Abstract We report the properties of more than 800 bursts detected from the repeating fast radio burst (FRB) source FRB 20201124A with the Five-hundred-meter Aperture Spherical radio Telescope (FAST) during an extremely active episode on UTC September 25-28, 2021 in a series of four papers. In this second paper of the series, we study the energy distribution of 881 bursts (defined as significant signals separated by dips down to the noise level) detected in the first four days of our 19-hour observational campaign spanning 17 days. The event rate initially increased exponentially but the source activity stopped within 24 hours after the 4th day. The detection of 542 bursts in one hour during the fourth day marked the highest event rate detected from one single FRB source so far. The bursts have complex structures in the time-frequency space. We find a double-peak distribution of the waiting time, which can be modeled with two log-normal functions peaking at 51.22 ms and 10.05 s, respectively. Compared with the emission from a previous active episode of the source detected with FAST, the second distribution peak time is smaller, suggesting that this peak is defined by the activity level of the source. We calculate the isotropic energy of the bursts using both a partial bandwidth and a full bandwidth and find that the energy distribution is not significantly changed. We find that an exponentially connected broken-power-law function can fit the cumulative burst energy distribution well, with the lower and higher-energy indices being -1.22 ± 0.01 and -4.27 ± 0.23 , respectively. Assuming a radio radiative efficiency of $\eta_r = 10^{-4}$, the total isotropic energy of the bursts released during the four days when the source was active is already 3.9×10^{46} erg, exceeding $\sim 23\%$ of the available magnetar dipolar magnetic energy. This challenges the magnetar models invoking an inefficient radio emission (e.g. synchrotron maser models).

Key words: transients: fast radio bursts - stars: individual (FRB 20201124A) - methods: data analysis

1 INTRODUCTION

Fast Radio Bursts (FRBs) are short-duration bright transients in radio band. Since the first discovery (Lorimer et al. 2007), more than 600 FRB sources have been detected (Petroff et al. 2016; CHIME/FRB Collaboration et al. 2021). While most of the FRBs were detected once,

more than 20 sources have been observed to emit repeated bursts¹. Whether FRBs can be divided into repeaters and non-repeaters is still an open question. The engine to power FRB sources and the physical mechanism to generate co-

¹ <https://www.wis-tns.org/>

herent radio emission are subject to intense study (Zhang 2020).

Emitted energy is a fundamental property of FRBs. For the FRB population, the luminosity function is usually assumed to be a power law function with an exponential high-energy cutoff (also called Schechter function Schechter 1976). In the literature, the power law index α of the Schechter luminosity function (dN/dL) has been constrained by different groups using different FRB samples (Lu & Kumar 2016, 2019; Luo et al. 2018; Bhandari et al. 2018; Macquart & Ekers 2018; Golpayegani et al. 2019; Luo et al. 2020; Zhang et al. 2021; Hashimoto et al. 2022), with α constrained to the range from -1.5 to -2.2. Lu et al. (2020) showed that an index ~ -1.8 can account for FRBs down to the low-luminosity Galactic FRB 200418. The observed FRB population is a convolution of the luminosity function and redshift distribution. For sources in Euclidean geometry with constant space density, the observed fluence distribution should follow a power-law distribution with an index -1.5 (Vedantham et al. 2016). As cosmological sources, FRBs spatial distribution deviates from this simple law and the unknown redshift distribution may play a role in shaping the observed population. If the progenitors of FRBs are young, the number density of FRBs should track the cosmic star formation history (Madau & Dickinson 2014; Nicholl et al. 2017) towards redshift about $z \sim 2$. Some studies have shown that the FRB samples show the trend of deviating from the star formation history (Hashimoto et al. 2020b; Zhang et al. 2021; Arcus et al. 2021; James et al. 2022). In particular, the CHIME first catalog sample seems to suggest a redshift distribution that is delayed from the star formation history (Zhang & Zhang 2022; Hashimoto et al. 2022), suggesting that a good fraction of FRB progenitors are likely old, with the number density decrease towards high redshift. In any case, various studies showed that the derived luminosity/energy functions are consistent with each other regardless of the assumption of redshift distribution (Lu & Kumar 2016, 2019; Luo et al. 2018; Bhandari et al. 2018; Macquart & Ekers 2018; Golpayegani et al. 2019; Luo et al. 2020; Zhang et al. 2021; Zhang & Zhang 2022; Hashimoto et al. 2022).

