Abstract

We consider the Markovian SIR epidemic model, but where individuals either recover naturally or are diagnosed, the latter implying isolation and subject to being contact traced. We focus on the novel digital contact tracing based on individuals using a tracing app and consider both the situation when this is the only form of contact tracing, and when combined with manual contact tracing. It is proven that the epidemic process converges to a limiting process as the population size n grows large. The limiting process is not a branching process (as is common for epidemic processes) because infectees may be contact traced "from" their infectors, thus creating dependencies. But by instead treating to-be-traced components as macro-individuals allows a multi-type branching process interpretation, thus giving an expression for the reproduction number R. This reproduction number (for the digital-only case) is then converted to an individual reproduction number $R^{(ind)}$ being easier to interpret. It is proven that, contrary to R, $R^{(ind)}$ decays monotonically with π (the fraction of app-users), and the two reproduction numbers are proven to have the same threshold at 1. The digital (only) contact tracing is then compared with earlier results for manual (only) contact tracing where a fraction p of all contacts are traced. It is proven that the critical fraction app-users π_c for which digital contact tracing is reduced to R = 1, and the critical fraction manually contact traced p_c to reach R = 1, satisfy $\pi_c > p_c$.

1 Introduction

One of the main reasons for modelling epidemics is to understand the effect of different preventive measures, such as vaccination and non-pharmaceutical interventions (NPI). During the recent Covid-19 pandemic, research about the effect of various NPIs, including social distancing, case isolation, contact tracing, lockdown, etc., has received much attention. Some related papers (e.g., [10, 12, 19]) have been highly influential on public health policies.

This paper focuses on the preventive measure: "contact tracing". Contact tracing is traditionally performed by public health agency officers who interview diagnosed individuals and then call the named contacts to advise them to self-quarantine and to test, which is often referred to as the manual contact tracing. This type of contact tracing has been successful in reducing transmission in many epidemics like Ebola [25], SARS [18], Influenza [1], and Measles [17]. In the present paper, we instead investigate a different type of contact tracing: digital contact tracing. In the case of Covid-19, [11] suggested that manual contact tracing is not rapid enough to control the Covid-19 epidemic, and the new idea of developing a "contact tracing app" was invented: once an app-user is diagnosed, a warning message will be instantaneously sent out to all the app-users who recently have been nearby for a sufficient duration with the confirmed case. Such notified contacts are then advised to test and quarantine themselves. Several contact tracing apps have been developed and released (e.g., in the UK [11, 26], in the Netherlands [14]).

There are several papers analysing digital contact tracing (e.g., [7, 15, 16, 21]) focusing on simulation-based epidemic models, and the results of [22] are based on a combination of simulations and mean-field analysis of the related percolation problem. Several papers on digital contact tracing analysing Covid-19 (e.g., [9, 11]) are based on the mathematical model first introduced by [13] in terms of recursive equations for analyzing the timing of infectiousness and the appearance of symptoms. In particular, the results from [11] showed that the Covid-19 epidemic was unlikely to be contained only by manual tracing.

Modelling contact tracing is mathematically challenging and does not easily lend itself to being analyzed using differential equations. Our focus in this paper is on the beginning of an outbreak before a massive fraction have been infected. For this reason, we apply stochastic models, which are also suitable because the outcome of contact tracing itself is random rather than deterministic. The early phase of an epidemic without preventive measures can often be approximated by a suitable branching process (e.g., [3]) using the underlying model assumption stipulating that once an individual has been infected, it behaves (transmits) independently of its infector. When contact tracing is introduced, this independence breaks down and other methods need to be developed. In the last decades, there has been some progress in more rigorous analyses of epidemic models with manual contact tracing, e.g., [5, 6, 20].

In [27], we considered a Markovian SIR epidemic model with manual contact tracing by assuming that once individuals are diagnosed, they perform manual tracing without delay, thus reaching each contact with probability p. In the present paper, we instead analyse a model with *digital* contact tracing by assuming that a fraction π of individuals installs a contact-tracing app (and follows the advice if notified). Once an app-user is diagnosed, all its app-using contacts are notified, with the result that they isolate and test themselves without delay. For those who test positive, their app-using contacts are also notified, and so on. Furthermore, for both manual and digital contact tracing, we assume that traced individuals who have recovered naturally are also identified and are subject to contact tracing. Please note the conceptual difference between digital and manual contact tracing: manual contact tracing may happen if a *contact* is traced (which happens with probability p), whereas digital contact tracing may happen if both *individuals* are app-users. The two types of tracing hence resemble a bit bond percolation and site-percolation respectively, with the difference that edges are closed rather than opened.

Using large population asymptotics, we prove that the early epidemic process with digital tracing may be approximated by a two-type branching process where type-1 "individuals" are *app-using components* (in terms of app-users) and type-2 are non-app-users. We then analyse the model having both types of contact tracing in place, i.e., reaching a fraction p of all contacts using manual contact tracing and additionally all app-using contacts if the tested individual is an app-user (making up a fraction π in the community). The limiting process in this case is shown to be a two-type branching process, where both the type-1 and type-2 "individuals" are the to-be-traced components, but type-1 starts with an app-user and type-2 with a non-app-user.

We derive the reproduction number for the two limiting processes. These reproduction numbers are, however hard to interpret being reproduction numbers for multi-type macro-individuals. We therefore also derive a more easily interpretable individual reproduction number for the digital-only model and show that the latter reproduction number has the same threshold as the former, thus also showing how much contact tracing is needed for the epidemic to become sub-critical. A surprising observation for the digital-only reproduction number for the two-type branching process may in fact *increase* with π , the fraction of app-users. Still, it is proven that the corresponding individual reproduction number is monotonically decreasing in π as expected.

We also compare the digital (only) contact tracing model and compare it with the manual (only) contact tracing model of [27] to see how the critical app-using fraction π_c relates to the critical fraction p_c of contacts that are manually contact traced, having all other model parameters equal. We prove that $\pi_c > p_c$ and, as a by-product, obtain a new explicit expression for p_c only given implicitly in [27].

In Section 2, we define the digital contact tracing model as well as the model having both manual and digital contact tracing. In Section 3, we present the main results and provide some intuition. Next, we give the proofs and explain more about approximating the initial phase of the epidemic in a large population (Section 4 for digital tracing only, Section 5 for both types of tracing). Then, in Section 6, we illustrate our results numerically, compare the effect of manual and digital contact tracing, and investigate their combined effect. Finally, we summarize our conclusions and discuss potential improvements of the present models in Section 7.

2 Model description

2.1 The epidemic model

First, we consider a Markovian SIR (Susceptible \rightarrow Infectious \rightarrow Recovered) epidemic spreading in a closed and homogeneous mixing population with fixed size *n*. Initially, there is one infectious individual, and the rest are susceptible. An infectious individual has contacts at rate β , each time with an individual uniformly chosen from the population. So the individual-toindividual contact rate is β/n . If such a contacted individual is susceptible, he/she becomes infected immediately; otherwise, nothing happens. Each infectious individual recovers naturally at rate γ and plays no further part in the epidemic (thus having a $T_I \sim Exp(\gamma)$ infectious period with mean $1/\gamma$).

To initiate contact tracing, we incorporate the testing strategy into this SIR model. Additionally, we assume that once he/she becomes infected, the infectives are tested positive and are immediately isolated (we refer to this as "diagnosed" in our paper) after random periods which are independent and identically distributed according to a random variable $T_D \sim Exp(\delta)$. In conclusion, infectious individuals could stop spreading disease after random time $min\{T_D, T_I\} \sim Exp(\gamma + \delta)$, i.e. either from natural recovery (rate γ) or diagnosis (rate δ). Here we assume that $\delta > 0$ unless otherwise specified. All the random quantities described above are assumed to be mutually independent. The epidemic stops when there is no infectious individual present in the population.

For this epidemic model (with testing but without contact tracing), each infectious period follows the exponential distribution with intensity $(\gamma + \delta)$. Hence, it is straightforward to compute the mean number of secondary infections produced by one single infective before recovery or diagnosis:

$$R_0 = \frac{\beta}{\gamma + \delta}.\tag{1}$$

To emphasize the effect of contact tracing, we somewhat incorrectly refer to this as the *basic reproduction number* R_0 . More correct would be to have R_0 for the situation with no testing (so β/γ), but since we want to study the effect of contact tracing vs. no contact tracing, we do this assuming unchanged testing rate and hence use the expression above instead.

2.2 The epidemic model with digital contact tracing

We add digital contact tracing to the epidemic model in Section 2.1 by assuming that a fraction π of individuals use the tracing app (and follow the recommendations) and that individuals mix uniformly irrespective of using the app or not, i.e., each individual is an app-user with probability π independently. In the following text, we assume that $0 < \pi \leq 1$ unless otherwise specified. Clearly, when $\pi = 0$ there is no digital tracing, so we would have the same epidemic model as in Section 2.1.

