Abstract

The emergence of exotic quantum phenomena in frustrated magnets is rapidly driving the development of quantum many-body physics, raising fundamental questions on the nature of quantum phase transitions. Here we unveil the behaviour of emergent symmetry involving two extraordinarily representative phenomena, i.e., the deconfined quantum critical point (DQCP) and the quantum spin liquid (QSL) state. Via large-scale tensor network simulations, we study a spatially anisotropic spin-1/2 square-lattice frustrated antiferromagnetic (AFM) model, namely the J_{1x} - J_{1y} - J_2 model, which contains anisotropic nearest-neighbor couplings J_{1x} , J_{1y} and the next nearest neighbor coupling J_2 . For small J_{1y}/J_{1x} , by tuning J_2 , a direct continuous transition between the AFM and valence bond solid phase is observed.(Of course, the possibility of weakly first order transition can not be fully excluded.) With growing J_{1y}/J_{1x} , a gapless QSL phase gradually emerges between the AFM and VBS
phases. We observe an emergent $O(4)$ symmetry along the AFM-VBS transition line, which is consistent with phases. We observe an emergent O(4) symmetry along the AFM–VBS transition line, which is consistent with the prediction of DQCP theory. Most surprisingly, we find that such an emergent O(4) symmetry holds for the whole QSL–VBS transition line as well. These findings reveal the intrinsic relationship between the QSL and DQCP from categorical symmetry point of view, and strongly constrain the quantum field theory description of the QSL phase. The phase diagram and critical exponents presented in this paper are of direct relevance to future experiments on frustrated magnets and cold atom systems.

Introduction

The concept of deconfined quantum critical point (DQCP) was proposed two decades ago to describe Landau forbidden continuous phase transitions between two ordered phases, such as the transition between the antiferromagnetic (AFM) and valence bond solid (VBS) phases [\[1,](#page-12-0) [2\]](#page-12-1). Since then, the DQCP has been investigated in a number of numerical studies on various spin, fermion, and classical loop models [\[3](#page-12-2)[–24\]](#page-12-3). One of the most remarkable discoveries is the appearance of enhanced symmetry [\[7,](#page-12-4) [17\]](#page-12-5), which is essential for understanding the underlying physics. However, in various DQCPrelated studies, unusual scaling violation has been observed and the expected continuous nature of the transition has been challenged by the possibility of weakly first-order transition. Such perplexing phenomena raise a puzzle regarding the nature of the DQCP.

In a recent breakthrough, the intrinsic relationship between the DQCP and gapless quantum spin liquid (QSL) was revealed that a gapless QSL phase can develop from a DQCP [\[24\]](#page-12-3). This demonstrates a new perspective to understand both DQCP and QSL, implying that they could be described by a unified quantum field theory. However, as the DQCP physics highly depends on microscopic symmetry such as spin and lattice symmetry [\[7,](#page-12-4) [17,](#page-12-5) [25–](#page-12-6)[32\]](#page-12-7), it is an open question whether this is a generic relation for systems with different symmetries. In particular, the behavior of emergent symmetry is a critical concern and a fundamental aspect in developing a quantum field theory description.

On the other hand, the categorical symmetry framework and holographic principle suggest that emergent symmetry may exist for generic quantum phase transitions beyond the Landau paradigm [\[33\]](#page-12-8). While some examples have been explored for one-dimensional systems [\[34\]](#page-12-9), it is still uncertain which types of quantum phase transitions in higher dimensions support emergent symmetry. Specifically, it is unknown whether the quantum phase transition into a gapless QSL also exhibits emergent symmetry or not.

Here we present an invaluable scenario that significantly enhances our understanding of both DQCP and QSL with C_2 lattice systems. Starting with the DQCP-type AFM-VBS transition, by tuning the coupling constants, a gapless QSL phase emerges in between the AFM and VBS phases. Most surprisingly, we observe that the emergent symmetry arises not only at the DQCP but also persists at the phase boundary of the QSL-VBS transition. Since the quantum phase transition at the phase boundary of a gapless QSL is unlikely to be first order, we believe that the corresponding emergent $O(4)$ symmetry should survive even in the thermodynamic limit. These findings shed new light on the intrinsic relation between DQCP and gapless QSL from the categorical symmetry perspective.

Results

Model.

We focus on the rectangular spin-1/2 model, the frustrated J_{1x} - J_{1y} - J_2 model [\[35,](#page-12-10) [36\]](#page-12-11), which contains anisotropic nearest-

Figure 1. Ground-state phase diagram of the $J_{1x} - J_{1y} - J_2$ model, including four phases: the AFM, VBS, and gapless QSL (red region) phases, and a stripe phase. The dashed blue lines denote the hypothetical shape of the VBS phase close to the origin. Solid blue lines in the middle region denote the unknown QSL shape close to the tricritical point (filled blue circle). Open blue circles have emergent O(4) symmetry.

neighbor AFM Heisenberg couplings $J_{1x} > 0$, $J_{1y} > 0$ and the next nearest neighbor AFM Heisenberg coupling $J_2 > 0$, with the Hamiltonian:

$$
H = J_{1x} \sum_{\langle i,j \rangle_x} \mathbf{S}_i \cdot \mathbf{S}_j + J_{1y} \sum_{\langle i,j \rangle_y} \mathbf{S}_i \cdot \mathbf{S}_j + J_2 \sum_{\langle \langle i,j \rangle \rangle} \mathbf{S}_i \cdot \mathbf{S}_j. \tag{1}
$$

This model was introduced to study the interplay between quantum frustration and spinon excitations [\[35\]](#page-12-10). The strong frustration present in this model makes it challenging to simulate accurately, and thus its global phase diagram remains elusive, despite previous studies [\[36–](#page-12-11)[38\]](#page-12-12).

Recently, the advancement in tensor network methods, specifically the finite projected entangled pair state algorithm [\[39,](#page-13-0) [40\]](#page-13-1), has provided a powerful tool for investigating frustrated models with high accuracy $[23, 24]$ $[23, 24]$ $[23, 24]$ By applying such a state-of-the-art method, we elaborately investigated this model through performing large-scale computations. The global phase diagram is shown in Fig. [1.](#page-1-0) In the small *J*1*^y* region, we observe a direct AFM–VBS transition with an emergent O(4) symmetry, formed by three-component AFM order parameters and the one-component VBS order parameter. In the larger J_{1y} region, we observe a gapless quantum spin liquid (QSL) phase between the AFM and VBS phases. Surprisingly, the emergent O(4) symmetry persistently exists on the QSL–VBS transition line.

Continuous AFM-to-VBS transition. We set $J_{1x} = 1$ throughout the paper and sweep J_2 with fixed J_{1y} to obtain the phase diagram. We first consider the large anisotropy region, where we find that a direct AFM–VBS transition can occur up to $J_{1y} = 0.55$ but probably vanishes at $J_{1y} \approx 0.6$. The AFM

order parameter $\langle M_0^2 \rangle$ is defined as the spin order parameter $m^2(\mathbf{k}) = \frac{1}{L^4} \sum_{i,j} \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle e^{i\mathbf{k} \cdot (\mathbf{i} - \mathbf{j})}$ at $\mathbf{k} = (\pi, \pi)$, where $\mathbf{i} = (i_x, i_y)$
is the site position. Taking $L = 0.4$ as an example, we show is the site position. Taking $J_{1y} = 0.4$ as an example, we show the AFM order parameter on different $L \times L$ systems up to 20×20 in Fig. [2\(](#page-1-1)a). The finite size scaling of the system suggests that the AFM order vanishes at $J_{c1} = J_2 \approx 0.17$ in the two-dimensional (2D) limit. We also use the crossing of the dimensionless quantity ξ_m/L to determine the transition point, where ξ_m is the spin correlation length defined as ξ_m = $rac{L}{2π}$ $\sqrt{\frac{m^2(\pi,\pi)}{m^2(\pi+2\pi/L,\pi)}} - 1$ [\[23\]](#page-12-13). This gives rise to a consistent *J*_{*c*1}, as shown in the inset of Fig. [2\(](#page-1-1)a).