For repeating FRBs, the energy/luminosity functions of individual sources can be studied in great detail. Detailed studies on the two well-known sources FRB 20121102A and FRB 20180916B suggested that they can be modeled by a power law function with the power-law indices ranging from -2.8 to -1.7 for bright bursts (Law et al. 2017; Wang & Zhang 2019; Gourdjji et al. 2019; Cruces et al. 2021; Aggarwal et al. 2021; CHIME/FRB Collaboration et al. 2020). These results can imply some differences for the two kinds of FRBs in respect to lumi-

nosity/energy functions (Hashimoto et al. 2020a). Owing to the high sensitivity of the Five-hundred-meter Aperture Spherical radio Telescope (FAST, Nan et al. 2011), Li et al. (2021) revealed a detailed energy function using more than 1600 bursts for the repeater FRB 20121102A. They found that the energy function cannot be fitted with one single power law, but requires a two-component model to fit the data. Besides the rough power law component in the high-energy end, there exists a log-normal low-energy component with characteristic values at $\sim 4.8 \times 10^{37}$ erg. It is unclear whether such a feature is universal among repeaters.

FRB 20201124A was first discovered by the Canadian Hydrogen Intensity Mapping Experiment Fast Radio Burst (CHIME/FRB) on 2020 November 24 and entered a high-active period in March 2021 (CHIME/FRB Collaboration 2021). Hundreds of bursts were reported during this period with a variety of radio telescopes (Hilmarsson et al. 2021; Marthi et al. 2021; Lanman et al. 2022; Kumar et al. 2022; Law et al. 2021; Xu et al. 2021). In particular, our previous FAST observations (Xu et al. 2021) detected 1863 bursts that revealed significant short-term evolution of the rotation measure (RM). Multiple independent follow-up observations with radio interferometers localized this source to a host galaxy, which has a spectroscopic redshift of $z = 0.0979$, corresponding to a luminosity distance of 451 Mpc with $h = 0.7$, $\Omega_\Lambda = 0.7$ and $\Omega_m = 0.3$ (Fong et al. 2021; Ravi et al. 2022; Piro et al. 2021a; Nimmo et al. 2022). Follow-up observations using the Keck optical telescope revealed that the host galaxy is a Milky-Way-like, metal rich, barred spiral galaxy with the FRB source residing in a low stellar density, interarm region at an intermediate galactocentric distance (Xu et al. 2021). This source also shows its diversity in the burst properties, such as extremely high brightness and complex structure (Kumar et al. 2022; Marthi et al. 2021), high degree of circular polarization and variation in the polarization position angle (Hilmarsson et al. 2021; Kumar et al. 2022; Xu et al. 2021), and obvious scintillation (Main et al. 2021). This previous active phase lasted until the end of May, 2021.

CHIME/FRB reported a new burst from FRB20201124A on September 21, 2021². Triggered by this event, we started to use FAST to monitor this source since September 25, 2021. The observations lasted until October 17 for a total of 17 days, leading to the detection of more than 700 bursts during the first four days. In this paper, we mainly focus on the energy distribution of FRB 20201124A. The morphology, polarization and periodicity search using the same set of data are discussed in paper I (Zhou et al. 2022), III (Jiang et al. 2022) and IV (Niu et al. 2022), respectively. Section 2 describes our observations, burst detection and data

² <https://www.chime-frb.ca/repeaters>

reduction procedures. Section 3 describes the results of our analysis on the burst energies and the energetics of this source. Section 4 discusses the comparison of the luminosity/energy function between this source and other sources. In Section 5, we present our conclusions.

2 OBSERVATIONS AND DATA PROCESSING

The observations of FRB 20201124A were carried out with the FAST’s L-band receiver Array of 19-beams (FLAN, Li et al. 2018; Jiang et al. 2020, covering a frequency bandwidth of 1 – 1.5 GHz, from 2021 September 25 to October 17 with a total of 19 hours of the observation time.

2.1 Burst Detection

The data recorded by FAST are in FITS format with 4096 frequency channels and a time resolution of 49.152 μ s. We first perform de-dispersion processing on the time-frequency data according to different DM values to construct new time-DM data. We then use the trained object detection model to identify the arrival time and DM of the bursts in the data. According to the DM value and burst arrival time, the data of pulse candidates are cut from the original data, and a binary classification neural network is used to determine whether they are true bursts or false signals. We also searched for bursts in dedispersed time series using a matched filtering algorithm as implemented by the PRESTO program (Ransom 2001). We combined the bursts detected by the two search methods as the final sample.

2.2 DM Optimization

Since DM is the integral of electron density along the path, we assume that the DM does not change significantly within an hour. We first use a uniform DM value of 413 pc/cm³ to select the pulses detected in one day from the data. Under 8 times down-sampling of time, bursts with a signal-to-noise ratio greater than 10 are selected. We then change the DM trials ranging from -5 pc/cm³ to 5 pc/cm³ from the central value for de-dispersion to maximize the structure of all the burst profiles, and reapply this DM value to all bursts on this day.