For the infectious individuals (either app-users or non-app-users), they recover naturally at rate γ and are diagnosed at rate δ . The digital contact tracing procedure is defined as follows. If and when an infectious app-user is diagnosed, all app-using contacts of the infective will be notified, with the result that they test and isolate themselves without delay, so stop spreading if infectious. The app-using contacts who have been infected, including those who have recovered, are then also assumed to trigger digital tracing among their app-using contacts without delay according to the same procedure, and so on.

2.3 The epidemic model with digital and manual contact tracing

Finally, we describe the epidemic model with digital contact tracing when there is also manual contact tracing in place and call this the *combined model*. First, following the assumption in Section 2.2, a community fraction π are app-users and follow the instructions. If such an app-user is diagnosed, then all of its app-using contacts (on average being a fraction π of all contacts) will be traced. To this, we now add the manual contact tracing by assuming that once an infectious individual is diagnosed, app-user or not, each of its contacts will be reached by manual tracing independently with probability p. It means that for diagnosed app-users, *all* app-using contacts will be traced, and each non-app-using contact will be traced manually with probability p. For diagnosed non-app-users, each contact, app-user or not, will be traced manually with probability p. Like before, all traced individuals are tested and isolated without delay if testing positive. Traced individuals who test positive, including those who have recovered, are then contact traced in the same manner without delay, and so on. The model parameters are summarized in Table 2.1.

 Table 2.1
 Table of Model Parameters

Parameter	Notation
size of population	n
transmission rate	β
rate of natural recovery	γ
rate of diagnosis	δ
community fraction using the contact tracing app	π
(and following the advice)	
probability that contact is manually traced	p

3 Main results

In this paper, our main goal is to analyse the initial phase of the epidemic having digital contact tracing. We start by showing that the epidemic converges to a limiting process, asymptotically as the population size n grows to infinity.

Let $E_D^{(n)}(\beta, \gamma, \delta, \pi)$ denote the epidemic model with digital contact tracing only in a population of size n (defined in Section 2.2). It is convenient to consider the epidemic as a two-type process where the type of an infective corresponds to whether he/she is an app-user or not. The limiting process, denoted $E_D(\beta, \gamma, \delta, \pi)$, is described as follows. Each alive (=infectious) individual gives birth to (infects) app-users at rate $\beta\pi$, to non-app-users at rate $\beta(1-\pi)$, recovers naturally at rate γ and is diagnosed at rate δ (the individual is considered dead, not giving any more births, in both cases). Moreover, if a diagnosed individual is an app-user, all of its app-using offspring as well as its parent (in case of an app-user) are diagnosed at the same time. Such diagnosed individuals will in turn lead to all app-users among its offspring and parent being diagnosed without delay, and so on.

The limit process in terms of app-users and non-app-users will *not* be a branching process when contact tracing is in place, since an infectious appuser maybe contact traced by its app-using infector or one of its app-using infectees, thus giving rise to dependence between individuals which violates the basic assumption of independence in branching processes. But if we instead consider non-app-users as one type of individual and "app-using components" (consisting of the whole transmission chain of app-users) as a second type of "macro-individual" this process will evolve according to a two-type branching process (see Figure 4.1 of the next section for an illustration). This holds because there will never be contact tracing between any combination of such individuals, thus making individuals behave independently.

Then we study the birth and death of app-using components. Such a component will start with one infectious app-user infected by a non-app user (we call this the *root* of the component). Then it can grow to include app-users infected by the root and app-users they in turn infected, and so on. Eventually, the whole app-using component will die out (i.e., stop spreading the infection) either by someone being diagnosed (when immediately the whole component gets traced and diagnosed) or if all individuals in the component have recovered naturally. While the component has infectious individuals, the component can also infect non-app-users. The infectious non-app-users can, in turn, infect other non-app-users as well as app-users, and in the latter case, new app-using components are created.

Following multi-type branching process theory ([2, 8]) we define

$$M = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix}$$

as the next generation matrix of the limiting two-type branching process, where m_{ij} is the expected number of secondary infections of type j produced by a single infected individual of type i, for i, j = 1, 2 (type 1 is app-using components and type 2 non-app-users). Then a major outbreak occurs with positive probability if and only if the largest eigenvalue of M denoted R_D , is above 1 (the elements of M are derived in Section 4.2). We call R_D the effective reproduction number for the epidemic with digital tracing.

We summarize our findings in the following proposition and corollary.

Proposition 3.1. Consider the sequence of epidemic processes with digital tracing $E_D^{(n)}(\beta, \gamma, \delta, \pi)$, for each population size n, starting with one random initial infective and the rest susceptible. Then on any finite time interval, $E_D^{(n)}(\beta, \gamma, \delta, \pi)$ converges in distribution to the limit process $E_D(\beta, \gamma, \delta, \pi)$ as $n \to \infty$.

Corollary 3.1. The limit process $E_D(\beta, \gamma, \delta, \pi)$ is super-critical, meaning that it will grow beyond all limits with positive probability, iff $R_D > 1$, where

$$R_D = \frac{R_0(1-\pi)}{2} + \sqrt{\frac{(R_0(1-\pi))^2}{4}} + f(\pi)R_0\pi.$$

Let $Z_D^{(n)}$ be the final number of infected in the whole epidemic $E_D^{(n)}(\beta, \gamma, \delta, \pi)$. Then if $R_D > 1$, $Z_D^{(n)} \to \infty$ with positive probability, whereas if $R_D \leq 1$ then the final fraction getting infected $\bar{Z}_D^{(n)} = Z_D^{(n)}/n \xrightarrow{p} 0$ (a minor outbreak for sure).

Our next result compares the effect of digital contact tracing with the effect of manual contact tracing. More precisely, we compare the current model with the manual contact model of ([27]). That model has the same transmission model, no digital contact tracing, but instead a manual contact tracing in that each contact is traced upon diagnosis, independently, with probability p. Keeping all epidemic parameters being fixed and equal in the two models, we compare π_c being the app-using fraction for which $R_D = 1$ with p_c being the critical fraction manually contact traced such that the corresponding manual reproduction number satisfies $R_M = 1$.

Theorem 3.1. Let $\beta, \delta, \gamma > 0$ be fixed parameters and assume $R_0 = \beta/(\delta + \gamma) > 1$ (otherwise contact tracing is unnecessary). Then we have

$$\pi_c > p_c = \frac{\beta - (\gamma + \delta)}{\beta - \gamma}$$

The reproduction number R_D cannot be interpreted as some mean number of infections caused by one individual since it is based on a two-type branching process in which one of the types is a to-be-traced component. A surprising consequence of this is seen in Figure 6.2a where we observe that R_D is not monotonically decreasing in π : in some situations, increasing the fraction of app-users can lead to a *larger* reproduction number!

In Section 4.4 we therefore derive an individual reproduction number $R_D^{(ind)}$ for the epidemic with digital tracing:

$$R_D^{(ind)} = \frac{\pi f(\pi)}{1 - \pi + \pi f(\pi)} + (1 - \pi) \frac{\beta}{\delta + \gamma}.$$

For this individual reproduction number $R_D^{(ind)}$, we have the following theorem.

Theorem 3.2. Let β, γ and δ be fixed. Then $R_D^{(ind)}$ is monotonically decreasing in π . That is, for any $0 \le \pi_1 < \pi_2 \le 1$, we have $R_D^{(ind)}(\pi_1) > R_D^{(ind)}(\pi_2)$.

The following theorem shows that $R_D^{(ind)}$ is indeed an epidemic threshold.

Theorem 3.3. Let β, γ and δ be fixed. Then $R_D = R_D^{(ind)} = 1$ at $\pi = \pi_c$, and $R_D > 1$ as well as $R_D^{(ind)} > 1$ if $\pi < \pi_c$ and the opposite if $\pi > \pi_c$.

Finally, we state related results as above, but now for the beginning of the epidemic in the combined model of Section 2.3 having digital as well as manual contact tracing, which we denote by $E_{DM}^{(n)}(\beta, \gamma, \delta, p, \pi)$.

Proposition 3.2. Consider a sequence of epidemic processes with both manual and digital tracing $E_{DM}^{(n)}(\beta,\gamma,\delta,p,\pi)$, for population size n, and starting with one initial infective. Then on any finite time interval, $E_{DM}^{(n)}(\beta,\gamma,\delta,p,\pi)$ converges in distribution to the limit process $E_{DM}(\beta,\gamma,\delta,p,\pi)$ as $n \to \infty$.

Corollary 3.2. Let $Z_{DM}^{(n)}$ be the final number infected in the whole epidemic $E_{DM}^{(n)}(\beta,\gamma,\delta,p,\pi)$. Then if the reproduction number $R_{DM} > 1$, $Z_{DM}^{(n)} \rightarrow \infty$ with non-zero probability; and if $R_{DM} \leq 1$, the final fraction $\bar{Z}_{DM}^{(n)} = Z_{DM}^{(n)}/n \xrightarrow{p} 0$, namely there will be a minor outbreak for sure.