The dimer order parameter $D_{\alpha} = \frac{1}{N_b} \sum_i (-1)^{i_{\alpha}} B_i^{\alpha}$ is used to detect possible VBS patterns, where $B_1^{\alpha} = S_i \cdot S_{i+\epsilon_{\alpha}}$ is the bond operator between nearest sites **i** and **i** + \mathbf{e}_{α} with $\alpha = x$ or *y*, and $N_b = L(L-1)$ is the total number of counted bonds along the α direction for open-boundary systems. Fig. [2\(](#page-1-1)b) presents the horizontal VBS order parameter $\langle D_x^2 \rangle$ with the largest system size up to a 20×20 matrix at fixed $J_{1v} = 0.4$. It is seen that the extrapolated value of $\langle D_x^2 \rangle$ for the 2D limit is zero at $J_2 = 0.16$ but nonzero at $J_2 = 0.18$. Note that the *y*-direction VBS order parameter $\langle D_y^2 \rangle$ is very small for finite sizes and clearly extrapolates to zero in the 2D limit. The results indicate that the VBS order sets in at $J_{c2} = J_2 \simeq$ 0.17, and there is thus a direct AFM–VBS transition at J_c = $J_{c1} = J_{c2}$. We later confirm such an AFM–VBS transition through other means. The order parameters for each system size have a smooth change with J_2 , as presented in the inset of Fig. [2\(](#page-1-1)b), and the AFM–VBS transition is thus likely to be continuous, although the possibility of a weakly first-order transition cannot be fully excluded.

Figure 2. (a) Finite size scaling of the AFM order parameter (main panel) and crossing of ξ_m/L (inset) at $J_{1y} = 0.4$. (b) Finite size scaling of the VBS order parameter (main panel) and J_2 -dependence of VBS order parameters at $J_{1y} = 0.4$. (c) Finite size scaling of the AFM order parameter (main panel) and crossing of ξ_m/L (inset) at J_{1y} = 0.85. (d) Finite size scaling of VBS order parameters including $\langle D_x^2 \rangle$
and boundary-induced dimerization $\langle D_x \rangle^2$ at $L = 0.85$. Secondand boundary-induced dimerization $\langle D_x \rangle^2$ at $J_{1y} = 0.85$. Second-
order polynomial fits are used for all extrapolations order polynomial fits are used for all extrapolations.

Emergence of the QSL phase. For $J_{1y} \geq 0.6$, we do not find a direct transition between the AFM and VBS phases, and instead, a QSL phase develops in between. Taking J_{1y} = ⁰.85 as an example, we present the AFM order parameter in Fig. [2\(](#page-1-1)c). The finite-size scaling of the AFM order parameter at different J_2 suggests that the AFM order begins to vanish at $J_{c1} = J_2 \approx 0.35$ in the 2D limit, which is further supported by the crossing of ξ_m/L . The horizontal dimer order parameter $\langle D_x^2 \rangle$ in the 2D limit develops above $J_2 \approx 0.4$, as seen in Fig. 2(d) We also examine the dimerization $\langle D \rangle^2$ induced Fig. [2\(](#page-1-1)d). We also examine the dimerization $\langle D_x \rangle^2$ induced by open boundaries as a further check. As shown in the inset of Fig. [2\(](#page-1-1)d), the extrapolated values at $J_2 = 0.4$ are zero whereas those at $J_2 = 0.41$ are 0.0012(7) for $\langle D_x^2 \rangle$ and 0.0018(3) for $\langle D_x \rangle$ ². The results consistently suggest the onset 0.0018(3) for $\langle D_x \rangle^2$. The results consistently suggest the onset of the VBS order at $J_{c2} \approx 0.405(5)$ and indicate a QSL phase for $0.35 \leq J_2 \leq 0.4$ by excluding spin and dimer orders. The calculations for other J_{1y} up to $J_{1y} = 0.98$ are shown in the Supplemental Information. The global phase diagram is presented as Fig. [1](#page-1-0) and shows that a (gapless) QSL phase can develop from a DQCP.

Figure 3. Ratios of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ (a,b) and $\langle M_z^2 D_x^2 \rangle / \langle M_z^4 \rangle$ (c,d) for J_{1y} = 0.4 and J_{1y} = 0.85 for the verification of emergent symmetry. The crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ and $\langle M_z^2 D_x^2 \rangle / \langle M_2^4 \rangle$
are approximately 0.171 and 0.176 for $L = 0.4$ and 0.402 and 0.407 are approximately 0.171 and 0.176 for *^J*1*^y* ⁼ ⁰.4 and 0.402 and 0.⁴⁰⁷ for $J_{1y} = 0.85$, respectively.

Emergent O(4) symmetry. For the rectangular anisotropy case that we consider here, it has been argued that O(4) symmetry emerges at the AFM–VBS transition point [\[41\]](#page-13-2) through the rotation of the three-component AFM vector $M =$ (M_x, M_y, M_z) and one-component VBS order parameter D_x into each other to form a superspin: $\mathbf{n} = (M_x, M_y, M_z, D_x)$.
According to Refs. [7, 17, 31] if $O(A)$ symmetry emerges. According to Refs. [\[7,](#page-12-4) [17,](#page-12-5) [31\]](#page-12-14), if O(4) symmetry emerges, the moments of the order parameter should satisfy certain relations. Once the SO(3) symmetry acting on the AFM vector $M = (M_x, M_y, M_z)$ is satisfied, it is sufficient to demonstrate the fully emergent O(4) symmetry by verifying an additional

emergent symmetry rotating M_z into D_x . In our calculation, we confirm the good SO(3) symmetry of the ground state around the transition point and inside the nonmagnetic phases, where each spin component is given as $\langle M_{\alpha}^2 \rangle = \frac{1}{3} \langle M_0^2 \rangle$ with $\langle M_0^2 \rangle$ being the AFM order parameter.

Once SO(3) symmetry is satisfied, we only need to check the additional symmetry formed by M_z and D_x . A simple but nontrivial quantity of the emergent O(4) symmetry is that at the transition point J_c , the ratio between the order parameters $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ should be independent of the system
size [7, 17, 31] In Fig. 3(a) for $L = 0.4$ we present the size [\[7,](#page-12-4) [17,](#page-12-5) [31\]](#page-12-14). In Fig. [3\(](#page-2-0)a) for $J_{1y} = 0.4$, we present the order parameter ratio for different system sizes at different J_2 , which give rise to almost the same crossing J_2 , with the phase transition point determined from the crossing of ξ_m/L and finite size scaling of order parameters. We also consider the higher-order moments of order parameters [\[7,](#page-12-4) [17,](#page-12-5) [31\]](#page-12-14), which are challenging to compute. Within our capability, we compute $\langle M_z^4 \rangle$ and $\langle M_z^2 D_x^2 \rangle$ to verify whether the crossing of the ratio $\langle M_z^2 D_x^2 \rangle / \langle M_z^4 \rangle$ is located at the transition point $I_z = 0.4$ the crossing I_z J_c . As shown in Fig. [3\(](#page-2-0)c) for $J_{1y} = 0.4$, the crossing J_2 value is indeed in good agreement with J_c determined in other ways. These results strongly support the emergence of O(4) symmetry at the AFM–VBS transition point. Results supporting the emergent O(4) symmetry at the AFM–VBS transition points for fixed $J_{1y} = 0.2$ and 0.55 can be found in the Supplemental Information.

