic BHMF and QLF dataset, which are compared to the observational dataset. The probability is evaluated by a χ^2 -type value defined by

$$
\chi^2 = \sum_{x,i} \frac{\left(\log \Phi_{x,i}^{\text{mod}} - \log \Phi_{x,i}^{\text{obs}}\right)^2}{(\log \Phi_{x,i}^{\text{err}})^2} - 2 \sum_a \ln P_a^{\text{prior}}.\tag{17}
$$

The first term on the right hand side is the classical χ^2 value that measures the dispersion of the observational data from the model prediction, where $\Phi_{x,i}^{\text{mod}}$ and $\Phi_{x,i}^{\text{obs}}$ represent the modeled and observational value on the *i*-th bin of the BHMF $(x = M_{\bullet})$ and QLF $(x = M_{1450})$, and $\Phi_{x,i}^{\text{err}}$ is the corresponding error. Adopting 10 mass bins and 12 magnitude bins, we treat the errors from comparison both in the BHMF and QLF with nearly equal weight. The second term denotes the deviation of the parameter set from the assumed prior distribution functions. The posterior distribution of the MCMC fitting is stabilized around the minimum value of χ^2 (highest probability), with the models best reproducing the $z = 6$ BHMF and QLF.

3. RESULTS

We discuss the MCMC fitting results and compare the BHMF and QLF with their observed distribution functions. The best-fit model parameters together with the χ^2 values for the three cases with $f_{\rm seed}$ are summarized in Table [1.](#page-9-0) We note that the ideal case with $f_{\text{seed}} = 1.0$, where environmental effects preventing BHs from growing is neglected, yields a χ^2 value nearly twice larger than those in the other two cases. Therefore, in the following, we focus only on the results with $f_{\rm seed} = 0.1$ and 0.01 in comparison with observations. In Fig. [3,](#page-9-1) we visualize the fitting results of the model parameters in two-dimensional posterior distribution for the case of $f_{\rm seed} = 0.1$ (left) and 0.01 (right), respectively. The three vertical dashed lines in the one-dimensional posterior distribution of each parameter correspond to 16%, 50%, and 84% quantiles in the cumulative distribution, respectively. The best-fit values shown with the red lines are listed in Table [1,](#page-9-0) and are consistent with the peak values in the one-dimensional distribution.

The best-fit solutions yield a small value of $\delta < 0.1$. This result favors the nearly exponential BH growth model (Eqs. [6](#page-5-1) and [7\)](#page-5-0). The typical duration of quasar activity is required to be $\tau \simeq 20-30$ Myr for both cases. This suggests that accreting seed BHs vary their growth speeds and their Eddington ratios $\simeq 30 - 40$ times toward the cosmic time at $z \simeq 6$. The timescale of τ is also related to the quasar lifetime of $t_{Q} \sim 1 - 10$ Myr, which is estimated by the measurement of the physical extents of hydrogen $Ly\alpha$ proximity zones observed in the restframe UV spectra (e.g., [Eilers et al.](#page-20-33) [2018;](#page-20-33) [Davies et al.](#page-20-34) [2019\)](#page-20-34). The characteristic Eddington ratio λ_0 needs to be close to unity, otherwise the highest luminosity and BH mass in the model would differ from those in ob-servations. As shown in Fig. [3,](#page-9-1) the power-law index α in the ERDF shows an anti-correlation with the characteristic Eddington ratio λ_0 . With a higher λ_0 (i.e., faster BH growth), the ERDF needs to be skewed toward the lower λ regime with a smaller value of α (i.e., a larger fraction of inactive BHs) to be consistent with the observed QLF and BHMF.

The best-fit parameters for the two cases reproduce the bulk properties of the BHMF and QLF at $z \sim 6$, despite the ten-fold difference in the seeding fraction. With the fitted values for the ERDF, the fraction of super-Eddington accreting BHs is estimated as $P(\lambda >$ $1) = 0.064$ and 0.075 for $f_{\text{seed}} = 0.1$ and 0.01, respectively. While the probability of rapid accretion in each cycle differs slightly between the two cases, multiple accretion episodes enlarge the difference and accelerate BH growth for the lower seeding fraction. Moreover, the case with $f_{\text{seed}} = 0.01$ requires a higher value of

Figure 3. Two dimensional posterior distribution of the four model parameters with $f_{\text{seed}} = 0.1$ (left) and 0.01 (right), along with the marginalized one dimensional projection. The three vertical dashed lines in the one-dimensional posterior distribution of each parameter correspond to 16%, 50%, and 84% quantiles in the cumulative distribution, respectively. The best-fit values shown with the red lines are listed in Table [1.](#page-9-0)

 $\delta (\simeq 0.055)$, promoting the growth of less massive BHs with $M_{\bullet} < 10^8$ M_{\odot} . Therefore, a larger fraction of seed BHs are delivered into the SMBH regime, and the tenfold difference in f_{seed} is nearly compensated.

In Fig. [4,](#page-10-0) we show the BHMFs at $z = 6$ reproduced by the best-fit parameters for $f_{\text{seed}} = 0.1$ (left) and 0.01 (right) as well as the 1σ standard deviation calculated from random parameter sampling in the Markov chain. For comparison, we present the BHMF inferred by [W10](#page-23-8) along with the statistical errors. Note that [W10](#page-23-8) constructed the BHMF using quasar samples with $10^8 M_{\odot} \lesssim M_{\bullet} \lesssim 3 \times 10^9 M_{\odot}$. Overall, our best-fit BHMF model agrees with their constraints in this mass range. The power-law index of the BHMF $(\gamma_{M_{\bullet}} \equiv \mathrm{d} \ln \Phi_{M_{\bullet}}/\mathrm{d} \ln M_{\bullet})$ is as steep as $\gamma_{M_{\bullet}} \lesssim -1$ at $M_{\bullet} \gtrsim 10^{7} \ (3 \times 10^{7}) \ M_{\odot}$ for $f_{\rm seed} = 0.1 \ (0.01)$. Thus, the total mass budget of the entire BH population is dominated by BHs with the characteristic mass (see also Section [4\)](#page-11-0). The discrepancy between the model and observational data enlarges at the high- and low-mass end, reflecting poor constraints on the BHMF from the current observations.