4 Approximation of the initial phase in a large community with digital tracing only

In the following subsections, we first prove Proposition 3.1 in Section 4.1, then derive the effective reproduction number for digital tracing and prove Corollary 3.1 in Section 4.2. In Section 4.3, the proof of Theorem 3.1 is presented, where we compare the effectiveness of manual and digital tracing analytically. Finally in Section 4.4, we derive an individual reproduction number for digital tracing and prove Theorem 3.2, 3.3.

4.1 **Proof of Proposition 3.1**

We recall that for the size of population n, the epidemic process with digital contact tracing is denoted by $E_D^{(n)}(\beta, \gamma, \delta, \pi)$, where there is one initial infective. The limit process $E_D(\beta, \gamma, \delta, \pi)$ is defined as follows. There are two types of individuals: non- and app-users. At time t = 0, there is one initial ancestor (who has the same type as the initial case in $E_D^{(n)}(\beta, \gamma, \delta, \pi)$). During the lifetime, each individual gives birth to app-users at rate $\beta\pi$ and non-app-users at rate $\beta(1-\pi)$. Individuals recover naturally at rate γ and are diagnosed at rate δ . Once an app-user is diagnosed, all of its app-using descendants and its parent (in case of an app-user) are diagnosed at the same time, and so on. In particular, if traced individuals have recovered, they will still be diagnosed, implying that also their app-using contacts will be traced, and so on.

First, we note that there is a new infection, recovery, or diagnosis in the epidemic whenever a new birth, death, or removal occurs in $E_D(\beta, \gamma, \delta, \pi)$, respectively. The rates of recovery (γ) and diagnosis (δ) are the same as those of death and removal. An infection is "successful" only when the contacted person is susceptible. Let $S_n(t)$ be the number of susceptibles in the n^{th} epidemic $E_D^{(n)}(\beta, \gamma, \delta, \pi)$ at time t, the probability that a given infective infects a new app-user is $\pi S_n(t)/n$. This implies that the rate of new infection to app-users is $\beta \pi S_n(t)/n$. On the other hand, the rate of birth to app-users is $\beta \pi$. When n is large and at the beginning of the epidemic, we have $S_n(t) \approx n$, so the rate of infection to app-users is close to the app-using birth rate in the limit process $E_D(\beta, \gamma, \delta, \pi)$. Similarly, the rate of infection to non-app-users $\beta(1-\pi)S_n(t)/n$ is close to the rate of birth to non-app-users $\beta(1-\pi)$. Using the standard coupling arguments for epidemic $E_D^{(n)}(\beta, \gamma, \delta, \pi)$ converges in distribution to the limit process $E_D(\beta, \gamma, \delta, \pi)$ as $n \to \infty$.

As discussed in Section 3, instead of describing $E_D(\beta, \gamma, \delta, \pi)$ in terms of the actual individuals, we consider it as a process of app-using components and non-app-users, which is a two-type branching process. If there are currently k alive (=infectious) app-users in an app-using component, each such individual gives birth to (infects) new app-users at rate $\beta\pi$, so the total birth rate is hence $k\beta\pi$. Each individual recovers naturally at rate γ , so the overall recovery rate equals $k\gamma$. Finally, the whole component is diagnosed once one of the k infectious individuals is diagnosed, so the total rate of diagnosis is $k\delta$. While having k infectious app-users, the component generates new (infects) non-app-users at rate $k\beta(1-\pi)$, whereas the component cannot give birth to new app-using components because any infected app-user will belong to the same component. On the other hand, the non-app-users give birth to new app-using components at rate $\beta\pi$ and non-app-users at rate $\beta(1-\pi)$.

In Figure 4.1, we illustrate how the two types of "individuals": app-using components (surrounded by dashed lines) and non-app-users (square-shaped nodes) grow and eventually die out. We set the app-user A1 to be the initial case. While the app-using component $C_1^{(app)}$ evolves (new app-users getting

infected or existing ones recovering), the component $C_1^{(app)}$ infects two nonapp-users N1 and N2. The non-app-user N1 infects one non-app-user and one new app-using component $C_2^{(app)}$ with root A2, whereas N2 infects two other non-app-users. Once the app-user A2 is diagnosed, the whole app-using component $C_2^{(app)}$ will die out.

Figure 4.1 Example of the dynamics of app-using components and non-appusers for the model with digital contact tracing: the circle nodes are app-users and the squares non-app-users. The white, black, and grey colors correspond to "infectious", "diagnosed" and "naturally recovered", respectively. The rectangular region surrounded by the dashed line symbolizes the app-using component, and the area is filled with diagonal lines when the whole component is diagnosed and removed.

The advantage of the approximation outlined above is that multi-type branching processes are well-studied (e.g.[2, 8]). As a consequence, in the following section, we derive an effective reproduction number which has a threshold value of 1, determining whether a major outbreak is possible or not.

4.2 Proof of Corollary 3.1

We recall that $M = (m_{ij})$ be the mean offspring matrix of the limit two-type branching process (type-1: app-using components, type-2: non-app-users) and m_{ij} is the mean number of secondary cases of type j produced by one type-i individual for i, j = 1, 2. From standard multi-type branching process theory [2,8], the limit process $E_D(\beta, \gamma, \delta, \pi)$ is known to be sub-critical if $R_D < 1$, critical if $R_D = 1$ and super-critical if $R_D > 1$, where R_D is the largest eigenvalue of M, which is given by

$$R_D = \frac{m_{11} + m_{22}}{2} + \sqrt{\frac{(m_{11} + m_{22})^2}{4} - m_{11}m_{22} + m_{12}m_{21}}.$$

Let Z_D be the total progeny of $E_D(\beta, \gamma, \delta, \pi)$, then $Z_D < \infty$ (the process goes extinct) with probability 1 if $R_D < 1$. And if $R_D > 1$, $Z_D = \infty$ (the process grows beyond all limits) with a strictly positive probability. Then it follows from Proposition 3.1 that if $R_D > 1$, $Z_D^{(n)} \to \infty$ with non-zero probability (there may be a large outbreak of the epidemic); if $R_D \leq 1$, $Z_D^{(n)} \to Z_D$, implying that the final fraction getting infected $Z_D^{(n)}/n \to 0$. Hence, we have proved that R_D is an epidemic threshold. We denote the effective reproduction number for the epidemic model with digital tracing by R_D .

To get an explicit expression of R_D , we derive the elements m_{ij} as follows. First, we note that the app-using components (type 1) cannot give birth to new app-using components since app-users infected by an app-using component will belong to the same component. Consequently, we have that

$$m_{11} = 0.$$
 (2)

As for non-app users, they will never be reached by digital tracing and thus spread the infection like in the epidemic without any contact tracing. That is, each infectious non-app-user infects non-app-users at rate $\beta(1 - \pi)$ and app-users at rate $\beta\pi$, where the infectious periods of non-app-users are independent and identically exponentially distributed with intensity ($\delta + \gamma$). Hence, the number of app-using components (type 1) and non-app-users (type 2) infected by one typical non-app-user is geometrically distributed with support $\{0, 1, 2, ...\}$ and mean

$$m_{21} = \frac{\beta \pi}{\delta + \gamma} = R_0 \pi, \tag{3}$$

and

$$m_{22} = \frac{\beta(1-\pi)}{\delta + \gamma} = R_0(1-\pi)$$
(4)

respectively.

