## ABSTRACT

Neural Radiance Field (NeRF) has widely received attention in Sparse-View (SV) CT reconstruction problems as a self-supervised deep learning framework. NeRF-based SVCT methods model the desired CT image as a continuous function that maps coordinates to intensities and then train a Multi-Layer Perceptron (MLP) to learn the function by minimizing loss on the SV measurement. Thanks to the continuous representation provided by NeRF, the function can be approximated well and thus the high-quality CT image is reconstructed. However, existing NeRF-based SVCT methods strictly suppose there is completely no relative motion during the CT acquisition because they require accurate projection poses to simulate the X-rays that scan the SV sinogram. Therefore, these methods suffer from severe performance drops for real SVCT imaging with motion. To this end, this work proposes a self-calibrating neural field that recover the artifacts-free image from the rigid motion-corrupted SV measurement without using any external data. Specifically, we parametrize the coarse projection poses caused by rigid motion as trainable variables and then jointly optimize these variables and the MLP. We perform numerical experiments on a public COVID-19 CT dataset. The results indicate that our model significantly outperforms two latest NeRF-based methods for SVCT reconstruction with four different levels of rigid motion.

**Index Terms**— Sparse-View CT Reconstruction, Rigid Motion Correction, Neural Radiance Field, Self-Supervised Learning.

## 1. INTRODUCTION

Sparse-View Computed Tomography (SVCT) can significantly reduce the radiation dose and shorten the scanning time by reducing the number of radiation views. However, the insufficient projection measurement (*i.e.*, SV sinogram) in SVCT will suffer from severe streaking artifacts if applying traditional analytical reconstruction algorithms such as Filtered Back-Projection (FBP) [1], which significantly degrade image quality.

Recently, a few self-supervised SVCT reconstruction methods [2–6] based on Neural Radiance Field (NeRF) [7] have been proposed. Different from supervised deep learning models [8, 9], these NeRF-based methods can recover the high-quality CT image from the SV sinogram without any external data. Specifically, NeRF-based methods represent the CT image as a continuous function that maps coordinates to intensities and trains a fully-connected neural network (*i.e.*, an MLP) to learn the function by minimizing prediction errors on the SV sinogram. Benefiting from the implicit image prior imposed by the continuous function and the neural network prior [10–12], the desired high-quality results can be recovered.

Existing NeRF-based SVCT methods [2–6] suppose there is completely no motion during the CT acquisition process, which

benefits that the *accurate* projection poses can be accessible for simulating the X-rays that scan the SV sinogram. However, relative motion, especially rigid motion, during the real CT acquisition is common and even inevitable [13–16] due to various factors (*e.g.*, imaging object’s movement and CT scanner’s rotation error, etc.). Therefore, this overly strict assumption will result in severe model performance drops in real SVCT reconstruction with motion.

In this paper, we propose a self-calibrating neural field that can recover the artifacts-free image from the rigid motion-corrupted SV measurement without using any external data. Like the previous works [2–6], our proposed model is also based on NeRF’s [17] framework (*i.e.*, using an MLP to learn the function of CT image through minimizing loss on the SV measurements). The major advantage of our model is that it models the rigid motion during the CT acquisition process and thus can produce robust and excellent results for the SVCT reconstruction task with rigid motion. Specifically, we first parameterize coarse projection poses caused by rigid motion as three trainable variables (a rotation angle and two translation offsets). Then, we jointly optimize these pose variables and the MLP. After the poses calibration and MLP optimization, the final high-quality CT image can be reconstructed. We conduct numerical experiments on a public COVID-19 CT dataset [18]. Experimental results shows that the proposed model significantly outperform two representative NeRF-based methods [2, 3] for SVCT reconstruction with four levels of rigid motion.

## 2. PRELIMINARY

Formally, NeRF-based SVCT methods [2–6] represent the unknown and high-quality CT image  $\mathbf{x} \in \mathbb{R}^{N \times N}$  as a continuous function:

$$\mathcal{M} : \mathbf{p} \rightarrow I, \quad (1)$$

where  $\mathbf{p} = (x, y) \in \mathbb{R}^2$  is any spatial coordinate in the imaging plane and  $I \in \mathbb{R}$  denotes the corresponding intensity value in the CT image  $\mathbf{x}$ .