2.3 Flux Calibration

For each burst, we estimate the peak flux density with the radiometer equation

$$S_\nu = \frac{\text{SNR} \times T_{sys}}{G \sqrt{n_p \times BW \times t_{samp}}}, \quad (1)$$

where T_{sys} is the system temperature and G is the gain of the telescope, which is modeled as a function of the zenith angle and observation frequency in Jiang et al. (2020),

$n_p = 2$ is the number of polarization summed, t_{samp} is the sampling time, BW is the used bandwidth for calibration.

Repeating FRBs tend to have a narrow emission bandwidth compared with apparent non-repeating events (Pleunis et al. 2021). The bandwidth may be related to the telescope sensitivity. For these narrow-band bursts, usually the energy is calculated using the flux density defined by the full bandwidth to be multiplied by the full bandwidth. Alternatively, the energy can be calculated using the flux defined with the narrow band in which the burst is detected and multiplied by this narrow band. We roughly estimate the emission bandwidth of each burst by dividing the whole bandpass into multiple 50-MHz sub-bands and identifying the sub-bands containing burst emission. If the calculations are performed correctly, the two methods should result in the same results. In order to check this, we calculate S_ν using two ways. The first is to assume that the burst energy is spread in the full bandwidth of the telescope $BW = 500$ MHz for all the bursts. The second is to use the true BW for each individual burst. When different bandwidths are adopted, the noise level and the signal-to-noise ratio of a pulse change. Therefore, when using the observed pulse bandwidth for flux calibration, we recalculated the signal-to-noise ratio and the T_{sys} and G of the corresponding frequency bandwidth.

3 RESULTS

3.1 Rate and Waiting Time

During the 17-day observation campaign, we detected 35, 72, 232, 542 bursts from FRB 20201124A in the first four days (i.e. from September 25 to September 28), for a total of number of 881 bursts. The bursts are defined as significant signals separated by dips down to the noise level in this paper³. The observation and detection are shown in Figure 1. The cumulative distribution is plotted in the linear-logarithmic scale. The linear line in the figure suggests that the accumulated number increases exponentially with time. Interestingly, the bursts suddenly disappeared in the next day, which is unexpected. The peak burst rate on the third and fourth day reached 232/hr and 542/hr, respectively, which exceeded all previously reported burst rates from this and other repeating FRBs, including 122/hr for FRB 20121102A (Li et al. 2021), 4.5/hr for FRB 20190520B (Niu et al. 2022), and 45.8/hr for FRB 20201124A itself during the previous active session (Xu et al. 2021).

³ We note that the definitions of a burst are different among the four papers in this series, because different groups adopted different criteria for the different scientific purposes in the respective papers.

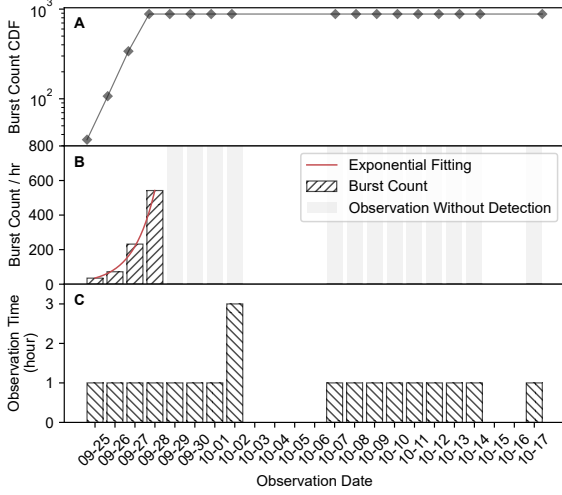

Fig. 1 Observation and Detection of FRB 20201124A. A: the cumulative distribution of burst detection. B: the burst count in each observation day. Gray bars are the observation sessions without bursts detection, the red line shows the exponential fitting of the burst detection. C: the length of each observation session.

Waiting time is defined as the difference between the arrival time of two adjacent bursts. All the waiting times were calculated in the same observation session to avoid the observation gap of about 23 hr. The waiting time distribution of FRB 20201124A is shown in Figure 2, which can be well-fitted by two log-normal functions peaking at 10.05 s and 51.22 ms, respectively. Note that the waiting time distribution of FRB 20201124A in the previous active period was also a bimodal distribution, but the characteristic timescale of the second (long-duration) peak was 135 s (Xu et al. 2021). Our observation suggests that this characteristic waiting time is not universal within one source, but rather depends on the activity level of the source. The bimodal form of waiting time has also been found in FRB 20121102A (Li et al. 2021; Hewitt et al. 2022; Aggarwal et al. 2021). The timescale of the second peak varies also significantly for telescopes with different sensitivities, with shorter waiting times for more sensitive telescopes (which detect more bursts).