Fig. [5](#page-10-1) presents the QLFs at $z = 6$ reproduced by the best-fit parameters as well as the 1σ spreads for $f_{\rm seed}=0.1$ (left) and 0.01 (right). The solid and dashed curve are the unobscured and intrinsic QLF, respectively. The latter includes both obscured and unob-

Table 1. Best-fit parameters for BH growth

$f_{\rm seed}$	τ (Myr) $\log \delta$ λ_0		α	
1.0	23.13		-2.97 0.96 -0.06 15.77	
0.1	20.07		-2.98 0.89 0.12 8.27	
0.01	18.76	-1.26 0.87 0.20		6.21

NOTE— The best-fit parameters optimized by MCMC sampling for the three different cases of f_{seed} . The fitting performance is quantified with the relative magnitudes of the χ^2 value.

scured quasars. For comparison, we overlay the observational data taken from [M18](#page-22-5) in blue and their parametric QLF with a double power-law function (dotted curve). Our best-fit unobscured QLF is consistent with the observed one at $-29 \text{ mag} \lesssim M_{1450} \lesssim -25 \text{ mag}$, but overproduces fainter quasars at $M_{1450} \gtrsim -24$ mag. Similarly to the BHMF, the difference between the model and observational data at the faint end becomes smaller with the lower seeding fraction. Since the progenitors of those faint quasars originate from lower mass seed BHs with $f_{\text{seed}} = 0.01$ (see discussion above), the BH population on the peak of the mass distribution naturally produces a flatter slope of the QLF at the faint end. Note that while our best-fit BHMF model over-produces the

Figure 4. The BH mass function at $z = 6$ with the best-fit parameters (black curve) and the 1σ statistical error (grey shaded region) for the cases with $f_{\text{seed}} = 0.1$ (left) and 0.01 (right). For comparison, the BHMF constructed by [W10](#page-23-8) and their statistical errors (see text) are shown with the cyan curve and shaded region.

Figure 5. The quasar luminosity function at $z = 6$ with the best-fit parameters (black curve) and the 1σ statistical error (grey shaded region) for the cases with $f_{\rm seed} = 0.1$ (left) and 0.01 (right). The solid and dashed curves are the unobscured and intrinsic QLF, respectively. We overlay the observational data for the unobscured QLF taken from [M18](#page-22-5) in blue and their parametric function with a double power-law function (dotted curve). Upper bounds of the number density of faint quasars are given by [Jiang et al.](#page-21-40) [\(2022\)](#page-21-40), based on the Hubble Space Telescope imaging observations (green). The QLF data based on X-ray selected quasars at $z \sim 5.55$ are overlaid in orange [\(Giallongo et al.](#page-20-35) [2019\)](#page-20-35), for which the normalization is scaled to $z = 6$ by a factor of $10^{-0.72\Delta z}$ [\(Jiang et al.](#page-21-2) [2016\)](#page-21-2), where $\Delta z = 0.45$.

BH abundance in the high mass end at $M_{\bullet} > 10^9$ M_{\odot} (although consistent within the 1-sigma error), the discrepancy becomes moderate in the brightest end of the QLF because low- λ BHs are more abundant with the best-fit EDRF ^{[5](#page-0-1)}. In addition, we show upper bounds of

the faint quasar abundance at $M_{1450} \gtrsim -22$ mag (green; [Jiang et al.](#page-21-40) [2022\)](#page-21-40) based on a search for point sources in the survey fields of the Hubble Space Telescope. Our unobscured QLF lies within the constraints.

Quasar observations in X-rays also provide useful constraints on the intrinsic population because of less obscuration in X-rays. Based on the X-ray selected faint quasars, [Giallongo et al.](#page-20-35) [\(2019\)](#page-20-35) reported a number density of faint quasars at $M_{1450} \gtrsim -22$ mag. Here, we show their $z = 5.55$ luminosity function in orange, for

⁵ The recent work by [Wu et al.](#page-24-9) [\(2022\)](#page-24-9) updates the construction of the $z = 6$ BHMF and shows a higher abundance at the high-mass end, consistent with our results.

Figure 6. Left: The predicted BH mass functions at $z = 6$ –10 for the case with $f_{\text{seed}} = 0.1$ (solid) and 0.01 (dashed), including the seed population. Right: the cumulative mass density for BHs in a comoving volume at three different mass ranges: $M_{\bullet} \leq 10^6$ M_{\odot} (blue), 10^6 $M_{\odot} < M_{\bullet} < 10^8$ M_{\odot} (orange), and $M_{\bullet} \geq 10^8$ M_{\odot} (green). The dashed-dotted curve shows the results from the cosmological simulations by [Ni et al.](#page-22-38) [\(2022\)](#page-22-38). The black arrows present upper bounds of the mass accreted onto BHs obtained from measurements of unresolved cosmic X-ray background radiation [\(Treister et al.](#page-23-42) [2013\)](#page-23-42).

which the normalization is scaled to $z = 6$ by a factor of $10^{-0.72\Delta z}$ [\(Jiang et al.](#page-21-2) [2016\)](#page-21-2), where $\Delta z = 0.45$, These values are substantially higher than those expected from extrapolation of the rest-UV based QLF by [M18](#page-22-5) (dotted curve) down to the faint end. In contrast, our best-fitted intrinsic QLF (dashed curve) is broadly consistent with the faint-end of the X-ray based QLF within the errors.

From another point of view, the discrepancy between the UV and X-ray QLFs at the faint end would be explained by the fact that only bright quasars outshining their host galaxies can be identified as point-like sources in the rest-UV quasar selection [\(M18;](#page-22-5) [Ni et al.](#page-22-36) [2020;](#page-22-36) [Adams et al.](#page-19-9) [2020;](#page-19-9) [Orofino et al.](#page-22-39) [2021;](#page-22-39) [Bowler et al.](#page-19-10) [2021;](#page-19-10) [Kim et al.](#page-21-41) [2022\)](#page-21-41). However, at the faint end of $M_{1450} \gtrsim -24$ mag, extended sources such as the brightest galaxies at z ∼ 6 dominate over quasars in number at the same UV magnitude [\(Harikane et al.](#page-20-36) [2022a\)](#page-20-36). Thus, the current observations might miss quasars embedded in extended galaxy populations. We leave this issue as an important caveat in high-z quasar observations.