Given the acquired SV sinogram  $\mathbf{y} \in \mathbb{R}^{M \times N}$ , where  $M$  and  $N$  denote the number of projections and X-rays per projection, respectively, NeRF-based methods leverage an MLP  $\mathcal{F}_{\Theta}$  with coordinate encoding module to learn the continuous function  $\mathcal{M}$  through optimizing the objective as below:

$$\Theta^* = \arg \min_{\Theta} \mathcal{L}(\mathbf{y}, \mathbf{A}\mathcal{F}_{\Theta}), \quad (2)$$

where  $\mathbf{A} \in \mathbb{R}^{N \times M}$  denotes differentiable projection operator (*e.g.*, Radon transform for parallel X-ray beam CT acquisition) and  $\mathcal{L}$  is similarity metric used for measuring data discrepancy between the generated SV sinogram  $\mathbf{A}\mathcal{F}_{\Theta}$  and the real SV sinogram  $\mathbf{y}$ . The function  $\mathcal{M}$  could be approximated well by the MLP  $\mathcal{F}_{\Theta}$  due to

Fig. 1. Pipeline of our proposed method for SVCT with rigid motion. Here the trainable parameters are highlighted in red.

the continuous image prior provided by the function and neural network’s learning bias toward low-frequency components [10–12]. After the optimization, the high-quality CT image  $\mathbf{x}$  is reconstructed by feeding all the coordinates  $\mathbf{p}$  into the well-trained MLP  $\mathcal{F}_{\Theta^*}$  to produce the corresponding intensity values  $I$ .

### 3. METHOD

Although existing NeRF-based SVCT reconstruction methods [2–5] have shown great potential, there still is a major limitation: The *accurate* projection poses have to be available for simulating the X-ray beam during scanning. However, inevitable relative motion during the CT acquisition process always results in the *inaccurate* projection poses. Inspired by NeRF— [17], we parametrize all the *inaccurate* projection poses as trainable variables, and jointly optimize these variables and the MLP. Therefore, our proposed method can recover the high-quality CT image from the rigid-motion-corrupted SV sinogram. In this section, our model is introduced in detail.

#### 3.1. Projection Pose Parameterization

In the proposed model, we make two basic assumptions: (1) The type of motion is rigid (*i.e.*, DoF = 3 for 2D parallel X-ray beam CT); (2) No motion among X-rays from the same projection acquisition. This assumption is reasonable because the single projection is very fast (*e.g.*, it only takes 0.3 seconds by using multi-slice CT [13]). Based on these two assumptions, the X-rays from the same projection acquisition thus can share the same pose parameters. Specifically, we leverage a rotation matrix  $\mathbf{R}_i \in \mathbb{SO}(2)$  and a translation vector  $\mathbf{t}_i \in \mathbb{R}^2$  to parametrize the pose of the  $i$ -th projection acquisition as below:

$$\mathbf{R}_i = \begin{bmatrix} \cos \theta_i & -\sin \theta_i \\ \sin \theta_i & \cos \theta_i \end{bmatrix}, \quad \mathbf{t}_i = \begin{bmatrix} t_x^i & t_y^i \end{bmatrix}^T, \quad (3)$$

where  $i = \{1, 2, \dots, M\}$ , we set the two elements  $t_x^i$  and  $t_y^i$  in the vector  $\mathbf{t}_i$  as trainable parameters for correcting translation motion, while we train the projection angle  $\theta_i$  in the matrix  $\mathbf{R}_i$  for correcting rotation motion. It is worth noting that we do not directly optimize the elements in the matrix  $\mathbf{R}_i$  since it is defined in the  $\mathbb{SO}(2)$  space.

#### 3.2. Jointing Pose Correction and MLP Optimization

Fig. 1 illustrates the pipeline of our proposed model. To generate projection value  $\mathbf{y}(\theta, s)$  of the acquired SV sinogram, we first build X-ray  $x = s$  in a standard space and sample pixel coordinates  $\mathbf{p}$  along the X-ray. Then, we transform these coordinates  $\mathbf{p}$  into a real physic space via pose correction, which is expressed as below:

$$\mathbf{p}_{\text{real}} = \mathbf{R}\mathbf{p} + \mathbf{t}, \quad (4)$$

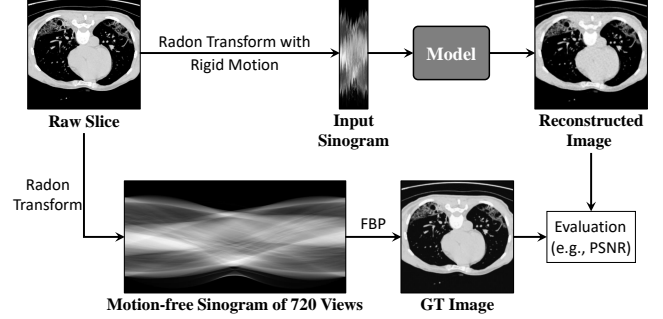

Fig. 2. Workflow of our data processing.