3.2 Energy calculation

We calculate the isotropic equivalent burst energy following the Equation:

$$E = 10^{39} \text{erg} \frac{4\pi}{1+z} \left(\frac{D_L}{10^{28} \text{cm}} \right)^2 \left(\frac{F_\nu}{\text{Jy} \cdot \text{ms}} \right) \left(\frac{\Delta\nu}{\text{GHz}} \right), \quad (2)$$

where $D_L = 453.3 \text{Mpc}$ is the luminosity distance of FRB 20201124A corresponding to the redshift $z = 0.09795$ acquired in Xu et al. (2021), $F_\nu = S_\nu \times W_{\text{eq}}$

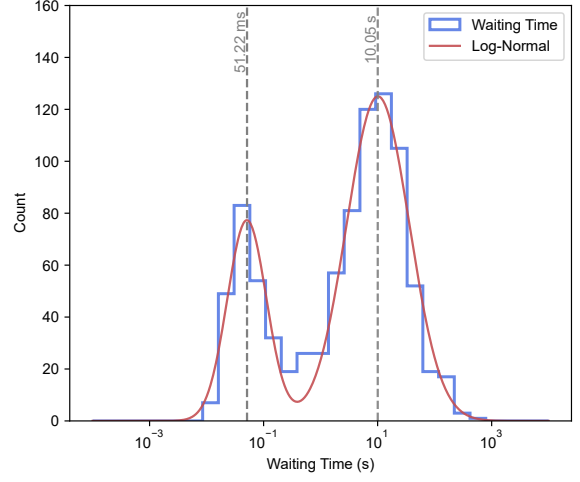

Fig. 2 Waiting time distribution of FRB 20201124A. The blue step and red line show the distribution of waiting time and two log-normal fitting.

is the specific fluence, S_ν is the peak specific flux, $\Delta\nu$ is the bandwidth of each pulse. The adoption of $\Delta\nu$ is more relevant for narrow-band FRBs, which is typically the case for the bursts in repeaters. As discussed in Section 2.3, we adopt two choices of BW to calculate S_ν and compare the derived E values.

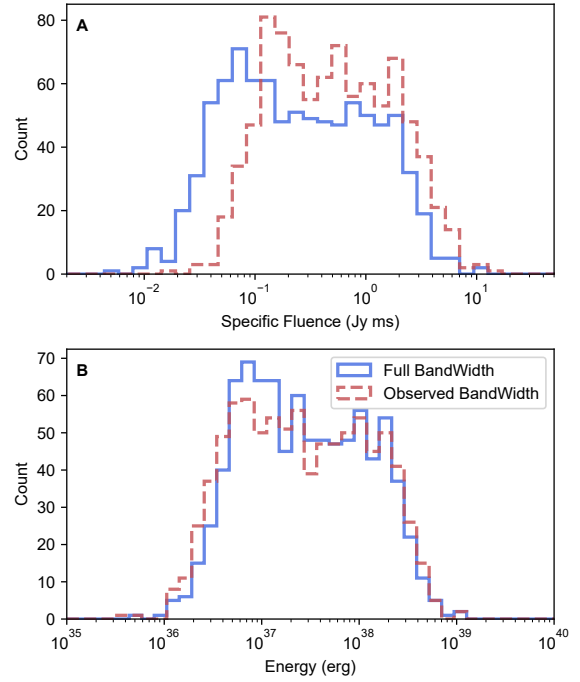

Fig. 3 Specific fluence and energy distribution. Energy is calculated by Eq. 2. Solid blue lines are distribution for full bandwidth, i.e. $\Delta\nu = 500 \text{MHz}$, red dashed lines are for observed burst bandwidth.

Figure 3A shows the specific fluence (F_ν) and the energy distribution of bursts calculated with $\Delta\nu = 500\text{MHz}$ and the observed bandwidth for individual bursts, respectively. The specific fluence derived using the observed narrow bandwidth is greater than that derived assuming the full bandwidth. This is natural because the definition of F_ν is the average over frequency channels. Since the energy contained in the observed bandwidth is similar to that in the full bandwidth but the observed bandwidth is narrower than the full bandwidth, the average value for the full bandwidth is smaller. Figure 3B presents the energy distribution of the two methods after multiplying by the respective bandwidth. It can be seen that the derived energy distributions between the two methods appear to be similar to each other, as is expected. The p-value from the K-S test of the energy distribution calculated with two types of bandwidth is 0.35, which cannot reject the hypothesis that the two energy distributions are consistent with each other. Therefore, we conclude that the energy calculation is not significantly affected by the adoption of the bandwidth, and the normal methods using the full bandwidth to calculate the energy is reliable.