4. COSMOLOGICAL EVOLUTION OF BH MASS AND QUASAR LUMINOSITY FUNCTION

In previous sections, we calibrate the model for early SMBH evolution based on the observational constraints of the BHMF and QLF at $z \sim 6$. Next, we apply our model to predict the statistical properties of quasars at higher redshifts ($z \ge 6$) and provide prediction for future explorations.

4.1. Black Hole Mass Functions

In the left panel of Fig. [6,](#page-11-1) we show the predicted BHMFs at five different redshifts of $z = 6{\text -}10$ for $f_{\rm seed} = 0.1$ (solid) and 0.01 (dashed). As shown in Fig. [1,](#page-4-0) the mass distribution of seed BHs establishes up to $M_{\bullet} \leq 2 \times 10^5$ M_{\odot} by $z \geq 17$. Subsequently, the BHMF develops toward higher mass ranges by the growth of seeds with a fraction of f_{seed} . In fact, the case with $f_{\text{seed}} = 0.1$ yields the number density of those growing seeds ten times higher than that with $f_{\text{seed}} = 0.01$, making the difference in the BH abundance at $M_{\bullet} \sim 10^{5-7} M_{\odot}$. Thus, the information on the seeding fraction still remains in this low mass regime. Toward lower redshifts, heavier BHs with $\gtrsim 10^7$ M_{\odot} emerge owing to efficient growth and thus BHMF in the high-mass tail increases. Since our model is calibrated against the $z \approx 6$ BHMF of [W10,](#page-23-8) the two cases with different seeding fractions yield similar shapes of mass distribution at $M_{\bullet} \simeq 10^8 - 3 \times 10^9$ M_{\odot} (see Fig. [4\)](#page-10-0). The BHMF at $M_{\bullet} \gtrsim 10^7$ M_{\odot} , which is potentially accessible by high-z quasar observations, can be characterized with a double power-law function,

$$
\Phi_{M_{\bullet}} = \frac{\Phi_{M_{\bullet}}^{*}}{(M_{\bullet}/M_{\bullet}^{*})^{-(\hat{\alpha}+1)} + (M_{\bullet}/M_{\bullet}^{*})^{-(\hat{\beta}+1)}}.
$$
(18)

This function shape is also used to characterize the BHMF of lower-z quasar populations (e.g., Kelly $&$ Shen [2013;](#page-21-42) [Schulze et al.](#page-23-39) [2015\)](#page-23-39). Here, $\Phi_{M_{\bullet}}^{*}$ (in units of Gpc^{-3} dex^{-1}) is the overall normalization, M_{\bullet}^* is the characteristic BH mass, and $\hat{\alpha}$ and $\hat{\beta}$ are the low and high-mass end slopes, respectively. In Table [2,](#page-12-0) we summarize those

Table 2. Parametric Black Hole Mass Function

Redshift	$\Phi_{M_{\bullet}}^*$	M^*	$\hat{\alpha}$		
	$(Gpc^{-3} \text{ dex}^{-1})$ $(10^7 M_{\odot})$				
$z \sim 6$	1310	6.13	-1.41	-2.58	
$z \sim 7$	166	8.12	-1.81	-2.88	
$z \sim 8$	23.2	9.98	-2.07	-3.12	
$z \sim 9$	5.61	9.44	-2.24	-3.29	
$z \sim 10$	2.13	7.68	-2.35	-3.41	

NOTE—The fitting parameters of the BHMF with a double power-law function for the case with $f_{\text{seed}} = 0.01$. The mass range used for fitting is 10^6 $M_{\odot} \leq M_{\bullet} \leq 10^{10}$ M_{\odot} .

parameters at $z = 6$ –10 for the best-fit model in the case of $f_{\text{seed}} = 0.01$.

In the right panel of Fig. [6,](#page-11-1) we present the cumulative BH mass density $\rho_{\bullet}(z)$ in a comoving volume for $f_{\rm seed} =$ 0.1 (solid) and 0.01 (dashed), which is equivalent to the integration of the BHMF:

$$
\rho_{\bullet}(z) = \int_{\mathcal{I}} \Phi_{M_{\bullet}}(z) M_{\bullet} \, \mathrm{d} \log M_{\bullet}.
$$
 (19)

Here, we consider three mass ranges: $M_{\bullet} \leq 10^6$ M_{\odot} (blue), 10^6 M_{\odot} < M_{\bullet} < 10^8 M_{\odot} (orange), and M_{\bullet} ≥ 10^8 M_{\odot} (green). Overall, the mass density of the heaviest BHs quickly grows toward lower redshifts, while for the lightest BHs the mass density barely evolves. At $z \leq 7-8$, heavier BHs with $\gg 10^6$ M_{\odot} begin to dominate the mass budget of the entire BH population, promoting the so-called downsizing or anti-hierarchical evolution of massive BHs in terms of mass occupation (e.g., [Ueda et al.](#page-23-4) [2014\)](#page-23-4). We note that our model considers a BH population formed in the overdense region, and neglects the contribution of BH seeds from ordinary PopIII remnants in lower-mass halos $(M_h < 10¹¹ M_o)$. The latter population is typically less massive $(M_{\star} \leq 10^3 M_{\odot})$ but more abundant (e.g., [Hirano et al.](#page-21-16) [2015;](#page-21-16) [Toyouchi](#page-23-21) [et al.](#page-23-21) [2023\)](#page-23-21). Therefore, the BHMF at the low-mass end in our model underestimates the abundance while the high-mass end at $M_{\bullet} \gtrsim 10^7$ M_{\odot} matches the observed distribution well.