Finally, it remains to compute m_{12} . Let X(t) be the number of infectious app-users in an app-using component at time t, with X(0) = 1. We know

that $\{X(t), t \ge 0\}$ behaves as a linear birth-death process with birth rate $\beta \pi$ (new app-users infected) and death rate γ (natural recovery), and this process stops when a diagnosis event happens at rate δ (the whole component is then diagnosed). Further, at time s, the component gives birth to new components at rate $X(s)\beta(1-\pi)$. Let T be the random variable representing the time of first diagnosis. Then

$$m_{12} = \mathbf{E}\left[\int_0^T \beta(1-\pi)X(t)dt\right]$$
$$= \beta(1-\pi)\mathbf{E}[A],$$

where we set

$$A := \int_0^T X(t) dt.$$

The process $\{X(t)\}$ is piecewise constant, and the jump rate of X(t) is proportional to X(t). More precisely, the contribution to the integral between two jumps T_i and T_{i+1} (prior to T) is $X(T_i)Y$, where $Y \sim Exp((\beta \pi + \gamma + \delta)X(T_i))$. But this contribution is simply $1 \cdot \tilde{Y}$ where $\tilde{Y} \sim Exp((\beta \pi + \gamma + \delta))X(T_i)$. But this contribution is simply $1 \cdot \tilde{Y}$ where $\tilde{Y} \sim Exp(\beta \pi + \gamma + \delta)$. For this reason, A equals the integral of 1 integrated up until the first time a new process $\{\tilde{X}(t), t \geq 0\}$, which is a random time-change version of the process $\{X(t), t \geq 0\}$, reaches the value 0. More precisely, the time span of $\{\tilde{X}(t)\}$ is slowed down by $\{X(t)^{-1}\}$ at time t. This new process $\{\tilde{X}(t), t \geq 0\}$ is hence a continuous-time random walk going up at $\beta \pi$, going down at γ and absorbing at zero. Let $\tilde{T}_{rw} = \inf\{t > 0 : \tilde{X}(t) = 0\}$, and $\tilde{T} = \tilde{T}_{rw} \wedge \tilde{T}_D$, where $\tilde{T}_D \sim Exp(\delta)$ which is independent of $\{\tilde{X}(t), t \geq 0\}$ and hence independent of \tilde{T}_{rw} . Then it follows that $A = \int_0^T X(t) dt$ and $\tilde{T} = \int_0^{\tilde{T}} 1 dt$ have the same distribution. As a consequence,

$$\begin{split} \mathbf{E}[A] &= \mathbf{E}[\tilde{T}] \\ &= \int_0^\infty \mathbf{P}(\tilde{T}_{rw} > t) \mathbf{P}(\tilde{T}_D > t) dt \\ &= \int_0^\infty \mathbf{P}(\tilde{T}_{rw} > t) e^{-\delta t} dt \\ &= \frac{1 - \phi(\delta)}{\delta}, \end{split}$$

where $\phi(\delta) := \mathbf{E}[e^{-\delta \tilde{T}_{rw}}].$

Further, if we condition on the first jump of $\{\tilde{X}(t), t \geq 0\}$, we get the following equation of $\phi(\delta)$:

$$\phi(\delta) = \frac{\beta\pi + \gamma}{\beta\pi + \gamma + \delta} \left(\frac{\beta\pi}{\beta\pi + \gamma}\phi(\delta)^2 + \frac{\gamma}{\beta\pi + \gamma}\right)$$

which has two roots $\phi(\delta) = (\beta \pi + \gamma + \delta \pm \sqrt{(\beta \pi + \gamma + \delta)^2 - 4\beta \pi \gamma})/2\beta \pi$. Since $\phi(0) = 1$, we get

$$\phi(\delta) = \frac{\beta \pi + \gamma + \delta - \sqrt{(\beta \pi + \gamma + \delta)^2 - 4\beta \pi \gamma}}{2\beta \pi},$$

implying that

$$\mathbf{E}[A] = \frac{\beta \pi - \gamma - \delta + \sqrt{(\beta \pi + \gamma + \delta)^2 - 4\beta \pi \gamma}}{2\beta \pi \delta}$$

Hence we obtain

$$m_{12} = f(\pi) := \frac{(1-\pi)}{2\pi\delta} (\beta\pi - \gamma - \delta + \sqrt{(\beta\pi + \gamma + \delta)^2 - 4\beta\pi\gamma})$$
(5)

for $0 < \pi \le 1, \delta > 0$.

In conclusion, the effective component reproduction number R_D for the model with digital tracing only is the largest eigenvalue to the matrix $M = (m_{ij})$, which is given by

$$R_D = \frac{R_0(1-\pi)}{2} + \sqrt{\frac{(R_0(1-\pi))^2}{4} + f(\pi)R_0\pi}$$
(6)

with $f(\pi)$ in Equation (5).

Remark 4.1. It can be easily checked that

$$\lim_{\pi \to 0} f(\pi) = \frac{\beta(\gamma + \delta) + \beta\delta - \beta\gamma}{2\delta(\gamma + \delta)} = \frac{\beta}{\gamma + \delta} = R_0$$

This implies that the reproduction number R_D converges to the basic reproduction number R_0 when $\pi \to 0$ as expected:

$$\lim_{\pi \to 0} R_D(\pi) = R_0 = \frac{\beta}{\gamma + \delta}.$$

Remark 4.2. The analytic expression for $f(\pi)$ can be used to obtain an analytic expression also for the manual tracing model considered in [27]. A related birth and death process was studied there. Considering such a to-betraced component with size k, the component would increase by 1 at rate $k\beta p$, decrease by 1 at rate $k\gamma$, and jump to 0 at rate $k\delta$. And before jumping, the component gave birth to new components with rate $k\beta(1-p)$. Using similar arguments as above, we hence get the following explicit expression for the reproduction number (which in [27] was expressed using an infinite sum):

$$R_M^{(c)}(p) = f(\pi = p) = \frac{1-p}{2p\delta}(\beta p - \gamma - \delta + \sqrt{(\beta p + \gamma + \delta)^2 - 4\beta p\gamma}).$$
(7)

4.3 Proof of Theorem 3.1

In this section, we compare the separate effects of manual and digital contact tracing by proving Theorem 3.1. Here we fix the epidemic parameters β , δ , γ such that $\beta/(\delta + \gamma) > 1$, and consider the reproduction number for manual tracing $R_M^{(c)}(p)$ and the one for digital tracing $R_D(\pi)$ as function of p and π respectively. We first state and prove two lemmas.

Lemma 4.1. Suppose $R_0 = \beta/(\delta + \gamma) > 1$. Then the critical manual reporting probability p_c (satisfying $R_M^{(c)}(p_c) = 1$) is given by

$$p_c = \frac{\beta - (\gamma + \delta)}{\beta - \gamma}.$$
(8)

Proof of Lemma 4.1. First of all, we show the existence of the critical probability p_c . Based on Remark 4.1 and 4.2, $R_M^{(c)}(p)$ is continuous in p with $R_M^{(c)}(0) = R_0 > 1$ and $R_M^{(c)}(1) = 0 < 1$. Then by intermediate value theorem (see [24], p126), there exists at least one p_c in (0, 1) such that $R_M^{(c)}(p_c) = 1$.

Next, we actually compute p_c and show there is only one p_c . Without loss of generality, we can assume that $\gamma + \delta = 1$, then the formula of $R_M^{(c)}$ in Equation (7) becomes

$$\begin{split} R_M^{(c)}(p) &= \frac{(1-p)}{2p(1-\gamma)} (\beta p - 1 + \sqrt{(\beta p + 1)^2 - 4\beta p\gamma}) \\ &= \frac{1}{2(1-\gamma)} \frac{(1-p)}{p} (\beta p - 1 + \sqrt{(\beta p - 1)^2 + 4\beta p(1-\gamma)}) \\ &= \frac{(1-p)}{2(1-\gamma)} (\beta - \frac{1}{p} + \sqrt{(\beta - \frac{1}{p})^2 + 4\beta(1-\gamma)\frac{1}{p}}). \end{split}$$

It follows by standard calculations that $R_M^{(c)}(p_c) = 1$ is equivalent to

$$p_c = \frac{\beta - 1}{\beta - \gamma}.$$

We recall that the parameters are so far scaled. Back to the original scale, we have

$$p_c = \frac{\beta - (\gamma + \delta)}{\beta - \gamma}.$$

Lemma 4.2. Let p_c be the critical manual reporting probability such that $R_M^{(c)} = 1$. Then there exists at least one π_c lying in $(p_c, 1)$ that satisfies $R_D(\pi_c) = 1$.

Proof of Lemma 4.2. First, we know that $R_D(\pi)$ is continuous in π and $R_D(\pi = 1) = 0$. Letting $\pi = p_c$ in Equation (6) gives

$$R_D(\pi = p_c) = \frac{R_0(1 - p_c)}{2} + \sqrt{\frac{(R_0(1 - p_c))^2}{4} + R_0 p_c} > 1$$
(9)

(the first equality follows from that $f(p_c) = R_M^{(c)}(p_c) = 1$). Then it follows by intermediate value theorem (see [24], p126) that there exists at least one π_c lying in $(p_c, 1)$ that satisfies $R_D(\pi_c) = 1$.

Lemma 4.3. For any critical app-using fraction π_c such that $R_D = 1$, we have the reproduction number with manual tracing at $p = \pi_c$ is below 1:

$$R_M^{(c)}(p=\pi_c) < 1.$$

Proof of Lemma 4.3. $R_D(\pi_c) = 1$ is equivalent to

$$R_M^{(c)}(p = \pi_c) = \frac{1 - R_0(1 - \pi_c)}{R_0 \pi_c} = 1 - \frac{R_0 - 1}{R_0 \pi_c}.$$

On the other hand, we get $(R_0 - 1)/R_0\pi_c > 0$, since $R_0 > 1$ by assumption. This implies that $R_M^{(c)}(p = \pi_c)$ is smaller than 1.

We are now ready to prove Theorem 3.1.