Li et al. (2021) introduced the detection of 1652 pulses from FRB 20201124A with FAST and proposes a bimodal energy distribution. The calculation there following Eq. 9 from Zhang (2018), which differs from Eq. 3 by a constant $\nu_c/\Delta\nu$, if we calibrate the fluence both with the full bandwidth⁴. Aggarwal (2021) claimed that he recalculated the energy using the bandwidth in Table 1 of Li et al. (2021), and the resulting distribution did not show a significant bimodality. As we have shown in Figure 3A, the specific fluence varies greatly with the bandwidth selection. The calculation in Aggarwal (2021) simply replaced the ν_c with the apparent observed bandwidth for individual bursts, but still used the fluence values derived from the full bandwidth to do the calculation. Therefore the calculations of Aggarwal (2021) resulted in incorrect results. The bimodal energy distribution for FRB 20201124A as claimed by Li et al. (2021) remains intact.

3.3 Energy Distribution

Energy/luminosity function can provide important hints on the emission mechanism of the source. As we demonstrated in the previous subsection, the use of limited bandwidth or full bandwidth does not change the energy distribution. Therefore, we uniformly use Eq. 2 and the full bandwidth fluence for energy calculation in the following analysis.

⁴ The method of Zhang (2018) applies to FRBs with emission bandwidth much wider than the telescope's bandwidth, which seems to be the case for at least some non-repeating FRBs.

Fig. 4 The energy distribution of FRB 20201124A. **A:** the cumulative energy distribution of FRB 20201124A (blue) with Band function and single-power-law function fitting. **B:** the index of single-power-law fitting as the function of energy threshold. **C:** the energy distribution of FRB 20201124A (blue) with two log-normal fitting.

As shown in Figure 4C, the energy distribution of FRB 20201124A also presents a clear bimodal distribution, which can be well-fitted by two log-normal functions peaking at 2.27×10^{37} erg and 2.28×10^{38} erg, respectively. This may indicate the existence of more than one emission mechanism to generate FRBs. The distribution of FRB 20201124A could be also fitted by a similar double log-normal distribution (Extended Data Fig. 5 in Li et al. 2021), but the peak energies is not the same for the two FRB sources.

For a power law energy/luminosity distribution $dN/dE = AE^\alpha$, the cumulative energy distribution can be calculated as

$$\begin{aligned} N(> E) &= \int_E^{E_{\max}} dN = \int_E^{E_{\max}} AE^\alpha dE \\ &= \frac{A}{-\alpha - 1} [E^{\alpha+1} - E_{\max}^{\alpha+1}] = \frac{A}{-\hat{\alpha}} [E^{\hat{\alpha}} - E_{\max}^{\hat{\alpha}}], \end{aligned} \quad (3)$$

where E_{\max} is the maximum energy for a certain sample, and $\hat{\alpha} = \alpha + 1$. One can see that in general, the cumulative energy distribution is also roughly a power law with index $\hat{\alpha}$ is $\hat{\alpha} < 0$. Different types of astrophysical sources have different $\hat{\alpha}$ values. For example, solar flare events have $-0.9 < \hat{\alpha} < -0.5$ (Maehara et al. 2015) and giant pulses of the Crab pulsar have $-2.8 < \hat{\alpha} < -1.1$

(Mickaliger et al. 2012; Lyu et al. 2021). Different repeating FRBs are observed to have different $\hat{\alpha}$ values: e.g. $-1.8 < \hat{\alpha} < -0.7$ for FRB 20121102A (Law et al. 2017; Cruces et al. 2021; Gourdjji et al. 2019), and $\hat{\alpha} \sim -1.3$ for FRB 20180916B (CHIME/FRB Collaboration et al. 2020). For FRB 20201124A, $\hat{\alpha} \sim -1.2$ was measured for the uGMRT bursts (Marthi et al. 2021) and $\hat{\alpha} \sim -3.6$ was measured for the CHIME bursts (Lanman et al. 2022). A broken power-law was also used to model the cumulative energy distribution of FRB 20121102A, the index $\hat{\alpha} = -1.4$ and $\hat{\beta} = -1.8$ around the turning point 2.3×10^{37} erg (Hewitt et al. 2022; Aggarwal et al. 2021). The bursts in our FAST sample also require a two-segment power law, but the turning point is not obvious. Therefore, we apply an exponentially connected broken-power-law function (which is called the Band function proposed by Band et al. (1993) to describe the gamma-ray spectra of gamma-ray bursts), which reads