For comparison, we overlay in the right panel of Fig. [6](#page-11-1) the BH mass density evolution at 10^6 M_{\odot} < M_{\bullet} < 10^8 M_{\odot} obtained from the cosmological simulations in [Ni et al.](#page-22-38) [\(2022\)](#page-22-38) (dashed-dotted curve). At $z \lesssim 7$, our results are in overall good agreement with those simulation results. However, our models predict a larger number of 10^{6-8} M_{\odot} BHs emerging at $z \sim 8 - 10$, owing to our model prescription that allows BH seed formation earlier

on and (modest) super-Eddington episodes. Furthermore, the unresolved fraction of the cosmic X-ray background at $z \gtrsim 5$ constrains the global BH accretion history [\(Salvaterra et al.](#page-22-40) [2012;](#page-22-40) [Treister et al.](#page-23-42) [2013\)](#page-23-42). Upper bounds on the accreted-mass density (black arrows) prohibit overproduction of low mass BHs at cosmic dawn. The mass density of BHs formed in the biased, overdense region of the universe is consistent with the constraint, unlike models that require a large number of stellar-mass BH remnants (see also [Tanaka & Haiman](#page-23-19) [2009\)](#page-23-19).

4.2. Quasar Luminosity Functions

Fig. [7](#page-13-0) presents our prediction of QLFs at $z \gtrsim 6$ taken from the BH growth model with $f_{\text{seed}} = 0.01$. We show QLFs at different epochs; (a) $z \sim 7$, (b) $z \sim 8$, (c) $z \sim 9$, and (d) $z \sim 10$ –13. The black solid and dashed curves of each panel show the QLF for the unobscured population and intrinsic population (including unobscured and obscured quasars), respectively. The obscured fraction derived in an X-ray quasar sample up to $z \sim 5$ by [Ueda](#page-23-4) [et al.](#page-23-4) [\(2014\)](#page-23-4) is applied to the conversion between the two populations, while we note that a large uncertainty exists at $M_{1450} \gtrsim -20$ mag. Similar to the BHMF, for all the redshift ranges, the shape of the QLF is well approximated with a double power-law function,

$$
\Phi_{M_{1450}} = \frac{\Phi_{M_{1450}}^{*}}{10^{0.4(\tilde{\alpha}+1)\Delta M_{1450}} + 10^{0.4(\tilde{\beta}+1)\Delta M_{1450}}}, \quad (20)
$$

where $\Phi_{M_{1450}}^{*}$ (in units of Gpc^{-3} mag⁻¹) is the overall normalization, M^*_{1450} is the characteristic magnitude, $\Delta M_{1450} \equiv M_{1450} - M_{1450}^*$, and $\tilde{\alpha}$ and $\tilde{\beta}$ are the faint and bright-end slopes, respectively. In Table [3,](#page-14-0) we summarize those parameters at $z = 6$ –10 for the best-fit models. From higher to lower redshifts, the QLF increases and the bright-end slope gets flatter.

We overlay the expected depths and survey volumes of upcoming near-infrared surveys by Euclid [\(Laureijs](#page-21-5) [et al.](#page-21-5) [2011;](#page-21-5) [Euclid Collaboration et al.](#page-20-37) [2019\)](#page-20-37) and RST [\(Akeson et al.](#page-19-1) [2019\)](#page-19-1). We here consider only their widearea survey layers because narrow-field deep surveys are not optimized for hunting high-z quasars (but see [Onoue](#page-22-41) [et al.](#page-22-41) [2023\)](#page-22-41). Table [4](#page-14-1) summarizes the expected number yields of quasars from those surveys. We first integrate the QLFs at the apparent magnitude $m_{1450} \leq 24$ mag and 27 mag for Euclid and RST, respectively. These depths correspond to the 5σ point source detection limits in the Y JH bands of the two facilities. Euclid will cover \simeq 100–700 quasars at $z \sim$ 7–8 down to the limiting magnitude ($M_{1450} \sim -24$ mag), and can reach up to $z \sim 9$. The RST will explore fainter $(M_{1450} \gtrsim -24 \text{ mag})$ and more abundant quasar populations up to $z \sim 10$. However, the estimated values above only give upper

Figure 7. The predicted quasar luminosity functions at (a) $z \sim 7$, (b) $z \sim 8$, (c) $z \sim 9$, and (d) $z \sim 10 - 13$. The black solid and dashed curves are the unobscured and intrinsic QLF, respectively, and the shaded region presents the 1σ statistical error. The expected depths and volumes of future surveys with Wide Euclid (blue; $m_{1450} = 23$ mag) and Wide RST (red; $m_{1450} = 27$ mag) are overlaid in each panel (see Table [4\)](#page-14-1). For comparison, the galaxy UV luminosity functions are plotted with the data points (grey) and the fitting functions in purple with a Schechter (solid) and double power-law (dashed) shape. The luminosity function data are taken from [McLure et al.](#page-22-42) [\(2013\)](#page-22-42), [Oesch et al.](#page-22-43) [\(2016\)](#page-22-43), [Morishita et al.](#page-22-44) [\(2018\)](#page-22-44), [Stefanon et al.](#page-23-43) [\(2019\)](#page-23-43), [Bowler](#page-20-38) [et al.](#page-20-38) [\(2020\)](#page-20-38), [Bouwens et al.](#page-19-11) [\(2021\)](#page-19-11), [Harikane et al.](#page-20-36) [\(2022a,](#page-20-36)[b,](#page-20-39) [2023\)](#page-21-43), [Donnan et al.](#page-20-40) [\(2023\)](#page-20-40), [Naidu et al.](#page-22-45) [\(2022\)](#page-22-45). The fitting forms of the galaxy luminosity functions are given by [Harikane et al.](#page-20-36) [\(2022a\)](#page-20-36) at z ∼ 7, [Bowler et al.](#page-20-38) [\(2020\)](#page-20-38) and [McLure et al.](#page-22-42) [\(2013\)](#page-22-42) at $z \sim 8$, and [Harikane et al.](#page-21-43) [\(2023\)](#page-21-43) at $9 \lesssim z \lesssim 13$.

bounds of the number of detectable high-z quasars, because selection completeness is not unity in identifying high-z quasars. [Euclid Collaboration et al.](#page-20-37) [\(2019\)](#page-20-37) investigated the efficiency of quasar selection with Euclid images and found that combined with ground-based optical observations, $z \sim 7-9$ quasars can be identified down to $J \sim 23$ mag due to photometric noise and contaminants in the color selection such as Galactic brown dwarfs and low-z early-type galaxies. Adopting $m_{1450} = 23$ mag as the effective depth, our predicted detection numbers are

in good agreement with their results but show a better match for the case where their QLFs are extrapolated from $z \sim 6$ with $10^{-0.72z}$ toward higher redshifts (see the fourth column of Table 3 in [Euclid Collaboration](#page-20-37) [et al.](#page-20-37) [2019\)](#page-20-37).