We now move to the weak-anisotropy region where QSL appears. In this situation, in contrast with the AFM–VBS transition, we find that the crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$
in the 2D limit are different from those of ϵ / I . Within in the 2D limit are different from those of ξ*^m*/*L*. Within our resolution, for each J_{1y} , we find that the crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ are almost the same as the QSL–VBS
transition points obtained by the finite size scaling of VBS transition points obtained by the finite size scaling of VBS order parameters [Fig. [3\(](#page-2-0)b)]. These values are listed in Table [I](#page-3-0) for convenient comparison. Usually, the crossings of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ have much smaller finite effects, as has been
observed in other DOCP studies [7, 17]. The crossings of observed in other DQCP studies [\[7,](#page-12-4) [17\]](#page-12-5). The crossings of ξ_m/L are somewhat shifted for small systems but seem to almost converge at large system sizes up to 20×20 , and we adopt collective fitting to collapse the data in accounting for the finite-size effects (see more results in the Supplemental Information). The crossing J_2 values of ξ_m/L and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$
coincide well in the strong-anisotropy region (for example coincide well in the strong-anisotropy region (for example, $J_{1v} = 0.2, 0.4,$ and 0.55) but disagree in the weak-anisotropy region ($J_{1y} = 0.6, 0.65, 0.75, 0.85, 0.95,$ and 0.98), which is strong evidence that in between the AFM and VBS phases for $J_{1y} \geq 0.6$ there exists an intermediate phase, namely the QSL. More interestingly, the coincidence of crossings from $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ and QSL–VBS transition points indicates
the emergence of $O(4)$ symmetry on the OSL–VBS phase the emergence of O(4) symmetry on the QSL–VBS phase boundary. We compute the four order moments of the order parameter at $J_{1y} = 0.85$ [Fig. [3\(](#page-2-0)d)], which gives rise to almost the same crossing as that of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ and further supports
the emergent $O(4)$ symmetry the emergent O(4) symmetry.

Note that in the QSL phase, $\langle M_0^2 \rangle$ is zero in the thermodynamic limit, but for a finite size, the ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ is

Table I. Phase transition points for different quantities and a fixed J_{1y} . The second column gives the transition points J_{c1} for the AFM– VBS or AFM–QSL transition obtained by the collective fitting of ξ_m/L . The third column gives the estimated crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ for $L \to \infty$. The last column gives the estimated AFM–
VBS or OSI –VBS transition point from the finite size scaling (FSS) VBS or QSL–VBS transition point from the finite size scaling (FSS) of VBS order parameters.

J_{1y}	ξ_m/L	$\langle D_x^2\rangle/\langle M_0^2\rangle$	FSS (VBS)
0.20	0.070(2)	0.071(2)	0.07(1)
0.40	0.171(3)	0.171(2)	0.17(1)
0.55	0.253(2)	0.255(2)	0.25(1)
0.60	0.273(4)	0.283(1)	0.29(1)
0.65	0.285(2)	0.309(1)	0.31(1)
0.75	0.327(2)	0.360(1)	0.365(5)
0.85	0.352(5)	0.402(3)	0.405(5)
0.95	0.390(2)	0.453(2)	0.455(5)
0.98	0.410(5)	0.465(3)	0.47(1)

still meaningful. The QSL is gapless with a power-law decay for both dimer and spin correlation functions, and the ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ for finite system sizes thus reflects the relative decay rate $I^{-(\alpha_d - \alpha_s)}$ assuming $\langle D_1^2 \rangle \propto I^{-\alpha_d}$ and $\langle M_1^2 \rangle \propto \chi$ decay rate $L^{-(\alpha_d-\alpha_s)}$ assuming $\langle D_x^2 \rangle \propto L^{-\alpha_d}$ and $\langle M_0^2 \rangle \propto$ $L^{-\alpha_s}$. At the QSL–VBS transition point, the size-independent $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ indicates that spin and dimer correlations both decay algebraically with the same exponents, which will be decay algebraically with the same exponents, which will be verified in the next section. We note that the dominant spin correlation in the QSL phase is still AFM; i.e., the peak of the spin structure factor is at $\mathbf{k}_0 = (\pi, \pi)$. This explains why $\langle M_0^2 \rangle$
should be used instead of other **k**-value magnetic moments should be used instead of other k−value magnetic moments.

Critical exponents. We extract the critical exponents of the AFM–VBS, AFM–QSL and QSL–VBS transitions to further analyze these unconventional phase transitions (see the Supplemental Information for more details). Figure [4](#page-4-0) shows the data collapse of physical quantities including $\langle M_0^2 \rangle$, $\langle D_x^2 \rangle$, and ξ_m with fixed $J_{1y} = 0.4$ for the AFM–VBS transition and with fixed J_{1y} = 0.85 for the AFM–QSL and QSL– VBS transitions as examples. Generally, for the AFM–VBS transition, subleading corrections are needed for a good data collapse. (However, the case $J_{1y} = 0.4$ does not need such a correction.) For the AFM–QSL and QSL–VBS transitions, we find that subleading terms are always unnecessary.

The extracted critical exponents for different J_{1y} cases are summarized in Table [II.](#page-3-1) For the AFM–VBS transition, the critical exponents for $\langle M_0^2 \rangle$ and $\langle D_x^2 \rangle$ indicate that $z + \eta_s^* = z + n^* \approx 1.36$ For the AEM-OSI and OSI-VBS transitions the rd</sup> exponents are clearly different from those of the AFM–VBS *d* ∼ 1.36. For the AFM–QSL and QSL–VBS transitions, the arguments are clearly different from those of the AFM–VBS transition. Roughly speaking, $z + \eta_{s1}^* \sim 1.2$ and $z + \eta_{d1}^* \sim 1.8$
for the AEM–OSI transition and $z + n^* \sim 7 + n^* \approx 1.5$ for the for the AFM–QSL transition and $z + \eta_{s2}^* = z + \eta_{d2}^* \sim 1.5$ for the CSI –VBS transition. For $L_z = 0.6$ very close to the tricritical QSL–VBS transition. For $J_{1y} = 0.6$ very close to the tricritical point, the exponents are slightly different, which might be due to finite-size effects. We note that $z + \eta_s^* = z + \eta_d^*$ and $z + \eta_{s2}^* = z + n^*$ also consistent with the emergent $O(4)$ symmetry. The $z + \eta_{d2}^*$ also consistent with the emergent O(4) symmetry. The obtained critical exponents including $y \approx 1.0$ strongly support obtained critical exponents including $v \approx 1.0$ strongly support new universality classes for the AFM–QSL and QSL–VBS transitions, which are different from the class for the DQCP.