The MLP  $\mathcal{F}_{\Theta}$  takes these intensity coordinates  $\mathbf{p}_{\text{real}}$  in the real physic space as input and predicts the corresponding intensity values  $I$ . The estimated projection value  $\hat{\mathbf{y}}(\theta, \rho)$  then are generated by using differentiable line integral projection operator. Finally, we jointly optimize the coarse pose  $\mathbf{R}, \mathbf{t}$  and the MLP  $\mathcal{F}_{\Theta}$  by using gradient descent back-propagation algorithm to minimize the objective as below:

$$\Theta^*, \mathbf{R}^*, \mathbf{t}^* = \arg \min_{\Theta, \mathbf{R}, \mathbf{t}} \mathcal{L}(\mathbf{y}, \mathbf{A}\mathcal{F}_{\Theta}), \quad (5)$$

where the loss function  $\mathcal{L}$  is implemented by  $\ell_1$  norm.

#### 3.3. Implementation Details

We combine hash encoding [19] with two fully-connected layers to implement the MLP  $\mathcal{F}_{\Theta}$ . Compared with frequency encoding modules (*e.g.*, Fourier encoding [2]), the hash encoding [19] is adaptive and thus can provide a better fitting ability. For the model training, we leverage the Adam optimizer [20] and the hyper-parameters are set as default. The learning rate is from  $10^{-3}$  and decays by a factor of 0.5 per 500 epochs, and the total training epochs is 5000. In addition, all the elements in the translation vector  $\mathbf{t}$  are initialed as 0 since any prior knowledge of the rigid motion is assumed not to exist.

## 4. NUMERICAL EXPERIMENTS

#### 4.1. Experimental Settings

**Dataset & Pre-processing** All the numerical experiments in this paper are performed based on COVID-19 dataset [18] that consists of 3D CT volumes from 1000+ patients with COVID-19 infections. We extract 2D slices of  $256 \times 256$  size from two 3D volumes in the COVID-19 dataset as experimental data. Fig. 2 shows the pipeline of our data processing. On the one hand, we build motion-free sinograms of 720 views by performing radon transformation on the raw

**Fig. 3.** Qualitative results of all the compared methods on a sample of the COVID-19 dataset for SVCT without motion and with moderate rigid motion ( $\pm 8^\circ$  &  $\pm 8$  pixels).

Mean	17.17/0.2788/0.4674	19.69/0.4001/0.3479	19.35/0.3994/0.3747	23.36/0.8008/0.0365

**Table 1.** Quantitative results (PSNR/SSIM/LPIPS) of all the compared methods on the COVID-19 dataset for SVCT with four levels of rigid motion. The higher PSNR and SSIM denote the better performance, while the lower LPIPS represent the better performance.

slices and then generate GT images by FBP [1]. The resulting GT images are used for model evaluation. On the other hand, we conduct radon transformation with rigid motion on the raw slices to generate motion-corrupted sinograms of 90 views. More specifically, for each projection simulation, the raw slices are translated by  $t_x$  and  $t_y$  pixels along X and Y axes respectively and then are rotated by  $\alpha^\circ$  around the origin. The three independent motion parameters for each projection are sampled from the Uniform distribution  $\mathcal{U}(-k, k)$ . We set  $k = \{0, 2, 8, 16\}$  to simulate a motion-free setting and three different levels of rigid motion. The generated sinograms are used for input data. All the compared methods directly recover CT images from the sinograms.

**Compared Methods** We compare our proposed model with three SVCT methods: (1) FBP [1], a classical filtered back-projection CT imaging algorithm; (2) GRFF [2], an earliest NeRF-based SVCT reconstruction method; (3) NeRP [3], a recent NeRF-based SVCT reconstruction method with prior embedding. Here FBP [1] is based on the scikit-image library [21] of Python, while GRFF [2] and NeRP [3] are implemented following the original papers.

**Evaluation Metrics** PSNR and SSIM [22], two well-known objective image quality metrics for low level vision tasks, are employed for quantitative evaluation. We also include LPIPS [23], a recent deep learning-based evaluation metric.

#### 4.2. Comparison with Other Methods

We compare the proposed model with three baselines on the COVID-19 dataset [18] for SVCT reconstruction with four motion settings.