Luminous quasars with $M_{1450} \leq -26$ mag are expected to be marginally detected by Euclid and the RST up to $z \sim 7$ and 8, respectively, with ~ 1 detection number predicted by the integration over the model QLFs. However, [Fan et al.](#page-20-4) [\(2019\)](#page-20-4) proposed that

		Unobscured QLF			Intrinsic QLF

RST	This work	2000	$m_{1450} \leq 27$ 6759 ⁺¹⁵ ₋₃₁₈₅		1514^{+169}_{-558}	349_{-131}^{53}	85^{+23}_{-48}	25^{+12}_{-15}

NOTE— Prediction of high-z quasar numbers yielded by the Euclid and RST wide-area surveys from $z \sim 6$ to 10 with $\Delta z = 1$. The QLFs we utilize to estimate the detection numbers are from the BH growth model with $f_{\text{seed}} = 0.01$. The integration of the QLF is conducted assuming 100% selection completeness for quasar populations brighter than the photometric depths, which are adopted as the 5σ point source detection limits of the YJH bands in each survey. To mimic realistic quasar identification capability, we also show the detection numbers with $m_{1450} \leq 23$ mag in comparison with [Euclid Collaboration et al.](#page-20-37) [\(2019\)](#page-20-37). The latter prediction is migrated from the fourth column of their Table 3 for three redshift ranges: $7.0 < z < 7.5$, $8.0 < z < 8.5$, and $8.5 < z < 9.0$, with trials on different extrapolations of the quasar number density at higher redshifts ($\propto 10^{k_{\text{L}}z}$); $k_{\text{L}} = -0.72$ and -0.92 . The prediction of no detection or no references in the literature are denoted by the symbol "–".

quasar detection can reach $z \sim 9$ by the two surveys, assuming a moderate decline of the quasar number density ($\propto 10^{-0.78z}$) in QLF extrapolations from $z \sim 6$ (see more discussion in Fig. [8\)](#page-15-1). The differences in those predictions will be tested by upcoming high-z quasar observations.

We also show the galaxy UV luminosity function in each panel of Fig. [7](#page-13-0) along with the fitting function in a Schechter (solid) and double power-law (dashed) shape extended to the bright end [\(McLure et al.](#page-22-42) [2013;](#page-22-42) [Oesch](#page-22-43) [et al.](#page-22-43) [2016;](#page-22-43) [Morishita et al.](#page-22-44) [2018;](#page-22-44) [Stefanon et al.](#page-23-43) [2019;](#page-23-43) [Bowler et al.](#page-20-38) [2020;](#page-20-38) [Bouwens et al.](#page-19-11) [2021;](#page-19-11) [Donnan et al.](#page-20-40) [2023;](#page-20-40) [Harikane et al.](#page-20-36) [2022a,](#page-20-36)[b,](#page-20-39) [2023;](#page-21-43) [Naidu et al.](#page-22-45) [2022\)](#page-22-45). Galaxies at $M_{1450} \gtrsim -23$ mag dominate in number at all the redshifts and impede the identification of relatively rare quasars among those faint objects. Since the extrapolated galaxy luminosity function with a Schechter

shape declines quickly with the luminosity increasing, the galaxy abundance becomes comparable to that of quasars at $M_{1450} \sim -23$ mag (z ~ 7–8), -24 mag $(z \sim 9)$, and -25 mag $(z \sim 10-13)$. On the other hand, if the bright end of the galaxy luminosity function is extended with the bright-end power-law slope, the critical UV magnitude shifts to $M_{1450} \sim -26$, -25 , and \ll -30 mag for each redshift range. Future deep and wide surveys will unveil the relative contribution of the two populations and their roles in cosmic reionization (see also [M18,](#page-22-5) [Jiang et al.](#page-21-40) [2022\)](#page-21-40).

In Fig. [8,](#page-15-1) we present the quasar number density evolution as a function of redshift. The solid curves show the cases for $f_{\text{seed}} = 0.1$ and the dashed curves show the cases for $f_{\text{seed}} = 0.01$, respectively. Each curve corresponds to the QLF value at a UV magnitude from $M_{1450} = -27$ mag to -23 mag. Our theoretical pre-

Figure 8. Redshift evolution of the QLF value at different UV magnitudes from $M_{1450} = -27$ mag to -23 mag. The theoretical model prediction from $z = 6$ to 10 are shown for the cases of $f_{\text{seed}} = 0.1$ (solid) and 0.01 (dashed), respectively. At $z \geq 6$, the quasar number is characterized with $\propto 10^{k_L z}$, where the index is $k_L \simeq -0.91$ and -0.62 for quasars at $M_{1450} = -27$ mag and -23 mag, respectively. The observational data at lower redshifts $0 \le z \le 6$ are compiled from the Subaru HSC results [\(Akiyama et al.](#page-19-12) [2018;](#page-19-12) [Matsuoka et al.](#page-22-5) [2018b;](#page-22-5) [Niida et al.](#page-22-46) [2020\)](#page-22-46), SDSS [\(Richards et al.](#page-22-47) [2006b;](#page-22-47) [McGreer et al.](#page-22-7) [2013\)](#page-22-7), the 2dFSDSS LRG and Quasar Survey (2SLAQ; [Croom et al.](#page-20-41) [2009\)](#page-20-41), and the Spitzer Wide-area Infrared Extragalactic Legacy Survey (SWIRE; [Siana et al.](#page-23-44) [2008\)](#page-23-44).