Proof of Theorem 3.1. By Lemma 4.2, we know that there exists at least one π_c lying between p_c and 1. Suppose there exists one π' smaller than p_c ($\pi' < p_c$) and $R_D(\pi = \pi') = 1$. Then by Lemma 4.3, the reproduction number with manual tracing at point $p = \pi'$

$$R_M^{(c)}(p=\pi') < 1.$$

Again using the fact that $R_M^{(c)}(p=0) = R_0 > 1$ and $R_M^{(c)}(p)$ is continuous in p, by intermediate value theorem [24], there shall exist one p' lying in $(0, \pi')$ such that

$$R_M^{(c)}(p=p') = 1.$$

On the other hand, by Lemma 4.1, we have shown that $p' = p_c$, implying that $\pi' > p_c$ which leads to a contradiction. Hence, there does not exists such π' which is smaller than p_c and $R_D(\pi = \pi') = 1$.

4.4 The effective individual reproduction number $R_D^{(ind)}$

The interpretation of R_D is complicated in that the two types in the limiting branching process are different types of objects: type-2 individuals are actual individuals (non-app-users), but type-1 are "macro individuals": the to-betraced app-using components. In this section, our aim is therefore to convert R_D to an individual reproduction number $R_D^{(ind)}$.

We first derive $R_{D-A}^{(ind)}$, the average number of individuals (of any type) infected by a newly infected app-user, and $R_{D-N}^{(ind)}$ the average number of individuals (of any type) infected by a newly infected non-app-user. We note that each infection, irrespective of the type of infector, is with an app-user with probability π and a non-app-user with probability $(1 - \pi)$. This implies that the $R_D^{(ind)}$ can be expressed as the sum:

$$R_D^{(ind)} = \pi R_{D-A}^{(ind)} + (1 - \pi) R_{D-N}^{(ind)}.$$
 (10)

It remains to compute $R_{D-A}^{(ind)}$ and $R_{D-N}^{(ind)}$. From the previous results in Section 4.2, we see that a given app-using component infects, on average, m_{12} number of non-app-users. Let $\mu_c^{(A)}$ be the mean number of app-users that ever get infected in an app-using component. All but one of these $\mu_c^{(A)}$ are infected within the component, and there are, on average, m_{12} number of "external" infections. So in total, there are on average $(\mu_c^{(A)} - 1) + m_{12}$ number of infections by an app-using component. As a consequence, the average number of infections *per app-user*, $R_{D-A}^{(ind)}$, equals

$$R_{D-A}^{(ind)} = \frac{(\mu_c^{(A)} - 1) + m_{12}}{\mu_c^{(A)}},\tag{11}$$

where we recall from Equation (5) that $m_{12} = f(\pi)$.

Next, we compute $\mu_c^{(A)}$. We recall that the size of an app-using component jumps up by 1 if there is a new app-user-infection, down by 1 if an app-user recovers naturally, and goes to 0 if an app-user is diagnosed. When only considering the number of jumps the process makes, we can forget the jump rates and simply let each time step correspond to a jump. The true process starts at $X_0 = 1$ and jumps up and down, or down to 0 with probabilities $\beta \pi/(\beta \pi + \gamma + \delta)$, $\gamma/(\beta \pi + \gamma + \delta)$ and $\delta/(\beta \pi + \gamma + \delta)$ respectively, and the process is absorbed when hitting 0 for the first time K. Let X^+ be the number of up-jumps before being absorbed in 0, and then we have

$$\mu_c^{(A)} = 1 + \mathbf{E}[X^+]. \tag{12}$$

In order to get an expression for $E(X^+)$, we extend the process $X = \{X_k\}$ to $\tilde{X} = \{\tilde{X}_k\}$ which is a renewal process (see Figure 4.2 for an illustration).

More precisely, $\tilde{X}_k = X_k$ for $k \leq K$; once absorbed, we continue the \tilde{X} process by making it jump up to 1 with probability $\beta \pi/(\beta \pi + \gamma + \delta)$ and with the remaining probability \tilde{X} stays at 0. As a consequence, \tilde{X} will jump up to 1 after a $N \sim Geo(\beta \pi/(\beta \pi + \gamma + \delta))$ number of time steps $(N \geq 1)$, and then the process restarts: a renewal has occurred. We also note that the process \tilde{X} makes an up-jump with probability $\beta \pi/(\beta \pi + \gamma + \delta)$ each time, whether currently at 0 or not.

Figure 4.2 Illustration of the extended process $\{\tilde{X}_k\}$. At first, the original process X hits 0 at the K_1 'th jump (in total $X^+ = 4$ up-jumps); then stays at zero for N_1 number of time-steps until jumping up to 1, so a renewal occurs. Next, the process restarts and makes K_2 number of jumps until absorbed in 0, and then after N_2 time steps, a second renewal happens. K_1 , K_2 are i.i.d. copies of K, and N_1 , N_2 i.i.d. copies of N.

Let \tilde{X}_k^+ denote the total number of up-jumps the extended process \tilde{X} has done up to k'th jump. Using the *reward renewal theorem* (see e.g., Chapter 7.4 in [23]), we have

$$\lim_{k \to \infty} \frac{\mathbf{E}[\tilde{X}_k^+]}{k} = \frac{\mathbf{E}[X^+] + 1}{\mathbb{E}[K] + \mathbb{E}[N]}.$$
(13)

Clearly $\tilde{X}_k^+ \sim Bin(k, \beta \pi/(\beta \pi + \gamma + \delta))$ with expectation $k\beta \pi/(\beta \pi + \gamma + \delta)$. The left hand side of Equation (13) hence equals $\beta \pi/(\beta \pi + \gamma + \delta)$. And as stated above, N is geometrically distributed with success probability $\beta \pi/(\beta \pi + \gamma + \delta)$ on the support $\{1, 2, 3, ...\}$, so

$$\mathbf{E}[N] = \frac{\beta \pi + \gamma + \delta}{\beta \pi}.$$

It follows from Equation (13) that

$$\mathbf{E}[X^+] + 1 = 1 + \frac{\beta \pi}{\beta \pi + \gamma + \delta} \mathbb{E}[K].$$
(14)

To derive $\mathbb{E}[K]$, we first recall that $f(\pi)$ is the total number of non-app-users infected by an app-using component, so we can write $f(\pi)$ as

$$f(\pi) = \mathbb{E} \Big[\sum_{i=1}^{K} X_i^{(na)} \Big],$$

where $X_i^{(na)}$ denotes the number of non-app-users infected between the (i - 1)'th and *i*'th jump. For the distribution of $X_i^{(na)}$, we briefly state the idea as follows. At (i - 1)'th jump, suppose that there are l infectives in the component, then the time until the next *i*'th jump is exponentially distributed with intensity $l(\beta \pi + \gamma + \delta)$. During this time, such a component infects non-app-users at rate $l\beta(1 - \pi)$. It follows that the distribution of $X_i^{(na)}$ is geometrically distributed with success probability

$$\frac{l(\beta\pi+\gamma+\delta)}{l(\beta\pi+\gamma+\delta+\beta(1-\pi))} = \frac{\beta\pi+\gamma+\delta}{\beta+\gamma+\delta}$$

on the support $\{0, 1, 2, ...\}$. Because the success probability is independent of the current state l implies that $X_i^{(na)}$ are not only independent but also identically distributed. Consequently, we obtain

$$f(\pi) = \mathbb{E}[K] \frac{\beta(1-\pi)}{\beta\pi + \gamma + \delta}.$$
(15)

Together with Equation (12) and (14) gives

$$\mu_c^{(A)} = 1 + \frac{\pi}{1 - \pi} f(\pi).$$
(16)

Finally, it follows with Equation (11) that

$$R_{D-A}^{(ind)} = \frac{f(\pi)}{1 - \pi + \pi f(\pi)}.$$
(17)

For non-app-users, it is easier to analyse since a given infectious non-appuser, on average, infects $(m_{21} + m_{22})$ individuals (app-users and non-appusers). Using Equation (3) and (4) it follows that

$$R_{D-N}^{(ind)} = m_{21} + m_{22} = \frac{\beta}{\delta + \gamma},\tag{18}$$

which is identical to R_0 in Equation (1). This is not surprising since nonapp-users will never be contact traced. Plugging in Equation (17) and (18) into (10) gives

$$R_D^{(ind)} = \frac{\pi f(\pi)}{1 - \pi + \pi f(\pi)} + (1 - \pi) R_0.$$
(19)

with $f(\pi)$ defined in Equation (5) and $R_0 = \beta/(\delta + \gamma)$.