Table II. Critical exponents of the J_{1x} - J_{1y} - J_2 model at the AFM–QSL and QSL–VBS transition points or at the AFM–VBS transition using fixed J_{1y} . Errors in exponents are from fitting. Errors in the critical point J_c are estimated from crossing points of physical quantities or fitting correlation lengths. Values of ν for QSL-related transitions are averages of several values obtained from fitting physical quantities; see the Supplemental Information. Spin and dimer exponents $z + \eta^*$
are obtained through data collanse using the listed values of *y* and *I*

are obtained through data collapse using the listed values of ν and J_c .

$J_{1y} = 0.98$	QSL-VBS	1.52(2)	1.52(2)	1.00(4)	0.465(3)			

Discussion

In summary, we study the J_{1x} - J_{1y} - J_2 model using the stateof-the-art tensor network method. In the strong-anisotropy region, we identify a continuous phase transition line between the AFM and columnar VBS phase, where emergent O(4) symmetry appears. With weakening anisotropy, the AFM– VBS transition line terminates at a tricritical point, from which a gapless QSL emerges between the AFM and VBS phases. Most surprisingly, we find that the emergent O(4) symmetry persists on the QSL–VBS phase boundary. We stress that the discovered QSL phase cannot be a finitesize effect for the following reasons. First, a peculiar point located at $(J_{1y}, J_2) \approx (0.6, 0.3)$ was suggested by a previous study using the coupled cluster (CC) method [\[38\]](#page-12-12), and this point is close to our estimated tricritical point at $(J_{1y}, J_2) \simeq$ (0.58, ⁰.27). Second, recent studies have consistently supported the appearance of a QSL phase in the J_1-J_2 and J_1 -*J*2-*J*³ models [\[23,](#page-12-13) [24,](#page-12-3) [42–](#page-13-3)[45\]](#page-13-4). Third, the emergent O(4) symmetry on the QSL–VBS boundary does not appear on the AFM–QSL boundary, which helps us clearly identify the QSL region. We note that in the $J_1-J_2-J_3$ model with C_4 lattice symmetry, the emergent SO(5) symmetry seems not to appear on the QSL–VBS phase boundary [\[24\]](#page-12-3), and precise numerical calculation of the correlation length exponent gives $v \sim 0.45$ for the SO(5) deconfined transition [\[15,](#page-12-15) [16,](#page-12-16) [46\]](#page-13-5), which is inconsistent with the conformal bootstrap constraint

Figure 4. Scaling analysis of physical quantities for AFM and VBS order parameters (main panels), and the spin correlation length (insets): (a) at the AFM–VBS transition point with fixed $J_{1y} = 0.4$, using $v = 0.85$, $J_c = 0.171$, and $z + \eta_s^* = z + \eta_d^* = 1.37$; (b) at the AFM–QSL transition
point with fixed $J_c = 0.85$, using $v = 1.0$, $J_c = 0.352$, $z + \eta_s^* = 1.18$, point with fixed $J_{1y} = 0.85$, using $v = 1.0$, $J_{c1} = 0.352$, $z + \eta_s^* = 1.18$, and $z + \eta_d^* = 1.85$; and (c) at the QSL–VBS transition point with fixed $J_{1z} = 0.85$ using $v = 1.0$, $J = 0.402$ and $z + \eta_s^* = z + \eta_s^* = 1.51$ $J_{1y} = 0.85$, using $v = 1.0$, $J_c = 0.402$, and $z + \eta_s^* = z + \eta_d^* = 1.51$. Subleading corrections are not used in these cases. Black dashed lines are notative curves drawn using corresponding critical exponents quadratic curves drawn using corresponding critical exponents.

 $v > 0.51$ [\[47\]](#page-13-6), suggesting a weakly first-order transition in the thermodynamic limit. In the J_{1x} - J_{1y} - J_2 model, since the QSL– VBS phase transition is unlikely to be weakly first order, we believe that such an emergent O(4) symmetry should survive in the thermodynamic limit.

Constructing a quantum field theory description for both the OSL and DOCP with emergent $O(4)$ symmetry is challenging in that it involves three different types of unconventional phase transition and a tricritical point. There have been theoretical attempts to understand the phase diagram for the J_1 - J_2 - J_3 model with C_4 lattice symmetry [\[48,](#page-13-7) [49\]](#page-13-8), but the theoretical predictions have contradicted the numerical results [\[24,](#page-12-3) [48\]](#page-13-7). For the J_{1x} - J_{1y} - J_2 model, the emergent O(4) symmetry at the AFM–VBS and QSL–VBS transitions provides a strong constraint for future theoretical studies. Specifically, in the strong-anisotropy region, the J_{1x} - J_{1y} - J_2 model comprises weakly coupled spin-1/2 chains [\[35,](#page-12-10) [36\]](#page-12-11). This well-understood model provides a starting point for understanding the emergent O(4) symmetry. Remarkably, an enlarged symmetry formed by spin and dimer order parameters has been indicated in a chain-mean-field study, although not rigorously established [\[36\]](#page-12-11). Experimentally, the J_{1x} - J_{1y} - J_2 model can be realized for cold atoms by coupling one-dimensional spin-1/2 chains [\[50,](#page-13-9) [51\]](#page-13-10), and the verdazylbased salt $[m-MePy-V-(p-F)_2]SbF_6$ is a real material having application potential [\[52\]](#page-13-11).

Methods

Tensor Network Method. The tensor network state, specifically, projected entangled pair state (PEPS), offers a powerful description for entangled quantum many-body states [\[53\]](#page-13-12), and has been extensively employed to characterize various types of states, including exotic topologically ordered phases. As an extension of the one-dimensional density matrix renormalization group (DMRG) method to higher dimensions, PEPS can efficiently capture the entanglement structure of 2D systems with systematically improvable precision controlled by the

tensor bond dimension *D*, and provides an excellent approach for the simulation of frustrated magnets where Quantum Monte Carlo (QMC) fails. We use the method of finite PEPS in the scheme of variational Monte Carlo, detailed in Ref. [\[39,](#page-13-0) [40\]](#page-13-1). Such an approach has been demonstrated as a powerful way for finite size calculations, through massive comparisons with available QMC, iPEPS, and density matrix renormalization group (DMRG) results on various physical models $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$ $[23, 24, 39, 40, 54]$. Tensor bond dimension $D = 8$ of PEPS is adopted for the simulations, which works excellently with high precision for the presented system sizes on other unfrustrated and frustrated systems [\[23,](#page-12-13) [24,](#page-12-3) [40\]](#page-13-1). This work took approximately 10 million CPU hours, as it is necessary to sweep a two-dimensional space of tuning parameters (J_{1y}, J_2) for different systems $L \times L$ with $L = 6 - 20$.

To further check the accuracy of the finite PEPS method with a bond dimension $D = 8$, the obtained results are compared with DMRG results on a long strip with $L_y = 12$ and $L_x = 28$, which is almost at the width L_y limit of the DMRG method. The point $(J_{1y}, J_2) = (0.85, 0.37)$ within the region of the QSL phase is chosen as the reference, which is believed to be very difficult for accurate simulation. The energies for different bond dimensions *M* of the DMRG are listed in Fig. [5](#page-5-0) (a), for comparison with the energy of the PEPS obtained using $D = 8$. The DMRG incorporating SU(2) spin rotation symmetry is used, such that the largest bond dimension $M = 12,000$ is equivalent to 48,000 U(1) states. All the comparisons of the energy, spin, and dimer correlations suggest that the PEPS with $D = 8$ provides excellent results in the critical phase. It is thus reasonable that $D = 8$ gives very good results for other cases with similar sizes. In fact, previous extensive comparisons of DMRG and PEPS methods applied to the spin-1/2 square lattice $J_1 - J_2$ model and J_1 - J_2 - J_3 model of Heisenberg antiferromagnets, as well as a comparison of results for PEPS $D = 4$ to 10, explicitly demonstrated that setting $D = 8$ enables good convergence of the results for system sizes up to 20×28 in

highly frustrated regions and for system sizes up to 32×32 in an unfrustrated Heisenberg model [\[23,](#page-12-13) [24,](#page-12-3) [40\]](#page-13-1).