$$N(> E) = \begin{cases} AE^{\hat{\alpha}} e^{(-E/E_0)} & E \leq (\hat{\alpha} - \hat{\beta})E_0 \\ AE^{\hat{\beta}} \left[\frac{(\hat{\alpha} - \hat{\beta})E_0}{e} \right]^{\hat{\alpha} - \hat{\beta}} & E \geq (\hat{\alpha} - \hat{\beta})E_0 \end{cases} \quad (4)$$

where $\hat{\alpha} = \alpha + 1$ and $\hat{\beta} = \beta + 1$ are the power-law indices of the lower and higher cumulative energy distributions, and E_0 is a characteristic energy. Note that strictly speaking the cumulative energy distribution of two log-normal functions should have a complicated shape. The simple power law function is insufficient. We therefore adopt the next simplest function, i.e. a smoothly joint two-segment broken power law function (the Band function) to fit it. As shown in Figure 4A, this function fits the data reasonably well. In principle, the turnover in the low-energy end of the low-energy log-normal component would demand an additional break in the function to fit the cumulative distribution and indeed there is a deviation at the low-energy end between the data and fitting function. In any case, when considering possible selection effect near the sensitivity threshold (which would compensate the deficit of low-energy bursts from the data), we believe that the Band function presents a reasonable description of the cumulative distribution function.

We exclude the bursts that are below the 90% detection threshold ($E_{\text{th}} = 3.6 \times 10^{36}$ erg), which makes up 1% of the total sample. We then randomly select 90% of the bursts in the sample to generate a cumulative energy distribution. We repeat this process 1000 times and fit these 1000 cumulative energy distributions with a power-law function and the Band function. The central limit theorem makes the fitting parameters converge to a Gaussian distribution. We use the mean and standard deviation of the Gaussian distribution as the standard value and error of the

fitting parameters. Figure 4A shows the fitting results of the cumulative energy distribution. The power-law index is $\hat{\alpha} = -0.08 \pm 0.01$. The index values in the Band function are $\hat{\alpha} = -0.22 \pm 0.01$ and $\hat{\beta} = -3.27 \pm 0.34$, with the turning point at $(1.1 \pm 0.2) \times 10^{39}$ erg. Note that the power-law indices and the break energy are all different from those derived from the CHIME bursts. Considering the uncertainties, the index of higher energy end is consistent with the CHIME result.

We repeat the fitting process with a varying energy threshold. The index $\hat{\alpha}$ of a single-power-law function does not converge to a single value in panel B of Figure 4. This is another indication that a single power-law distribution is inadequate to describe the cumulative energy distribution of this FRB source.

4 DISCUSSION

4.1 Comparison with other repeating FRBs

FRB 20121102A, FRB 20190520B and FRB 20201124A are three repeating FRBs which have been extensively studied by FAST. FRB 20121102A is the first known repeating FRB (Spitler et al. 2014, 2016). FRB 20190520B is a repeating FRB detected by Commensal Radio Astronomy FAST Survey (CRAFTS) (Li et al. 2019; Niu et al. 2022). Both FRB 20121102A and FRB 20190520B are found to be associated with a compact persistent radio source (PRS) (Chatterjee et al. 2017; Marcote et al. 2017; Niu et al. 2022). FRB 20201124A is also associated with persistent radio emission, but it is not a point source and is rather extended in space (Ravi et al. 2022; Piro et al. 2021b). The FAST-measured energy distributions of these three FRB sources can be directly compared against each other to reduce the possible selection biases caused by using different telescope systems. Figure 5 shows the energy distributions of the three FRBs in the form of both power density distribution (PDF) and cumulative density distribution (CDF). Both the PDF and CDF show that the energy distributions of the three FRB sources are not consistent.

Table 1 shows the observed isotropic radio energy and the inferred burst energy of the three FRBs. The total observed energy E_{radio} is the sum of all the observed burst energies in the radio band, which is corrected to the total energy released during the bursts via Eq.5.

$$E_{\text{bursts}} = E_{\text{radio}} \times F_b \times \eta^{-1} \times \zeta^{-1}, \quad (5)$$

where E_{bursts} is the total energy emitted by FRB source during bursts, F_b is the beaming factor, η is the radio efficiency which is normalized to $\sim 10^{-5}$ (similar order to FRB 20200428), and ζ is the observation duty cycle. For example, the observations of FRB 20201124A this time were carried out in 4 sessions in 4 days with 1 hour