dictions are shown at $z \geq 6$ (thick curves), while observational results compiled in [Niida et al.](#page-22-46) [\(2020\)](#page-22-46) are shown at lower redshifts (thin curves). The evolutionary trend can be fitted as $\propto 10^{k_L z}$ at high redshifts. The best-fit indexes are $k_L \simeq -0.91$ and -0.62 for the brightest and faintest population at $z \geq 6$, respectively. For the abundance of luminous quasars with $M_{1450} \lesssim -26$ mag, a rapid decay toward higher redshifts is suggested by observational studies (e.g., [Fan et al.](#page-20-42) [2001;](#page-20-42) [McGreer](#page-22-7) [et al.](#page-22-7) [2013;](#page-22-7) [Jiang et al.](#page-21-2) [2016;](#page-21-2) [Wang et al.](#page-23-10) [2019\)](#page-23-10). For instance, [Wang et al.](#page-23-10) [\(2019\)](#page-23-10) proposed a decay index of $k_{\text{L}} = -0.78 \pm 0.18$ for those bright quasars at $6 \lesssim z \lesssim 7$. The slopes in our model prediction of $M_{1450} \le -26$ are slightly steeper ($k_L \simeq -0.84$ at $M_{1450} = -26$), but consistent with their finding within the 1σ error range.

5. DISCUSSION

5.1. Individual BH growth

From the BH growth model described in Section [2.3,](#page-6-3) we further explore individual BH evolutionary tracks starting from their seeding phases. We generate a sample of 10⁶ BHs, whose formation time and mass distribution at birth follow the model described in Section [2.1.](#page-2-1) Adopting the best-fit parameters in the case of $f_{\rm seed} = 0.01$, in every time interval $\tau = 18.76$ Myr, we assign a constant Eddington ratio generated from the Schechter-type ERDF characterized with $\lambda_0 = 0.87$ and $\alpha = 0.20$ (see Section [3\)](#page-8-0). With those parameters, we grow the individual BHs until $z = 6$ and study their statistical properties.

First, we estimate the duty cycle between at $6 \leq z \leq$ 10 defined as $f_{\text{duty}} \equiv \mathcal{N}\tau/\Delta t_{\text{H}}$, where \mathcal{N} is the frequency of super-Eddington accretion bursts with $\lambda \geq 1$ and $\Delta t_{\rm H} \simeq 450$ Myr. For BH populations grown to $M_{\bullet} \geq 10^7$, 10^8 and 10^9 M_{\odot} at $z = 6$, the average duty cycle is found to be $\langle f_{\text{duty}} \rangle \simeq 0.12, 0.15, \text{ and } 0.19, \text{ re-}$ spectively. The trend of the duty cycle on the mass suggests that those massive BHs experience multiple active accretion phases to reach the SMBH regime. On the other hand, the average duty cycle for the entire BH population is calculated as $\langle f_{\text{duty}} \rangle = 0.075$ adopt-

ing this ERDF (see Section [3\)](#page-8-0), and is significantly lower than those for the massive BH sub-samples. Therefore, we suggest that SMBHs observed in $z \sim 6$ quasars are a biased population that undergoes longer active accretion episodes.

In Fig. [9,](#page-17-1) we show the BH growth tracks that end up with $M_{\bullet} > 10^8$ M_{\odot} by $z = 6$ (grey curves). In this sub-sample, we find six BHs heavier than $M = 10^9 M_{\odot}$ (highlighted with colored solid curves), all of which indicate $\lambda \leq 1$ at the $z = 6$ snapshot. Tracing the BH growth curves back with the Eddington ratio observed at $z = 6$ (dashed curves), the extrapolated masses of those massive, sub-Eddington BHs at $z = 6$ are as heavy as $M_{\bullet} \gg 10^6$ M_{\odot} at $z \sim 30$, which is substantially higher than the mass range for seed BHs. It has been pointed out by [Onoue et al.](#page-22-6) [\(2019\)](#page-22-6) that such simple extrapolation of the growth history for low- λ quasars does not work properly (see their Figure 10). For comparison, we show the mass growth tracks assuming continuous Eddington accretion ($\lambda = 1$; dashed-dotted curves), where the extrapolated seed mass is $M_{\bullet} \leq 10^2 M_{\odot}$ at $z \sim 30$. In conclusion, therefore, multiple accretion episodes with different values of λ should be taken into account to infer the seeding mass for the observed SMBHs as bright quasars at $z \geq 6-7$, instead of assuming one single number of the Eddington ratio.

[Wang et al.](#page-23-45) [\(2021\)](#page-23-45) discovered the currently known most distant quasar at $z = 7.642$, with $M_{\bullet} \simeq 1.6 \times$ 10^9 M_{\odot} and $\lambda \simeq 0.67$ (red diamond in Fig. [9\)](#page-17-1). Assuming continuous Eddington accretion, the extrapolated BH is as massive as 10^{4-6} M_{\odot} at $z = 30$. Our best-fit model naturally explains the existence of this most extreme BH, taking into account the episodical accretion nature of quasars (see the red solid curve; $M_{\bullet} \simeq 1.7 \times 10^9$ M_{\odot} and $\lambda \simeq 0.6$ at $z = 7.6$). The result demonstrates that one possible formation channel of the highest-z quasar is through the combination of rare halo environments planting a seed BH with $\sim 2 \times 10^5$ M_⊙ at $z \sim 30$ and several (modest) super-Eddington accretion bursts. The mass range of the highest-z SMBHs can be achieved by previous cosmological simulations with a certain type of sub-grid models for BH feeding and feedback [\(Di Matteo](#page-20-28) [et al.](#page-20-28) [2017;](#page-20-28) [Barai et al.](#page-19-8) [2018;](#page-19-8) [Lupi et al.](#page-21-37) [2019\)](#page-21-37).