4.4.1 Proof of Theorem 3.2

Our aim is to prove that the derivative $R_D^{(ind)}(\pi)$ is negative. Without loss of generality, we assume that $\delta + \gamma = 1$, then we have $R_0 = \beta$ and $f(\pi) = (1 - \pi)g(\pi)/2\pi\delta$ with $g(\pi) := \beta\pi - 1 + \sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta} \ge 0$. It implies with Equation (19) that

$$R_D^{(ind)}(\pi) = \frac{(1-\pi)g(\pi)/2\delta}{(1-\pi) + (1-\pi)g(\pi)/2\delta} + (1-\pi)\beta = \frac{g(\pi)}{2\delta + g(\pi)} + (1-\pi)\beta.$$

By differentiating the equation above w.r.t. π , we get

$$R_D^{(ind)\prime}(\pi) = \frac{g'(\pi)(2\delta + g(\pi)) - g(\pi)g'(\pi)}{(2\delta + g(\pi))^2} - \beta = \frac{2\delta g'(\pi)}{(2\delta + g(\pi))^2} - \beta.$$

Further, the derivative of g is given by

$$g'(\pi) = \beta + \frac{(\beta\pi - 1)\beta + 2\beta\delta}{\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta}}$$
$$= \beta(1 + \frac{\beta\pi - 1 + 2\delta}{\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta}})$$
$$= \frac{\beta(2\delta + g(\pi))}{\sqrt{(\beta\pi + 1)^2 - 4\beta\pi\gamma}}.$$

Then $R_D^{(ind)\prime}(\pi)$ satisfies

$$R_D^{(ind)\prime}(\pi) = \frac{2\delta\beta(2\delta + g(\pi))}{(2\delta + g(\pi))^2\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta}} - \beta$$
$$= \frac{2\delta\beta}{(2\delta + g(\pi))\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta}} - \beta$$
$$= \frac{\beta h(\pi)}{(2\delta + g(\pi))\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta}}$$

with

$$h(\pi) := 2\delta - 2\delta\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta} - g(\pi)\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta} = 2\delta - 2\delta\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta} - (\beta\pi - 1)\sqrt{(\beta\pi - 1)^2 + 4\beta\pi\delta} - (\beta\pi - 1)^2 - 4\beta\pi\delta$$

Since $\beta, \delta > 0, g(\pi) \ge 0$, we complete our proof by showing that

$$h(\pi) \le 2\delta - 2\delta(1 - \beta\pi) - (\beta\pi - 1)^2 - (\beta\pi - 1)^2 - 4\beta\pi\delta$$

= $-2(\beta\pi - 1)^2 - 2\beta\pi\delta < 0,$

where the first inequality follows from that $\sqrt{(\beta \pi - 1)^2 + 4\beta \pi \delta} \ge 1 - \beta \pi$.

4.4.2 Proof of Theorem 3.3

First, we assume $0 < \pi < 1$. By simple calculations, $R_D^{(ind)} = 1$ is equivalent to

$$\pi f(\pi)R_0(1-\pi) = (1-\pi) - (1-\pi)^2 R_0$$

(by multiplying both sides in Equation (19) by $(1 - \pi + \pi f(\pi))$). As a consequence,

$$f(\pi) = \frac{1 - R_0(1 - \pi)}{\pi R_0}.$$
(20)

On the other hand, it follows from Equation (6) that $R_D = 1$ is equivalent to $(D_{1}(1-1))^{2}$

$$\frac{(R_0(1-\pi))^2}{4} - R_0(1-\pi) + 1 = \frac{(R_0(1-\pi))^2}{4} + f(\pi)R_0\pi$$

which implies that

$$f(\pi) = \frac{1 - R_0(1 - \pi)}{\pi R_0}.$$
(21)

Hence, we have showed that $R_D^{(ind)} = 1$ is equivalent to $R_D = 1$. Identical arguments can be used to show that $R_D^{(ind)} < 1$ is equivalent to $R_D < 1$ as well as the opposite inequality.

In addition, when $\pi = 0$, it can be easily shown that $R_D^{(ind)} = R_D = R_0$. If $\pi = 1$, i.e., everyone is an app-user, there is one app-using component that will eventually die out, implying that $R_D^{(ind)}$ will be below 1 (sub-critical). And using Equation (6) gives $R_D = 0$. So both R_D and $R_D^{(ind)}$ are below 1 when $\pi = 1$.

Remark 4.3. Similar to the situation for the individual component reproduction for manual contact tracing ([27]), this individual reproduction number $R_D^{(ind)}$ does not possess the traditional interpretation of the basic reproduction number: the average number of infections caused by infected people at the beginning of the outbreak. This is due to the delicate timing of event issues in an exponentially growing situation, closely related to those explained in [4]. More specifically, when we derive the component reproduction number (upon which the individual reproduction number is based), we consider how many new components a component infects, but we do not keep track of when in time individuals of components get infected. For instance, rootindividuals of components might on average infect more new individuals than other individuals in the component since they are not traced by their infector, and root individuals are infected earlier than other individuals in the component. So, in the beginning of an epidemic that grows exponentially, these root-individuals are over-represented when computing the mean number of infections among those infected early in the epidemic. However, our individual reproduction number $R_D^{(ind)}$ still possesses the important threshold property as shown in Theorem 3.3.

5 Approximation of the initial phase in a large community for the combined model

We now analyse the early stage of the epidemic with both manual and digital contact tracing. First, we define the limit process $E_{DM}(\beta, \gamma, \delta, p, \pi)$ as follows. In the process, individuals are either app-users or non-app-users. There is one initial ancestor who has the same type of the initial case in $E_{DM}^{(n)}(\beta,\gamma,\delta,p,\pi)$. During the lifetime, each individual gives birth to appusers with manual tracing link at rate $\beta \pi p$, and without link at rate $\beta \pi (1-p)$, and to non-app-users with manual tracing link at rate $\beta(1-\pi)p$, and without link at rate $\beta(1-\pi)(1-p)$. Individuals recover naturally at rate γ and are diagnosed at rate δ . Once diagnosed, each of its descendants and parent with manual tracing link are diagnosed immediately, and so on. If such a diagnosed individual is an app-user, all of its app-using descendants as well as its parent (in case of an app-user), will also be diagnosed at the same time, and so on. Please note that tracing is also iterated for traced individuals who have recovered naturally upon diagnosis, so their parents and descendants are diagnosed according to the same rule. We first prove Proposition 3.2, which is similar to the proof of Proposition 3.1.

5.1 Proof of Proposition 3.2

First, we note that the only difference between the *n*-epidemic $E_{DM}^{(n)}(\beta, \gamma, \delta, p, \pi)$ and the limit process $E_{DM}(\beta, \gamma, \delta, p, \pi)$ is that the rate of new infections in the epidemic is deflated by the factor S(t)/n since infectious contacts only result in infection if the contacted person is still susceptible. Using standard coupling arguments as described in the proof of Proposition 3.1, it can be shown that the time T_n of the first contact with an already infected person converges to ∞ in probability as $n \to \infty$, and prior to this the epidemic and the limiting process agree completely. Consequently, the *n*-epidemic converges in distribution to $E_{DM}(\beta, \gamma, \delta, p, \pi)$ on any finite time interval.

Following a similar idea as in the proof of Theorem 4.1 in Section 4.1, we describe this limit process $E_{DM}(\beta, \gamma, \delta, p, \pi)$ in terms of to-be-traced components. For the combined model, the app-users could not only be traced by app-users, but also by non-app-users with probability p. Further, non-app-users could be traced by individuals (either app-users or non-app-users)

with probability p. Accordingly, to-be-traced components also contain infections between app-users and non-app-users and pairs of app-users, who will be traced manually. Moreover, new components are created if an appuser infects a non-app-user without manual contact tracing taking place or if a non-app user infects either type and there is no manual contact tracing. The new components hence differ only in how they are created: with an app-user (infected by a non-app-user without manual contact tracing) or a non-app-user (without manual contact tracing), and given the current state, the evolvement of such components does not depend on how they were initiated and is hence the same for both types of components. There will be no contact tracing between any of these components, which thus makes them evolve independently, as stipulated for branching processes. Here, we give an example in Figure 5.1 to illustrate how the two types of components (starting with an app-user or a non-app-user) grow and reproduce. We start with case 1, which is the root of the component $C_1^{(NA)}$, which generates two new components $C_2^{(NA)}$ and $C_3^{(A)}$. The component $C_2^{(NA)}$ is with root 2 as a non-app-user and $C_3^{(A)}$ starts with an app-user 3. Once individual 1 is diagnosed, the whole component $C_1^{(NA)}$ is diagnosed.

Figure 5.1 Example of the process of to-be-traced components started by appusers and non-app-users for the combined model: the circles are app-users and squares non-app-users. The nodes in white, black, and grey are "infectious", "diagnosed" and "naturally recovered", respectively. The rectangular region surrounded by the dashed line is for the component, whereas the whole rectangle is dashed when the component is diagnosed. Solid edges stand for contacts that could be traced either by manual or digital contact tracing (so always full edges between each pair of app-users), whereas dashed edges are infectious contacts that will not be traced.