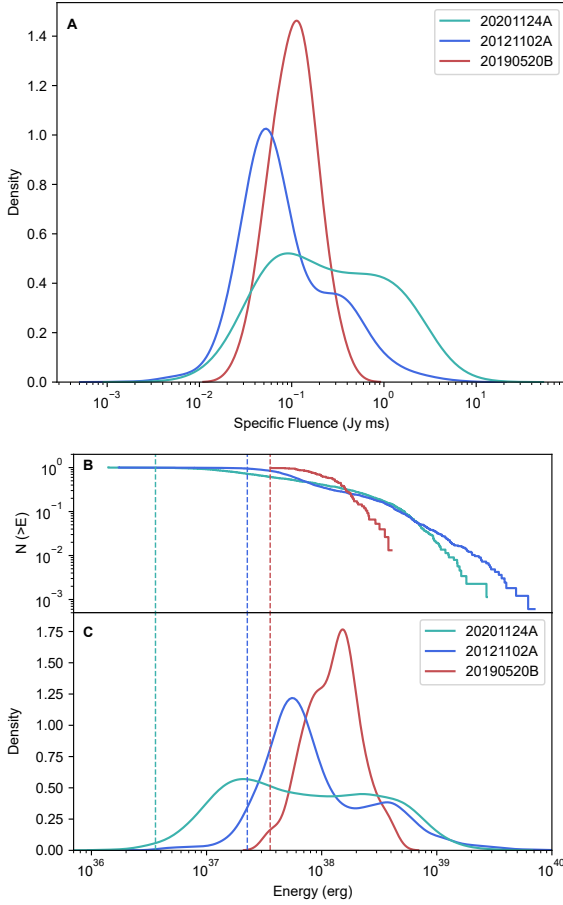

Fig. 5 Fluence and energy distribution of FRB 20201124A (green), FRB 20190520B (red) and FRB 20121102A (blue). **A** is the kernel density estimation (KDE) of the three FRBs’ fluence. **B** and **C** are cumulative distributions and KDEs of the three FRBs’ energy. The dashed lines are the detection thresholds.

per session. The duty cycle ζ is therefore estimated as $(4 \times 1 \text{ hour}) / (4 \times 24 \text{ hours}) = 1/24$.

Compared with other repeaters, FRB 20201124A has the largest averaged energy, especially on September 28. Taking the nominal values of $\eta = 10^{-5}$ and $F_b = 0.1$, the total burst energy released on September 28 has reached $(2.46 \times 10^{46} \text{ erg}) \eta_{-5}^{-1} F_{b,-1}$. Compared with the total dipolar magnetic energy of a magnetar $E_{\text{mag}} = (1/6) B_p^2 R^3 \sim (1.7 \times 10^{47} \text{ erg}) B_{p,15}^2 R_6^3$, the burst energy emitted on this day already exceeded 14.3% $\eta_{-5}^{-1} F_{b,-1}$ of the available magnetar energy. This raises an even more severe energy budget problem compared with FRB 20121102A (Li et al. 2021). This requires that the radio emission efficiency should be quite high for the magnetar model or that the magnetar engine does not apply. For magnetar models, since the synchrotron maser models invoking relativistic shocks are quite inefficient, the data favors magnetospheric models for FRBs, which can have a higher efficiency as ob-

served in radio pulsars (Kumar et al. 2017; Yang & Zhang 2018; Lu et al. 2020; Zhang 2022). The synchrotron maser model may be still relevant if the central engine is not a magnetar, but rather an accreting black hole system (e.g. Sridhar et al. 2021), whose total energy budget is not limited by the total magnetic energy of a magnetar.

4.2 Comparison of different burst definition schemes

To quantify the specific morphological characteristics of the bursts, we differentiate two kinds of pulse profile classification schemes. The first classification scheme is based on a judgment of pulse flux threshold, taking the pulse profile above the detection threshold as a separated burst. For conservative considerations, we take the detection threshold using a 3σ noise level of the baseline due to the complicated effect on the actual sensitivity, e.g., the bandwidth limited structure of the bursts and radio frequency interference (RFI) events. This definition is also the pulse definition used in previous work, and is the same as the definition used for FRB 20121102A (Li et al. 2021) and FRB 20190520B (Niu et al. 2022). In the following text, we call this definition Combined Bursts Definition (CBD).

Fig. 6 A burst event example detected on September 26.

For another method, we try to differentiate the bursts by referring to the morphological clustering characteristics of the pulses in the dynamic spectrum, which means that pulses that can be distinguished in the time-frequency diagram are treated as different bursts, like Figure 6. We call this definition Separated Bursts Definition (SBD). As a result, the event in Figure 6 contains 2 bursts under SBD but 1 burst under CBD. All bursts under SBD are artificially isolated and flux calibration is performed independently.

Figure 7A shows the waiting time distribution of bursts with SBD, which is still a bi-modal distribution and can be modeled with two log-normal functions peaking at 13.56 ms and 10.05 s, respectively. The second peak time around

Table 1 Energy budget of three repeating FRBs.