Figure 5. Comparison of spin and dimer correlations between PEPS and DMRG on a 12×28 lattice at $(J_{1y}, J_2) = (0.85, 0.37)$. Energy persite is presented in the legend.

$$
\mathbf{A.}\,J_{1y}=0.95
$$

Figure 6. (a) J_2 dependence of local order parameters on a 16×16 lattice at $J_{1y} = 0.95$, including Néel AFM order parameters $\langle M_z^{\text{AFM}} \rangle$, houndary-induced VBS, order parameters $\langle D \rangle^2$ and $\langle D \rangle^2$ (both boundary-induced VBS order parameters $\langle D_x \rangle^2$ and $\langle D_y \rangle^2$ (both magnified by a factor of 7 for clarity), and collinear AFM order parameters $\langle M_z^{\text{strip}} \rangle$ for the stripe phase. Black dashed lines separate four phases: (I) AFM, (II) QSL, (III) columnar VBS, and (IV) stripe. (b) J_2 dependence of local order parameters on small 6×6 and 8×8 lattices.

We consider the phase diagram with respect to J_2 at fixed $J_{1y} = 0.95$. Taking the ground states on a 16 \times 16 lattice as an example, we show how the local order parameters change. In our calculations, we always sample in the $S_{\text{tot}}^z = \sum_i S_i^z$ subspace, which is equivalent to imposing $U(1)$ symmetry on the wave function, and we thus need only to consider the *z*−component of local magnetic order parameters. The magnetic properties of the AFM and stripe phases can be determined using the local Néel AFM order parameters,

$$
M_z^{\text{afm}} = \frac{1}{L^2} \sum_{\mathbf{i}} (-1)^{i_x + i_y} S_{\mathbf{i}}^z,\tag{2}
$$

and collinear AFM order parameters,

$$
M_z^{\text{strip}} = \frac{1}{L^2} \sum_{\mathbf{i}} (-1)^{i_y} S_{\mathbf{i}}^z.
$$
 (3)

Note that $M_z^{\text{afm}} \equiv M_z$ in our notation. The possible VBS pattern is reflected by boundary-induced order parameters $\langle D_{\alpha} \rangle^2$, where $\alpha = x, y$.
Figure 6 presents to

Figure [6](#page-6-0) presents the local order parameters in the whole *J*² region of interest, which includes four phases: AFM, QSL, VBS, and stripe phases. The vertical dashed lines for AFM–QSL and QSL3–VBS transitions denote the phase boundaries obtained in the thermodynamic limit, and the other vertical dashed line for the VBS–stripe transition is the phase boundary from 16×16 . Figure [6\(](#page-6-0)a) shows that $\langle M_z^{\text{afm}} \rangle$ and $\langle M_z^{\text{stripe}} \rangle$ have large values in the AFM and stripe phases, respectively, whereas they are almost zero in other phases. Theoretically, these values should be zero in each phase because in finite systems, the exact ground state should be a singlet. In small systems like the 6×6 lattice, the local magnetic order indeed is almost zero. The obvious

nonzero values in magnetic phases in large systems are in fact a reflection of the spontaneous symmetry breaking in the thermodynamic limit. Phenomena of spontaneous symmetry breaking are also observed in finite size calculations and have already been fully discussed for the DMRG method [?]. The almost zero local magnetic order parameters in QSL and VBS phases indicate the recovery of spin rotation symmetry, and we indeed find that $\langle M_{\alpha}^2 \rangle = \frac{1}{3} \langle M_0^2 \rangle$ ($\alpha = x, y, z$).
The houndary induced VBS order parameters

The boundary-induced VBS order parameters $\langle D_x \rangle^2$ and $\langle D_y \rangle^2$ are such that $\langle D_x \rangle^2$ is larger than $\langle D_y \rangle^2$, especially in the VBS phase, which is a clear signature of anisotropy. Of course, $\langle D_y \rangle^2$ always has a zero extrapolated value for $L \rightarrow \infty$. Interestingly, different from $\langle D_x \rangle^2$, in the VBS phase, $\langle D_y \rangle^2$ first increases and then decreases at some J_2 (here, the $\langle D_y \rangle^2$ peak is around *J*₂ = 0.5), and $\langle D_y^2 \rangle$ has the same habouter. Note that $\langle D_x \rangle^2$ and $\langle D_x^2 \rangle$ are saided to zero in same behavior. Note that $\langle D_y \rangle^2$ and $\langle D_y^2 \rangle$ are scaled to zero in the thermodynamic limit.

The VBS–stripe phase transition is a typical first-order transition. The variations in local order parameters on 6×6 , 8×8 , and 16×16 lattices are presented in Fig. [6.](#page-6-0) In all the cases, an increase in J_2 results in a sharp change in $\langle D_x \rangle^2$ near $J_2 = 0.60$, with $\langle D_x \rangle^2$ falling to zero. On the 6×6
lattice $/M^{\text{strip}}$ is almost zero for all presented *L*, whereas lattice, $\langle M_z^{\text{strip}} \rangle$ is almost zero for all presented J_2 , whereas on larger systems, $\langle M_z^{\text{strip}} \rangle$ has nonzero values in the stripe phase, indicating that the spin rotation symmetry is broken. The transition point $J_{c3}(L)$ at different sizes *L* shifts with increasing *L*, as seen for the previous J_1 - J_2 model [\[23\]](#page-12-13). The 2D limit transition point J_{c3} is easily evaluated at $J_{c3} \approx 0.573$ by using the methods from Ref.[\[23\]](#page-12-13).

Figure 7. *J*₂ dependence of $\langle D_x \rangle^2$ (times a factor of 5) and $\langle M_z^{\text{strip}} \rangle$ on a 16×16 lattice for $J_{1y} = 0.65$ (a) and $J_{1y} = 0.4$ (b). Insets show $\langle D_x \rangle^2$ for $L = 6 - 16$.

B. $J_{1y} = 0.65$ and $J_{1y} = 0.40$

We consider large anisotropy regions corresponding to say J_{1v} =0.65 and 0.4. It is seen that the VBS–stripe transition is still of first order, as clearly signaled by the behavior of $\langle M_z^{\text{strip}} \rangle$. For $\langle D_x \rangle^2$, the peak gradually becomes narrower as the system size increases, which is consistent with a first-order transition. Compared with the case for $J_{1v} = 0.95$, the peaks of $\langle D_x \rangle^2$ for J_{1y} =0.65 and 0.4 on the 16 × 16 lattice are much broader. This indicates that the transition is not as strong as

that for $J_{1y} = 0.95$. A comparison of the broadness of the $\langle D_x \rangle^2$ peak on the 16 × 16 lattice for $J_{1y} = 0.95, 0.65$, and 0.4 suggests that with *L*, decreasing the transition becomes 0.4 suggests that with J_{1y} decreasing, the transition becomes gradually weaker.