5.2 Proof of Corollary 3.2

We see that the combined model can be approximated by a suitable twotype branching process during the early stage of the epidemic, where type-1 "individuals" are to-be-traced components starting with an app-user and type-2 are with a non-app-user as root. Let $M^{(c)}$ be the corresponding mean offspring matrix

$$M^{(c)} = \begin{pmatrix} m_{11}^{(c)} & m_{12}^{(c)} \\ & & \\ m_{21}^{(c)} & m_{22}^{(c)} \end{pmatrix}, \qquad (22)$$

where element $m_{ij}^{(c)}$, is the mean number of new components of type j produced by a single component of type i, for i, j = 1, 2. Let R_{DM} be the largest eigenvalue of $M^{(c)}$, then

$$R_{DM} = \frac{m_{11}^{(c)} + m_{22}^{(c)}}{2} + \sqrt{\frac{(m_{11}^{(c)} + m_{22}^{(c)})^2}{4} - m_{11}^{(c)}m_{22}^{(c)} + m_{12}^{(c)}m_{21}^{(c)}}.$$
 (23)

Similar to the digital reproduction number R_D , R_{DM} determines whether a major outbreak is possible or not. We refer R_{DM} to the effective component reproduction number for the combined model.

As shown in the proof of Corollary 3.1, it follows by the standard multitype branching process theory [2,8] that the limit process E_{DM} will surely go extinct if $R_{DM} \leq 1$. If $R_{DM} > 1$, the process will grow beyond all limits with non-zero probability. Then, by Proposition 3.2, it can be shown that if $R_{DM} > 1$, there will be a large outbreak of the epidemic with non-zero probability, whereas if $R_{DM} \leq 1$, there will be a minor outbreak for sure.

In the following text, we derive the elements $m_{ij}^{(c)}$. We first note that the to-be-traced components may also contain non-app-users that are manually traced. So, it is necessary to track both the number of infectious app-users and infectious non-app-users in the component. Let $N_j^{(i)}(t)$ be the number of infectious type-j individuals in the component starting with one type-i individual at time t (i, j = 1, 2), where we set type-1 to be app-users and type-2 to be non-app-users. When the components are born (t = 0), we have $N^{(1)}(0) = (1, 0)$, whereas $N^{(2)}(0) = (0, 1)$. Suppose that at time t there are k infectious app-users and l infectious non-app-users in a component starting with a type-i individual, denoted by

$$N^{(i)}(t) := (N_1^{(i)}(t), N_2^{(i)}(t)) = (k, l).$$

There are 5 different competing events that can occur: an app-user is newly infected by an app-user or with a manual tracing link by a non-app-user $(N^{(i)}(t) + (1,0))$, one of the k app-users recovers naturally $(N^{(i)}(t) - (1,0))$, a non-app-user is newly infected with a manual tracing link irrespective of the type of the infector $(N^{(i)}(t) + (0,1))$, one of the *l* non-app-users recovers naturally $(N^{(i)}(t) - (0,1))$, or one of the (k + l) infectious individuals (of either type) is diagnosed, so the whole component is diagnosed (drops to (0,0)). The corresponding transition rates are given by

$$N^{(i)}(t^{-}) \rightarrow \begin{cases} N^{(i)}(t) + (1,0) & \text{at rate } k\beta\pi + l\beta\pip \\ N^{(i)}(t) + (-1,0) & \text{at rate } k\gamma \\ N^{(i)}(t) + (0,1) & \text{at rate } (k+l)\beta(1-\pi)p \\ N^{(i)}(t) + (0,-1) & \text{at rate } l\gamma \\ (0,0) & \text{at rate } (k+l)\delta. \end{cases}$$

Next, we describe the birth of new components. We note that only infections with no digital or manual contact tracing links create a new component. This can only occur to pairs of non-app-users or pairs of app-users and nonapp-users, but it never happens between two app-users. As a consequence, given that $N^{(i)}(t) = (k,l)$ (k infectious app-users and l infectious non-appusers), the component gives birth to new components with an app-user as root at rate $l\beta\pi(1-p)$, and new components with a non-app-user as root at rate $(k+l)\beta(1-\pi)(1-p)$. Based on the previous discussion, we have derived the birth rates of new components of type *i* conditional on $N^{(i)}(t)$. The expected total numbers $m_{ij}^{(c)}$ of new type-*j* components produced by a type-*i* component are hence the expected values of these expressions integrated over time:

$$m_{11}^{(c)} = \int_0^\infty \mathbb{E}[N_2^{(1)}(t)]\beta\pi(1-p)dt,$$
(24)

$$m_{12}^{(c)} = \int_0^\infty (\mathbb{E}[N_1^{(1)}(t)] + \mathbb{E}[N_2^{(1)}(t)])\beta(1-\pi)(1-p)dt,$$
(25)

$$m_{21}^{(c)} = \int_0^\infty \mathbb{E}[N_2^{(2)}(t)] \beta \pi (1-p) dt, \qquad (26)$$

$$m_{22}^{(c)} = \int_0^\infty (\mathbb{E}[N_1^{(2)}(t)] + \mathbb{E}[N_2^{(2)}(t)])\beta(1-\pi)(1-p)dt.$$
(27)

We have not been able to derive $\mathbb{E}[N_j^{(i)}(t)]$ analytically. The main reason is that not all the four jump rates are linear in the number of infectious individuals. In particular, the rate at which $N^{(i)} = (k, l)$ increases in the first component equals $k\beta\pi + l\beta\pi p$ (non-linear in k + l).

In Section 6, we perform simulations to derive the m_{ij} and numerically compute the component reproduction number R_{DM} for given parameters. Based on the numerical results, we analyze how R_{DM} depends on the manual tracing probability p and the app-using fraction π .

6 Numerical Illustration

In this section, we numerically illustrate the effects of digital contact tracing, as well as the combined effect of both types of contact tracing. For all the numerical results below (except Table 6.1), we set the epidemic parameters to be fixed: $\beta = 6/7, \gamma = 1/7$ so that the reproduction number without any testing or contact tracing is $\beta/\gamma = 6$. When also considering diagnosis ($\delta > 0$), we would have the basic reproduction number $R_0 = \beta/(\gamma + \delta)$ smaller than 6. The code used for this section is openly-available in https://github.com/dongnizhang/Epidemic-models-withdigital-and-manual-contact-tracing.

6.1 Comparison of digital and manual tracing only

In Figure 6.1a, we plot the necessary testing rate (measured by testing level $(\delta/(\delta + \gamma))$ for which the manual $R_M^{(c)}$ (Equation (7)) equals 1 and digital component reproduction number R_D (Equation (6)) equals 1, for a given value of p and π respectively. The figure confirms Theorem 3.1 that that for a given testing level $\delta/(\delta + \gamma)$, a larger app-using fraction π is required compared to the tracing probability p for the model with manual contact tracing.

One potential explanation for this could be that the effectiveness of digital contact tracing is more related to the square of the fraction of app-users (π^2) : the digital tracing is carried out only if both the confirmed case and the contact are app-users. In Figure 6.1b, we therefore plot the critical combination of $\delta/(\delta + \gamma)$ against π^2 instead. It can be seen that the curve for π^2 is closer to the one for p but still different: we still need a larger value on π^2 for the reproduction number to equal unity.

6.2 The individual and component reproduction numbers for digital tracing only

In Figure 6.2a and 6.2b, we plot how the digital reproduction number R_D and individual reproduction number $R_D^{(ind)}$ vary with the testing fraction $\delta/(\delta+\gamma)$ and the fraction of app-users π . By looking at the colors at the bottom or the dashed curves at $R_D = 6, 8$, and 10 in Figure 6.2a, we note that the component reproduction number R_D is not monotonically decreasing in π . This is at first surprising since we expect a smaller reproduction the more app-users there are.

This non-monotonicity of R_D is explained as follows. First of all, it can be easily seen from Equation (3) and (4) that the element m_{21} is increasing

Figure 6.1 Plot a). The red curve shows which combinations of the testing fraction $\delta/(\delta + \gamma)$ and fraction π of app-users for which $R_D = 1$ for digital contact tracing, and the blue curve which combinations of testing fraction $\delta/(\delta + \gamma)$ and tracing probability p for which $R_M = 1$ in the manual contact tracing. Plot b) shows the same curves, but now having π^2 on the x-axis (motivated by both individuals having to be app-users for digital tracing to take place).

and m_{22} is decreasing with π . Then, at a very low level of testing fraction, increasing π leads to more app-users, and thus the *size* of the app-using component will grow even if fewer non-app-users will be infected *per* app-user. The average number of non-app-users infected by one app-using component m_{12} may hence increase with π . Then according to the expression of R_D (see Equation (6)), R_D could increase with π when the testing fraction $\delta/(\delta + \gamma)$ is low. On the other hand, we see from Figure 6.2b that the individual reproduction number $R_D^{(ind)}$ is monotonically decreasing in π as was proven in Theorem 3.2.