Name	ObDays (day)	ObTimes T_{obs} (hour)	Total Observed Energy ^a E_{radio} (erg)	Averaged Energy ^b \bar{L}_{radio} (erg/s)	Total Energy ^c E_{bursts} (erg)
FRB 20201124A	4	4	1.60×10^{41}	1.11×10^{37}	3.85×10^{46}
FRB 20201124A-0928	1	1	1.02×10^{41}	2.84×10^{37}	2.46×10^{46}
FRB 20121102A	47	59.5	3.41×10^{41}	1.59×10^{36}	6.47×10^{46}
FRB 20190520B	11	18.5	1.10×10^{40}	1.65×10^{35}	1.56×10^{45}

^a Sum of the observed isotropic radio energies of all bursts.

^b Defined as $E_{\text{radio}}/T_{\text{obs}}$

^c $E_{\text{bursts}} = E_{\text{radio}} \times [(\zeta = \text{ObTimes}/\text{ObDays})^{-1} \times (\eta = 10^{-5})^{-1} \times (F_b = 0.1)]$

10 s is consistent with the waiting time distribution of CBD. However, the first peak time is significantly reduced. The distributions of specific fluence and energy exhibit distinct distributions under the two burst definitions. We use the K-S test to check whether the energies calculated from the two burst definition schemes belong to the same distribution. The p-value is 0.2%, meaning we could rule out the hypothesis that they were from the same distribution. We also use the Band function to fit the cumulative energy distribution of the bursts with SBD. The index values in the Band function are $\hat{\alpha} = -0.18 \pm 0.01$ and $\hat{\beta} = -3.27 \pm 0.16$, respectively. The index in the high energy regime is the same with CBD, while the index in the lower energy regime is slightly smaller than that of CBD. The turning point is $(6.4 \pm 0.1) \times 10^{38}$ erg, which is smaller than that for CBD. While we still do not know the true nature of FRBs, different definitions of bursts may lead to somewhat different analysis results. We caution that when studying burst energy distributions of FRBs, one needs to specify a burst definition scheme.

5 CONCLUSIONS

FRB 20201124A is a repeating FRB discovered by CHIME (CHIME/FRB Collaboration 2021). FAST has monitored source multiple times. Besides an earlier observational campaign reported by Xu et al. (2021), we study a very active 4-day emitting episode on September 25-28, 2021, in this series of papers. The main results of this paper are as follows.

- Using our CBD definition method, a total of 881 bursts were detected between September 25 to September 28.
- The apparent event rate increased exponentially in 4 days and then dropped to zero after Sep. 29.
- The waiting time of FRB 20201124A shows a bimodal structure, which can be well-fitted by two log-normal functions. The longer waiting times peak around 10 s and is insensitive to the burst definition criterion. It is much shorter than that of the previous epoch (Xu et al. 2021), suggesting that it is related to the active level of the source.
- The shorter waiting times peak around either 51 ms or 14 ms, depending on the definition of burst separation (see Section 3).
- The peak event rate of 542/hr exceeds all the detected FRBs in the past, including 122/hr of FRB 20121102A (Li et al. 2021), and FRB 20201124A itself, which was 45.8/hr during the last active period (Xu et al. 2021). The total burst energy released during this epoch is a significant fraction of magnetar total energy unless the radio emission frequency is high. This challenges the synchrotron maser mechanism for FRBs and even the magnetar source model.
- The energy distribution cannot be described by a single power-law. The cumulative distribution of energy can be well modeled by an exponentially connected broken power law known as the Band function. The slopes at low and high energy regimes are $\hat{\alpha} = -0.22 \pm 0.01$ and $\hat{\beta} = -3.27 \pm 0.23$, respectively.
- The energy distributions of three active repeating FRBs, namely FRB 20121102A, FBR 20190520B, and FRB 20201124A, do not appear to be identical. This suggests that repeating FRBs may have diverse emission properties.

AUTHOR CONTRIBUTIONS

Y.K.Z., P.W., D.L., and B.Z. developed the concept of the manuscript. B.Z. and W.W.Z. proposed and chaired the FAST FRB key science project. Y.K.Z. conducted the data analysis and visualization. Y.K.Z., P.W., and C.H.N. searched the bursts and analyzed the burst properties. Y.K.Z., Y.F., D.L., B.Z., C.W.T., and R.L. led the discussion on the interpretation of the results and writing of the manuscript. D.J.Z. studied bursts morphology and classification with the details presented in paper I of this series. J.C.J performed the analysis of the polarization properties and the results are presented in the Paper III. J.R.N. performed periodicity search with the results presented in paper IV. All authors contributed to the analysis or interpretation of the data and to the final version of the manuscript.