Multiple episodes of BH accretion naturally yield variable quasar light curves and leave ionized gas with a complex structure. The measurement of the ionization state of the intergalactic medium surrounding a quasar is a powerful tool to constrain the timescale of t_{Ω} in a luminous quasar phase [\(Bolton & Haehnelt](#page-19-13) [2007;](#page-19-13) [Khrykin et al.](#page-21-44) [2016;](#page-21-44) [Eilers et al.](#page-20-43) [2017;](#page-20-43) [Davies et al.](#page-20-34) [2019\)](#page-20-34). Recent observations of the line-of-sight hydrogen $Ly\alpha$ proximity zone sizes indicate a short quasar

age of $t_{\rm Q} \sim 1$ Myr on average, while the ages of some individual quasars are inferred to be even shorter than $t_{\rm Q} \sim 0.1$ Myr (e.g., [Ishimoto et al.](#page-21-45) [2020;](#page-21-45) [Eilers et al.](#page-20-44) [2021\)](#page-20-44). However, we note that the line-of-sight proximity effect is only sensitive to the most recent activity of quasars. Alternatively, the transverse proximity effect is useful to probe a longer quasar activity comparable to a Salpeter timescale [\(Adelberger](#page-19-14) [2004;](#page-19-14) [Visbal](#page-23-46) [& Croft](#page-23-46) [2008;](#page-23-46) [Schmidt et al.](#page-23-47) [2019\)](#page-23-47). Recently, [Kakiichi](#page-21-46) [et al.](#page-21-46) [\(2022\)](#page-21-46) proposed a new technique to photometrically map the quasar light echoes using $Ly\alpha$ forest tomography and discussed an efficient observational strategy. With our MCMC fitting result reproducing the observed QLF and BHMF, each quasar activity is required to last for $\tau \simeq 20$ Myr on average. Moreover, a significant fraction ($\sim 10-20\%$) of the massive BHs with $M_{\bullet} \geq 10^8$ M_{\odot} in our sample experience two successive active phases with a total active duration of $\sim 30 - 40$ Myr at $z \approx 6$. Therefore, direct measurements of the distribution of τ in future observations will test our prediction on quasar activity and improve our understanding on the BH growth histories through luminous quasar phases.

5.2. The distribution of the Eddington ratio: observed v.s. underlying populations

Even with the current observational facilities, it is challenging to unveil the properties of the underlying quasar population because of the limitation of the photometric depths of quasar surveys. In this section, we examine how the unavoidable bias affects the properties of the ERDF for observed quasars, taking our complete sample of high- z BH populations in the whole luminosity range.

Based on the quasar sample from the best-fit model described in Section [5.1,](#page-15-2) we select quasars with bolometric luminosity limits of L_{45} = 10^{45} erg s⁻¹ and $L_{46} = 10^{46}$ erg s⁻¹. In Fig. [10,](#page-18-0) we present the intrinsic ERDF for the whole BH sample (blue) and the apparent ERDFs for selected samples with a luminosity cut of $L_{\text{bol}} \geq L_{45}$ (orange), and $L_{\text{bol}} \geq L_{46}$ (green), respectively. For illustration purposes, we scale the normalization of the ERDFs with the luminosity cuts, multiplied by a factor of 5 and 30, respectively. The Eddington ratio for the whole sample follows a Schechter shape with a majority of inactive quasars, while the observed Eddington ratio is biased toward higher values and the distribution results in a log-normal shape, consistent with that of the brightest quasars at $z \sim 6$ (e.g., [Willott et al.](#page-23-8) [2010b;](#page-23-8) [Shen et al.](#page-23-9) [2019;](#page-23-9) [Yang et al.](#page-24-10) [2021;](#page-24-10) [Farina et al.](#page-20-45) [2022\)](#page-20-45). The log-normal shape still holds with the lower luminosity cut, but a lower luminosity threshold allows

Figure 9. Evolutionary tracks of individual seed BHs with the the best-fit growth model parameters in the $f_{\text{seed}} = 0.01$ case. Among all the samples, we select BHs that reach $M \ge 10^8$ M_{\odot} at $z = 6$ (grey thin curves). The six heaviest SMBHs $(M_{\bullet} \geq 10^{9}$ M_o at $z = 6$) are highlighted with colored curves. For those BHs, we draw the assembly history assuming an exponential growth with a constant Eddington ratio: the λ -value seen at $z = 6$ for each BH (dotted) and $\lambda = 1$ (dashed). Our best-fit model explains the existence of the most massive BHs via multiple accretion episodes with different values of λ , and reproduces the mass and Eddington ratio for the highest-z quasar [\(Wang et al.](#page-23-45) [2021;](#page-23-45) red diamond).

us to unveil more hidden quasars with low Eddington ratios. The existence of those sub-Eddington BHs at $z > 6$ will be probed by the ongoing survey of the Subaru HSC and JWST [\(Onoue et al.](#page-22-6) [2019,](#page-22-6) [2021\)](#page-22-48), as well as upcoming wide-field surveys such as the Vera C. Rubin Observatory, Euclid, and RST.

6. SUMMARY

In this paper, we propose a theoretical model for the redshift-dependent QLF and BHMF at $z \geq 6$, applying the mass distribution function of seed BHs over 10^2 $M_{\odot} \leq M_{\bullet} \leq 10^5$ M_{\odot} that originate from massive primordial stars formed in quasar host galaxies. In our accretion model, those early BH populations are assumed to experience multiple accretion bursts, in each of which a constant Eddington ratio is assigned following a Schechter distribution function. We further conduct the MCMC fitting to optimize the BH growth parameters so that the observed QLF and BHMF at $z \simeq 6$ are simultaneously reproduced. Our major findings are summarized as follows.