**Fig. 4.** Average running time of GRFF [2], NeRP [3], and our model on the COVID-19 dataset.

Table 1 shows the quantitative results and it indicates that the reconstruction capacity of all the compared models decreases with increasing movement range. For motion-free setting, the three NeRF-based methods (GRFF [2], NeRP [3], and our model) all produce significant improvements compared to FBP [1]. While for the three levels of rigid motion, our proposed model is far better than the three baselines (FBP [1], GRFF [2], and NeRP [3]). For example, PSNR respectively improve 6.17 dB, 5.6 dB, and 5.9 dB for the moderate rigid motion ( $\pm 8^\circ$  &  $\pm 8$  pixels). Fig. 3 shows the qualitative results. For the motion-free setting, the three NeRF-based methods greatly improve the resulting image quality compared with FBP [1]. And compared with GRFF [2] and NeRP [3], the result of our model has clearer and sharper image details benefiting from the learnable hash encoding [19]. From the visualization, GRFF [2] and

**Fig. 5.** Qualitative results of our model without and with poses correction on a sample of the COVID-19 dataset for SVCT with severe rigid motion ( $\pm 16^\circ$  &  $\pm 16$  pixels).

Motion Settings	w/o Pos. Corr.	w/ Pos. Corr.
$\pm 2^\circ$ & $\pm 2$ pixels	19.78/0.5496/0.3060	24.17/0.8694/0.0276
$\pm 8^\circ$ & $\pm 8$ pixels	13.71/0.2860/0.4708	19.60/0.7564/0.0387
$\pm 16^\circ$ & $\pm 16$ pixels	10.58/0.2071/0.5794	16.85/0.6339/0.0570
Mean	14.69/0.3476/0.4521	20.21/0.7532/0.0411

**Table 2.** Quantitative results (PSNR/SSIM/LPIPS) of our model without and with poses correction on the COVID-19 dataset for SVCT with three levels of rigid motion.

NeRP [3], however, almost are failed for the moderate rigid motion ( $\pm 8^\circ$  &  $\pm 8$  pixels). This is because they do not model the motion during the CT acquisition. While our method still produces an excellent result that is very close to GT. In addition, Fig. 4 shows the average running time of GRFF [2], NeRP [3], and our model on the COVID-19 dataset. Our model has a better performance on time consumption benefiting from the adaptive hash encoding module [19]. The time efficiency of our model is  $3\times$  better to GRFF [2] and about  $5\times$  better to NeRP [3].

#### 4.3. Effectiveness of Poses Correction

We conduct an ablation study to confirm the effectiveness of the pose correction in our model. Table 2 shows the qualitative results. We can observe that the pose correction significantly improves the model performance. For example, PSNR and SSIM respectively improve 4.39 dB (24.17 vs 19.78) and 0.3198 (0.8694 vs 0.5496) for the mild rigid motion ( $\pm 2^\circ$  &  $\pm 2$  pixels). Fig. 5 shows the qualitative results for the severe rigid motion ( $\pm 16^\circ$  &  $\pm 16$  pixels). Obviously, the proposed model with the pose correction could recover image structure and details clearly while the model without the pose correction performs very poorly. We also demonstrate the visual comparison of the coarse, true, and optimized poses in Fig. 6. All the coarse projection poses are almost precisely corrected. Overall, the pose correction module is crucial for our model performance.

### 5. CONCLUSION AND LIMITATION

This work proposes a novel self-supervised NeRF-based model for SVCT reconstruction. Different from existing NeRF-based SVCT methods, the proposed model additionally models the rigid motion in the CT acquisition process. Therefore, it can reconstruct robust and high-quality CT results from the rigid motion-corrupted measurement. Experiments on a public CT dataset indicate that our pro-

**Fig. 6.** Visual comparison of coarse, true, and optimized projection poses on a sample of the COVID-19 dataset for SVCT with severe rigid motion ( $\pm 16^\circ$  &  $\pm 16$  pixels).

posed model are greatly superior to two latest NeRF-based method for SVCT reconstruction with rigid motion.

Although the proposed model produces excellent reconstruction performance for SVCT imaging task with motion, there still are two limitations: (1) Our model is based on the 2D parallel X-ray beam CT, while more advanced types of X-ray beams (*e.g.*, 2D fan beam, 3D cone beam, and others.) are not implemented; (2) Our model can calibrate the rigid motion in the CT acquisition, while more complex non-rigid motion cannot be handled now.

### 6. COMPLIANCE WITH ETHICAL STANDARDS

This research study is conducted retrospectively using human subject data made available in open access by Harvard Dataverse, COVID19-CT Dataset [18] (<https://doi.org/10.7910/DVN/6ACUJZ>). Ethical approval was not required as confirmed by the license attached with the open-access data.

### 7. ACKNOWLEDGMENTS