In Figure 6.3 we illustrate Theorem 3.3 statisting that the two reproduction numbers R_D and $R_D^{(ind)}$ have the same threshold at 1. As before, we fix $\beta = 6/7$, $\gamma = \delta = 1/7$ such that $R_0 = 3$ and half of the infected are diagnosed (and subject to being contact traced). The two reproduction numbers are plotted as a function π , the fraction of app-users. In the figure it is seen that the reproduction numbers are different, but that they both attain the value 1 for the same critical fraction of app-users $\pi_c \approx 94\%$.

Figure 6.2 Heatmaps of the effective reproduction numbers for digital tracing: 6.2a for R_D and 6.2b for $R_D^{(ind)}$ varies with testing fraction $\delta/(\delta + \gamma)$ in [0.01, 5/6] and fraction of app-users π in [0.01, 0.99]; $\beta = 6/7, \gamma = 1/7$ fixed. The white solid lines indicate where the corresponding reproduction number equals 1, the black dashed lines in 6.2a are for $R_D = 1, 2, 4, 6, 8, 10$ from up to down and in 6.2b for the cases when $R_D^{(ind)}$ equals 3, 2.5, 2, 1.5, respectively from left to right.

Figure 6.3 Plot of two curves of $R_D^{(ind)}$ (in red) and R_D (in blue) against π with $\beta = 6/7, \gamma = 1/7$ and $\delta = 1/7$ fixed. The horizontal dashed line stands for when the reproduction number equals 1, and the vertical dashed line for the critical $\pi_c \approx 0.94$.

6.3 Effect of combining digital and manual tracing

We now illustrate the effect of the combined model by computing R_{DM} numerically as follows. For $\beta = 6/7$, $\gamma = 1/7$ and two distinct values for δ : 1/7and 1/28, and a grid of values for π (the fraction of app-users) and p (the fraction of contacts that are traced manually), we perform 10000 simulations to compute the integrals in Equation (24)-(27) for each simulation (without expectation). We then take averages over the simulations to obtain estimates of the four elements $m_{ij}^{(c)}$, and compute the largest eigenvalue to obtain estimates of R_{DM} using Equation (23). In Figure 6.4a and 6.4b, we show the heatmaps of R_{DM} as a function of p and π for the two choices of δ . We see from the left figure that R_{DM} seems monotonically decreasing in both π and p as expected when $\delta = 1/7$ (as one would expect), but this fails when δ is smaller as seen in the right figure. This can be explained in a similar way as for R_D . For example, suppose π and δ are both small, then the size of a component (either starting with an app-user or non-app-user) may increase with p since more infections happen within a component. As a consequence, such a component may, in fact, infect slightly more new components, thus resulting in a larger reproduction number. However, on the individual scale, a much larger component infecting slightly more new components would still imply that each individual will infect fewer new individuals. Here, it might be possible to derive an individual reproduction number, $R_{DM}^{(ind)}$, which one would expect decreases monotonically in both π and p, but we have not pursued this wrote, partly because the expression for the component reproduction number R_{DM} is complicated in itself. But if we focus on the curve $R_{DM} = 1$ in Figure 6.4b, this curve seems to be monotone, suggesting that decreasing one of the contact tracing procedures requires the other to be increased in order to maintain herd immunity. A proof of this is missing.

All results above are for the limiting processes E_D and E_{DM} respectively. To see how the results fit the finite *n* case, we perform 10000 simulations of the epidemic for n = 5000, starting with one initial infective. We choose the parameters in four different cases: without any contact tracing $(p = \pi = 0)$; with digital tracing only $(p = 0, \pi = 2/3)$; with manual tracing only: $(p = 2/3, \pi = 0)$ and with both manual and digital tracing $(p = \pi = 2/3)$, while keeping $\beta = 0.8, \gamma = 1/7, \delta = 1/7$ fixed. It can be seen from Table 6.1 that the fraction of major outbreaks (defined by having more than 10% infected) is distinct away from 0 when the reproduction number exceeds 1 and is very close to 0 when the reproduction is smaller than 1 (thus supporting Corollary 3.1 and 3.2).

Figure 6.4 Heatmaps of the effective reproduction number R_{DM} varying with manual tracing probability p in [0,0.99) and fraction of app-users π in [0,0.99); with $\beta = 6/7$, $\gamma = 1/7$ fixed, 6.4a for $\delta = 1/7$ and 6.4b for smaller $\delta = 1/28$. The white solid lines indicate where $R_{DM} = 1$, the black dashed lines in 6.4a are for the cases when R_{DM} equals 2.5, 2, 1.5, respectively from left to right, and in 6.4b for $R_{DM} = 8, 6, 4, 2$.

Table 6.1 Simulation results in four different cases of p and π

p	π	the reproduction number	fraction of major outbreaks	mean fraction of infected among major outbreaks
0	0	$R_0 = 2.80$	0.64	0.93
0	2/3	$R_D = 2.20$	0.49	0.81
2/3	0	$R_M = 1.49$	0.46	0.75
2/3	2/3	$R_{DM} = 0.92$	0.01	0.14

7 Discussion

In this paper, we analyzed a Markovian epidemic model with digital contact tracing, without or with manual contact tracing. For the epidemic model with digital tracing only, the early stage of the epidemic was proven to converge to a two-type branching process (as the population size $n \to \infty$) with one type being to-be-traced app-using components and the other being non-app-users, and R_D being the largest eigenvalue of the of mean offspring matrix of the two-type branching process. An individual reproduction number $R_D^{(ind)}$ was also derived. It was investigated both analytically and numerically how R_D and $R_D^{(ind)}$ depended on model parameters as well as with each other.

Surprisingly, R_D was shown not monotone in π (the fraction of app-users) in general, whereas the individual reproduction number $R_D^{(ind)}$ was proven to be monotonically decreasing in π . When comparing digital tracing with manual tracing, it was proven that a smaller tracing probability p is needed than the corresponding app-using fraction π in order to lower the reproduction number down to 1.

We then analyzed the combined model and proved that the beginning of the epidemic converges to a different two-type branching process, with both types being to-be-traced components and only differing on the type of the root (app-user or non-app-user). The corresponding reproduction number had a rather complicated expression, which currently can only be evaluated numerically, and it was shown numerically not to be monotonically decreasing in π and p in general.

There are several extensions of the present model that would make it more realistic. On the one hand, we assume that there is no delay in both manual and digital contact tracing, i.e., any traced contact (either by manual or digital tracing) is assumed to be immediately diagnosed. This neglects a crucial difference between manual and digital tracing: manual tracing is timeand labor-intensive, so there is often a delay between the case confirmation and notification of contacts, whereas digital tracing is designed to avoid (or shorten) this delay. Additionally, a limitation of a contact tracing app is that there could be close contacts that can lead to transmission but are too short to be registered by the app. For this reason, it would be of interest to extend our model to allow for infectious contacts between app-users that are not registered with a certain (small) probability and thus not leading to tracing. It is however not straightforward to analyse such an extended model since it somehow mixes aspects of both digital (requiring both to be appusers) and manual (the possibility that such an app-contact is not recorded) contact tracing. Further, we make the simplifying assumption that traced individuals who have by then recovered are also identified and contact traced (see [20] which does not make this assumption). In reality, this may happen for individuals who have recently recovered, but perhaps not for those who have recovered several weeks earlier. Therefore, our results in this paper give an upper bound on how effective the real contact tracing would be.

A different extension would be to consider a structured community (e.g., a social network) combined with homogeneous random contacts. Then, digital contact tracing would work in the same way for random contacts and contacts in the social network (as long as both are app-users), whereas manual contact tracing would most likely only happen on the social network (very rarely could you e.g., name whom you sat next to in the bus).

On the mathematical side, we only focus on the early stage of the epidemic in this paper. Analysing later parts of the epidemic remains open. Moreover, obtaining a more explicit expression for R_{DM} in the combined model could shed more light on the effect of combining digital and manual contact tracing. For instance, it was shown numerically not to be monotone in π and p, but one would expect the critical curve $R_{DM} = 1$ to be monotone in the (π, p) plane (cf. Figure 6.4a and 6.4b), but a proof of this missing. Further, it would be of interest to derive an individual reproduction number $R_{DM}^{(ind)}$ and prove properties for this reproduction number, e.g. that it has the same threshold as R_{DM} and that it decreases monotonically in both π and p.

Despite these model limitations, we consider our contribution an important step in increasing understanding of the effect of different contact tracing forms on spreading disease.

Acknowledgments

T.B. is grateful to the Swedish Research Council (grant 2020-04744) for financial support. We thank Frank Ball for his idea to derive a simplified expression of component reproduction number $R_M^{(c)}$ for manual tracing in [27], which also made it possible to simplify the reproduction number R_D in the current paper.