C. Comparison with early studies

Our overall phase diagram combines previous seemingly conflicting results in a consistent way. Analytical and exact diagonalization (ED) studies have suggested a VBS phase between the AFM and stripe phases for all $J_{1y} \le 1$ [\[36,](#page-12-11) [37\]](#page-12-17). In fact, the analytical results hold only for small J_{1y} and the ED results are limited to small system sizes. Our results agree well with the results of these studies at small J_{1y} . Additionally, a CC analysis has suggested a direct continuous transition between AFM and stripe phases below a particular point at $(J_{1y}, J_2) \approx (0.6, 0.3)$, and above the point where the AFM and stripe phases are separated by a nonmagnetic phase [\[38\]](#page-12-12). Our tensor network results show that at small J_{1y} there exists a VBS phase between the AFM and stripe phases. The CC results in this region contradict our results, as well as the aforementioned analytical and ED results [\[36,](#page-12-11) [37\]](#page-12-17). The suggested continuous AFM–stripe phase transition in the CC results violates both Landau and existing DQCP paradigms. Note that we find that the VBS–stripe phase transition is weak at small J_{1y} . The discovered VBS phase between the AFM and stripe phases and the weakness of the VBS– stripe transition adequately explain why a continuous AFM– stripe phase transition is observed in the CC study. Hence, our results reconcile the CC results with the results of other analyses, and place all the phase transitions in the Landau paradigm and DQCP paradigm. Finally, the nonmagnetic phase suggested by the CC results in fact contains a QSL phase and a VBS phase according to our results. This finding connects the results of the J_1 - J_2 model and small- J_{1y} results through an AFM–VBS transition via a tricritical point.

2. Gapless QSL region

A. Crossing points

We show the crossings from ξ_m/L and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ and
alwze their finite effects by plotting crossing points from analyze their finite effects by plotting crossing points from $(L, L + 2)$ for $L \le 14$ and $(L, L + 4)$ for $L = 16$ versus $1/L$ in Fig. [8.](#page-8-0) Generally, the crossing J_2 values of ξ_m/L give the AFM–VBS transition point $J_2 = J_{c1}$, as expected. This result is consistent with the finite-size extrapolation results of AFM order parameters for small $J_{1y} = 0.2, 0.4,$ and 0.55. The quantities of ξ_m/L and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ give the same crossing J_2
value for each case, which is consistent with a direct AFM value for each case, which is consistent with a direct AFM– VBS transition with emergent O(4) symmetry. For larger $J_{1y} \geq 0.65$, it is seen that in this context the crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ are different from those of ξ_m/L ; see
Fig. 8. Considering the coincidence of crossing *L* values Fig. [8.](#page-8-0) Considering the coincidence of crossing J_2 values

between ξ_m/L and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ at AFM–VBS transitions, the discrepancies for larger L, provide strong evidence for the discrepancies for larger J_{1y} provide strong evidence for the existence of a different phase, namely the QSL phase.

A feature of great interest is that the crossing J_2 values of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ are almost the same as the QSL–VBS tran-
sition points $L_2 = L_2$ obtained by the finite-size scaling sition points $J_2 = J_{c2}$ obtained by the finite-size scaling of VBS order parameters. This motivates us to evaluate the crossing J_2 values as precisely as possible. We note that the crossing values with respect to 1/*^L* cannot be fitted well by a simple polynomial function, possible due to the imperfect optimization of wave functions. Nevertheless, the crossing points from $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ have very small finite-size effects, which has also been observed in other studies [\[7,](#page-12-4) [17\]](#page-12-5). This enables us to evaluate the thermodynamic limit value by simply averaging the large-size values. For ξ_m/L , the crossing J_2 values for large system sizes can be estimated as the thermodynamic limit transition point J_{c1} . We also use the collective fitting of J_{c1} and correlation length ν for data collapse to take into account the finite-size effects and obtain consistent results. Furthermore, we compute more J_2 points to reduce the uncertainty in finite size scaling for locating the VBS phase boundary, as seen in the insets of Fig.2(d) in the main text, as well as Fig. $10(b)$ $10(b)$, and Fig. $11(b)$ $11(b)$. The values are summarized in Table. I in the main text. We see that for several different cases with fixed $J_{1y} = 0.60, 0.65, 0.75, 0.85$, 0.95, and 0.98, within our resolution, the ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$
and finite size scaling of $\langle D_x^2 \rangle$ give the same results. The and finite size scaling of $\langle D_x^2 \rangle$ give the same results. The quantity $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ is only related to the emergent symmetry,
which indicates that the OSI-VBS phase transition points which indicates that the QSL–VBS phase transition points have emergent O(4) symmetry.

B. Finite size scaling of order parameters

We consider the $J_{1x} - J_{1y} - J_2$ model at fixed $J_{1y} = 0.65$. Figure $9(a)$ $9(a)$ shows that the AFM order parameter vanishes around $J_2 \approx 0.28$; this is consistent with the behavior of ξ_m/L , which gives $J_2 \simeq 0.285$. Meanwhile, the finite-size scaling of VBS order parameters $\langle D_x^2 \rangle$ shows that the VBS order begins to appear between $J_2 = 0.30$ and $J_2 = 0.32$, which is confirmed by the boundary-induced order parameters $\langle D_x^2 \rangle^2$, as presented in Fig. [9\(](#page-8-2)b). The ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ gives a crossing value $J_2 \approx 0.309$, which is well located within the region [0.30, ⁰.32]. Additionally, we show the VBS order parameters $\langle D_x^2 \rangle$ w.r.t. *J*₂ on different systems with *L* = 6,8,10, and 12 in the inset of Fig. $9(a)$ $9(a)$. The order parameters have peaks for all systems, indicating the VBS–stripe transition point. The corresponding boundary-induced dimerizations $\langle D_x \rangle^2$ have already been presented in Fig. [7.](#page-6-1) When we scale the VBS order parameters for data collapse, the values near the peaks do not collapse well, as shown in Fig. [9\(](#page-8-2)c) and (d), perhaps because they are far from the critical region.

Similarly, we make computations for other fixed J_{1y} = 0.75, 0.85, and 0.95. The results for $J_{1y} = 0.75$ and J_{1y} = 0.95 are presented in Fig. [10\(](#page-8-1)a–d) and Fig. [11\(](#page-9-0)a– d), respectively. Note that the simulated systems are under

Figure 8. Crossing points for dimensionless quantities ξ_m/L (top row) and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ (middle row) at different fixed J_{1y} . The bottom row
shows the scaling of crossing points between the sizes of *L* and *L* shows the scaling of crossing points between the sizes of *L* and $L + 2$ (except at $L = 16$, where crossing points between $L = 16$ and $L = 20$ are shown).