- The best-fitted model requires the typical duration of accretion bursts to be $\tau \simeq 20 - 30$ Myr, which is a fraction of the Salpeter time ($t_S \approx 45$) Myr). The ERDF with a Schechter-like shape is constrained to produce the observed BHMF and QLF at $z \approx 6$; namely, the characteristic Eddington ratio and power-law slope are $\lambda_0 \simeq 0.88$ and $\alpha \simeq 0.12-0.2$, depending the fraction of seed BHs that participate in the assembly of SMBHs (see Fig. [3\)](#page-9-1).
- The cosmological evolution of the BHMF and QLF at $6 \leq z \leq 10$ is predicted based on the model parameters calibrated with the observational data (see Figs. [6,](#page-11-1) [7,](#page-13-0) and [8\)](#page-15-1). The fitting parameters of the BHMF and QLF with a double power-law function are summarized in Tables [2](#page-12-0) and [3.](#page-14-0) We find that the number density of luminous quasars decays toward higher redshifts as $\propto 10^{k_L z}$, where $k_L \approx -0.91$ and -0.62 for the brightest and faintest population at $6 < z < 10$. We also show

Figure 10. The intrinsic Eddington ratio distribution function for the whole BH sample (blue) and the apparent distribution function for selected samples with a luminosity cut of $L_{\text{bol}} \geq 10^{45} \text{ erg s}^{-1}$ (orange) and $L_{\text{bol}} \geq 10^{46} \text{ erg s}^{-1}$ (green), respectively. The normalization of the ERDFs with the luminosity cuts is scaled by a factor of 5 and 30, respectively, for illustration purposes. The intrinsic ERDF follows the best-fitted Schechter function (dashed curve), while the observed ERDF with a detection limit results in a log-normal shape where most sub-Eddington quasars are excluded. The log-normal shape still holds with the lower luminosity cut, but a lower detection limit alleviates the selection effect against quasar populations with low Eddington ratios.

the detection number of high-z quasars expected in Euclid and RST observations (see Table [4\)](#page-14-1). Those results will be tested with upcoming deep and wide-field surveys.

• We apply the best-fit model for BH growth to evolution of individual BHs and examine their statistical properties. We find that the existence of SMBHs hosted in $z \geq 6$ quasars can be explained by multiple accretion episodes with vari-

In our modeling for BH growth, we introduce a time duration τ of individual quasar activity, where a single value of the Eddington ratio λ generated from the ERDF is assigned to all the BHs (see Section [2.2\)](#page-4-1). Multiple sampling of λ between the seeding epoch and $z = 6$ reduces the probability that one BH keeps a fast growth speed at $\lambda \geq \lambda_0$ all the way to $z = 6$, compared to the case with a single sampling of λ . In what follows, we demonstrate the role of τ in shaping the BHMF and QLF.

able Eddington ratios, instead of assuming continuous Eddington-limited growth (see Fig. [9\)](#page-17-1). In fact, the average duty cycle of active accretion phases with $\lambda \geq 1$ is as high as $\simeq 15$ % for massive BHs that reach $\geq 10^8$ M_{\odot} by $z \simeq 6$. This result indicates that those biased BH populations undergo longer active accretion episodes to be observed as quasars. We also find that the observed Eddington-ratio distribution function is skewed to a log-normal shape from the intrinsic Schechter function owing to detection limits of quasar surveys (see Fig. [10\)](#page-18-0). The log-normal shape still holds with a lower luminosity cut of $L_{\text{bol}} \gtrsim 10^{45} \text{ erg s}^{-1}$. The existence of those underlying sub-Eddington BHs at $z > 6$ will be probed by the ongoing survey of the Subaru HSC and JWST, as well as upcoming wide-field surveys such as the Vera C. Rubin Observatory, Euclid, and RST.

APPENDIX

In the left panel of Fig. [11,](#page-19-15) we present the BHMF at $z = 6$ for three different values of $\tau = 14$, 18, and 37 Myr, but keeping the other parameters to the best-fit values ($\delta = 0.055$, $\lambda_0 = 0.87$, and $\alpha = 0.20$) for the case with $f_{\text{seed}} = 0.01$. We note that $\tau \simeq 18$ Myr is the best-fit value reproducing the observed BHMF and QLF at $z = 6$, and the other two choices correspond to the 16% and 84% quantiles in the cumulative onedimensional posterior distribution of τ , respectively (see Fig. [3\)](#page-9-1). With the shorter quasar activity of $\tau = 14$ Myr, the frequency of Eddington ratio assignment increases

Figure 11. The BH mass function (left) and quasar luminosity function (right) at $z = 6$ in the case of $f_{\text{seed}} = 0.01$, with different values of $\tau = 14$, 18 (the best-fit value), and 37 Myr, respectively. Note that the other parameters are fixed to the best-fit values ($\delta = 0.055$, $\lambda_0 = 0.87$, and $\alpha = 0.20$). For comparison, we overlay the BHMF [\(W10\)](#page-23-8) and QLF [\(M18\)](#page-22-5) at $z \approx 6$ in blue. With the shorter (longer) timescales of each accretion episode τ , the number of BHs at the high mass end and bright end is under(over)-produced. Multiple accretion bursts with each duration of $\tau \approx 18$ Myr, which is nearly half of the e-folding time of the exponential BH mass growth, reproduce the observed BHMF and QLF at $z \simeq 6$.

by a factor of 1.3 until $z = 6$, compared to the best-fit case. Therefore, continuous rapid growth of BHs with $\lambda \gtrsim \lambda_0$ is less likely to take place, preventing heavy BHs from forming. Moreover, even if a high Eddington ratio is given with a certain but low probability, the BH hardly grows in mass within such a short time $\tau = 14$ Myr, which is $\simeq 30\%$ of the e-folding timescale. On the other hand, with the longer quasar activity of $\tau =$ 37 Myr, a substantial fraction of BHs experience high accretion rates with $\lambda \gtrsim \lambda_0$ through their assembly history. Therefore, the high mass end of the BHMF is extended and massive BH populations with $\gg 10^8$ M_{\odot} are overproduced compared to the observed abundance.

In the right panel of Fig. [11,](#page-19-15) we show the QLF at $z = 6$ with the three different values of τ . Overall, the dependence of the QLF on the choice of τ shows the same trend as in the BHMF, i.e., a longer (shorter) τ leads to under(over)-production of the luminous quasar population. This result demonstrates the importance of multiple accretion episodes for the earliest BHs to reproduce the observed BHMF and QLF at $z \sim 6$.