Figure 9. Order parameters of the $J_{1x} - J_{1y} - J_2$ model at fixed J_{1y} = ⁰.65. (a) Finite size scaling for AFM order parameters (main panel) and the variance in VBS order parameters $\langle D_x^2 \rangle$ with respect to J_2 (inset). (b) Finite-size scaling for VBS order parameters $\langle D_x^2 \rangle$ (main panel) and $\langle D_x \rangle^2$ (inset). Second-order polynomial fits are used. (c) Data collapse of AFM and VBS order parameters and the correlation length ξ_m at AFM–QSL transition point $J_{c1} = 0.285$, with $\nu = 1.00$, $z + \eta_{s1}^* = 1.23$, and $z + \eta_{d1}^* = 1.70$. (d) Data collapse of AFM and VRS order parameters at OSI –VRS transition point $I_0 = 0.309$ VBS order parameters at QSL–VBS transition point $J_{c2} = 0.309$, with $v = 1.00$ and $z + \eta_{s2}^* = z + \eta_{d2}^* = 1.49$. Black dashed curves
in (c) and (d) are second-order curves with corresponding critical in (c) and (d) are second-order curves with corresponding critical exponents.

open boundary conditions. The dimer structure factor is not well defined in this situation and hence one cannot obtain the corresponding dimer correlation length to determine the VBS boundaries [\[23](#page-12-13)?]. For the QSL–VBS transition, to compare with the crossing *J*₂ value of the ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$, we try our best to reduce the uncertainty in the transition we try our best to reduce the uncertainty in the transition point by computing more J_2 points, as well as using different fitting functions and different system sizes for the finite size

Figure 10. Scaling of spin and dimer order parameters of the J_{1x} - J_{1y} - J_2 model at fixed $J_{1y} = 0.75$ for AFM–QSL (a,c) and QSL–VBS (b,d) transitions. Panels(a) and (b) show the finite-size scaling for AFM and VBS order parameters, $\langle M_0^2 \rangle$ and $\langle D_x^2 \rangle$. The inset of (b) shows the boundary-induced VBS order parameters $\langle D_x \rangle^2$. Second-order polynomial fits are used. (c) Data collapse of AFM and VBS order parameters and the correlation length ξ_m at the AFM–QSL transition point $J_{c1} = 0.327$, with $\nu = 1.01$, $z + \eta_{s1}^* = 1.23$, and $z + \eta_{d1}^* = 1.74$. (d)
Data collapse of AFM and VBS order parameters at the OSI –VBS Data collapse of AFM and VBS order parameters at the QSL–VBS transition point $J_{c2} = 0.360$, with $\nu = 1.01$ and $z + \eta_{s2}^* = z + \eta_{d2}^* = 1.47$. Black dashed curves in (c) and (d) are second-order curves with ¹.47. Black dashed curves in (c) and (d) are second-order curves with corresponding critical exponents.

scaling of $\langle D_x^2 \rangle$ and $\langle D_x \rangle^2$. As stated in the main text, the results suggest that the crossing J_2 value for $L \rightarrow \infty$ from $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ is the same as that from finite size scaling within our resolution our resolution.

We now consider smaller $J_{1y} = 0.6, 0.55,$ and 0.2. At J_{1y} = 0.6, the QSL region shrinks to a narrow region 0.273 \leq $J_2 \leq 0.283$. At $J_{1y} = 0.55$ and 0.2, the QSL disappears and instead a direct AFM–VBS transition is suggested by

Figure 11. Scaling of spin and dimer order parameters of the J_{1x} - J_{1y} - J_2 model at fixed J_{1y} = 0.95 for AFM–QSL (a,c) and QSL–VBS (b,d) transitions. Panels (a) and (b) show the finite-size scaling for AFM and VBS order parameters, $\langle M_0^2 \rangle$ and $\langle D_x^2 \rangle$. The inset of (b) shows boundary-induced VBS order parameters $\langle D_x \rangle^2$. Second-order polynomial fits are used. (c) Data collapse of AFM and VBS order parameters and the correlation length ξ_m at the AFM–QSL transition point $J_{c1} = 0.39$, with $v = 1.05$, $z + \eta_{s1}^* = 1.21$, and $z + \eta_{d1}^* = 1.88$. (d)
Data collapse of AEM and VBS order parameters at the OSI -VBS Data collapse of AFM and VBS order parameters at the QSL–VBS transition point $J_{c2} = 0.453$, with $\nu = 1.05$ and $z + \eta_{s2}^* = z + \eta_{d2}^* = 1.52$. Black dashed curves in (c) and (d) are second-order curves with ¹.52. Black dashed curves in (c) and (d) are second-order curves with corresponding critical exponents.

Figure 12. Scaling of spin and dimer order parameters of the J_{1x} - J_{1y} - J_2 model at fixed $J_{1y} = 0.6$ for the AFM–QSL (a) and QSL– VBS (b) transitions. The main panels show the data collapse and the insets show the finite size scaling of $\langle M_0^2 \rangle$ and $\langle D_x^2 \rangle$ with secondorder fits. At the AFM–QSL transition (a), $v = 0.97$, $J_{c1} = 0.273$ λ , $z + \eta_s^* = 1.36$, and $z + \eta_d^* = 1.55$ are used for the quantities $\langle M_0^2 \rangle$
and $\langle D_1^2 \rangle$ At the OSL-VBS transition (b) $y = 0.97$, $L_2 = 0.283$ and $\langle D_x^2 \rangle$. At the QSL–VBS transition (b), $v = 0.97$, $J_{c2} = 0.283$, and $z + n^* = z + n^* = 1.45$. Black dashed lines are fitted curves with and $z + \eta_s^* = z + \eta_d^* = 1.45$. Black dashed lines are fitted curves with corresponding critical exponents corresponding critical exponents.

the analysis of ξ_m/L and $\langle D_x^2 \rangle / \langle M_0^2 \rangle$. The results indicate a
tricritical point between $L_1 = 0.55$ and $L_2 = 0.6$ which is tricritical point between $J_{1y} = 0.55$ and $J_{1y} = 0.6$, which is roughly located at $(J_{1y}, J_2) \approx (0.58, 0.27)$. These important results explicitly show how a gapless QSL emerges with J_{1y} increasing. The data on collapse in Fig[.9–](#page-8-2)[13](#page-9-1) and critical exponents therein indeed support universality classes different from the class of the DQCP. Note that the spin and dimer correlation exponents $z + \eta_{s,d}$ at the QSL–VBS transition point have the same values, consistent with the emergent symmetry.

Figure 13. Scaling analysis of spin and dimer order parameters of the $J_{1x} - J_{1y} - J_2$ model at fixed $J_{1y} = 0.2$ (a) and $J_{1y} = 0.55$ (b) for the AFM–VBS transition. Insets show respective scaling of the correlation lengths. At $J_{1y} = 0.2$, using $v = 0.84$, $J_c = 0.071$, $z + \eta_s^* = z + \eta_d^* = 1.36$, and $\omega = 2$. The prefactors *a* are 4.5,
8. and 0 for the quantities $\mathcal{L} = \langle M^2 \rangle$ and $\langle D^2 \rangle$ respectively. At 8, and 0 for the quantities ξ_m , $\langle M_0^2 \rangle$, and $\langle D_x^2 \rangle$, respectively. At $L = 0.55$ using $y = 0.85$, $I = 0.255$, $z + n^* = z + n^* = 1.34$. *J*_{1*y*} = 0.55, using $v = 0.85$, $J_c = 0.255$, $z + \eta_s^* = z + \eta_d^* = 1.34$, and $\omega = 1.5$. The prefactors *a* are 2.2, and 4 for the quantity ϵ . and $\omega = 1.5$. The prefactors *a* are 2, 2, and 4 for the quantity ξ_m , $\langle M_0^2 \rangle$, and $\langle D_x^2 \rangle$, respectively. Black dashed curves are second-order curves with corresponding critical exponents.

C. Case that $J_{1y} = 0.98$

The J_{1x} - J_{1y} - J_2 model is reduced to the J_1 - J_2 model by setting $J_{1y} = 1$, which was well studied in our previous work using the same method [\[23\]](#page-12-13). Therefore, we finally compute the case for fixed J_{1y} = 0.98, as shown in Fig[.14.](#page-10-0) The finite size scaling of the AFM order parameter and correlation length quantities ξ_m/L suggests that the AFM order vanishes at $J_2 \approx 0.41$. The QSL–VBS transition point estimated by the finite-size scaling of $\langle D_x^2 \rangle$ is $J_2 \approx 0.47$, which is close
to the crossing value of $\langle D_2^2 \rangle / \langle M_2^2 \rangle$ (i.e. $J_2 \approx 0.465$). The to the crossing value of $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ (i.e., $J_2 \simeq 0.465$). The critical exponents for AEM-OSI and OSI-VBS transitions critical exponents for AFM–QSL and QSL–VBS transitions obtained from the data collapse are well consistent with those obtained for other J_{1y} . However, we find that $\langle D_y^2 \rangle$ in the 2D limit is potentially nonzero for $J_2 > 0.46$. Note that $\langle D_y^2 \rangle$
on a 16 \times 16 lattice at $J_1 = 0.98$ has a behavior similar to on a 16×16 lattice at $J_{1y} = 0.98$ has a behavior similar to that at $J_{1y} = 0.95$, both having a peak in the VBS phase as seen in Fig[.14\(](#page-10-0)f) and Fig[.6.](#page-6-0) We plot the scaling behavior of $\langle D_x^2 \rangle$ and $\langle D_y^2 \rangle$ at $J_2 = 0.46$, as shown in the inset of Fig[.14\(](#page-10-0)f), and find that $\langle D_y^2 \rangle$ decays more rapidly than $\langle D_x^2 \rangle$. Therefore, we cannot exclude the possibility that nonzero values of $\langle D_y^2 \rangle$ in 2D space are a finite-size effect. In fact, when close to $J_{1y} = 1.0$, there is an intermediate range of scale with approximate C_4 symmetry, which makes it challenging to get conclusive results in this situation. However, if it is not a finite-size effect, the nature of the VBS at $J_{1y} = 0.98$ will be a mixed columnar-plaquette VBS phase where $\langle D_x^2 \rangle$ and $\langle D_y^2 \rangle$ have unequal nonzero values in the 2D limit.

Note that the lattice symmetry is C_2 for $J_{1y} \neq 1.0$ but C_4 for $J_{1y} = 1.0$ (i.e., we have the J_1-J_2 model). It would be a little subtle to directly extend the anisotropic results to the J_1 - *J*² model, especially for the VBS phase. Note that whether the nature of the VBS in the J_1-J_2 model is a columnar VBS (cVBS) phase or plaquette VBS (pVBS) phase in the thermodynamic limit is not clear. There are two possibilities assuming that the extension is continuous. (I) The VBS is in a cVBS phase in the J_1 - J_2 model; this indicates that the VBS is also in the cVBS phase in the anisotropic case. The nonzero extrapolated $\langle D_y^2 \rangle$ values at $J_{1y} = 0.98$ should then be finite-
size effects (II) The VBS is in the pVBS phase in the *L*₁-*L*₂ size effects. (II) The VBS is in the pVBS phase in the J_1 - J_2 model, and to realize a continuous extension, there should be a mixed columnar–plaquette VBS phase that intervenes the cVBS and pVBS phases [?]. In this situation, the $\langle D_y^2 \rangle$ values in the VBS region at $J_{1y} = 0.98$ cannot be finite-size effects for a mixed columnar–plaquette VBS phase to be obtained. The two scenarios cannot be distinguished based on current capability.

Figure 14. Physical behaviors at fixed $J_{1y} = 0.98$. (a) Finite scaling of the AFM order parameter $\langle M_0^2 \rangle$ (main panel) and spin correlation length ξ_m (inset). (b) Finite size scaling of VBS order parameter $\langle D_x^2 \rangle$ (main panel) and the order parameter ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$ (inset).
Second-order polynomial fits are used (c) Data collapse at the Second-order polynomial fits are used. (c) Data collapse at the AFM–QSL transition point J_{c1} = 0.41, with critical exponents $z + \eta_{s1} = 1.27$, $z + \eta_{d1} = 1.86$, and $v = 1.0$. (d) data collapse at the QSL–VBS transition point $J_{c2} = 0.465$, with critical exponents $z + \eta_{s2} = z + \eta_{d2} = 1.52$ and $v = 1.0$. (e) Second-order fit of the VBS order parameter $\langle D_y^2 \rangle$. (f) *J*₂-dependence of $\langle D_y^2 \rangle$ on a 16 × 16 lattice. The inset of (f) shows the order parameter scaling $A \propto L^{-\alpha}$ for $\langle M_0^2 \rangle$, $\langle D_x^2 \rangle$ and $\langle D_y^2 \rangle$ at $J_2 = 0.46$. The exponents are $\alpha = 1.54(2)$, 1.57(3), and 1.70(2) respectively and 1.70(2), respectively.

D. Correlation functions

In Fig. [15](#page-10-1) (a) and (b), we show the spin correlation functions along *x* and *y* directions at $J_2 = 0.35, 0.42,$ and 0.48 on a 20 \times 20 matrix with $J_{1y} = 0.95$; these J_2 are within the regions of AFM, QSL, and VBS phases, respectively. We also show the spin correlation functions on long strips $L_v \times L_x$ with $L_v = 4 - 12$ and $L_x = 28$ at $(J_{1v}, J_2) = (0.85, 0.37)$, which is located within the region of the QSL phase. The dimer correlation functions on a 20 \times 20 matrix for (J_{1y}, J_2) = (0.85, ⁰.38) (in the region of the QSL phase) are shown in Fig. [15](#page-10-1) (d). These results suggest that the QSL phase is gapless with a power law behavior for both spin and dimer correlation functions. Note that on the 20×20 lattice, the correlations along *x* and *y* directions are different, reflecting the anisotropy of the x and y directions in the finite size calculations. Nevertheless, it is expected that the anisotropy in the QSL phase will recover in the infrared limit. Note that without loss of generality, the distance between the reference site and the left edge used here is one lattice spacing for the 20×20 lattice and three lattice spacings for the 12×28 lattice. One can also choose other reference sites, such as those having two or four lattice spacings between the reference site and the left edge, and they also show a power law decay behavior of correlation functions.

Figure 15. Spin and dimer correlation functions. Upper panels: (a) and (b) present the spin correlation functions along the *x* direction on the central row and along the *y* direction on the central column on the 20×20 lattice at different J_2 with fixed $J_{1y} = 0.95$. Lower panels: (c) presents spin correlation functions along *x* on the central row on the long strip $L_y \times L_x$ at $(J_{1y}, J_2) = (0.85, 0.37)$, with $L_y = 4 - 12$ and $J_y = 28$; (d) shows the dimer correlations along x and y directions on $L_x = 28$;(d) shows the dimer correlations along *x* and *y* directions on the 20 × 20 lattice at $(J_{1y}, J₂) = (0.85, 0.38)$. Dashed lines show the nower law fit $y = cr^{-a}$ with $r < 10$ (6) for snin (dimer) nower α , (α) power law fit $y = cr^{-\alpha}$ with $r \le 10$ (6) for spin (dimer) power $\alpha_s(\alpha_d)$ as presented.

3. Extracting critical exponents

Generally speaking, the accurate computing of critical exponents is a challenging task in numerical simulations. Here, we have huge volumes of data with different J_{1y} , J_2 , and size *L*, which makes it possible to extract meaningful critical exponents. Following Ref. [\[24\]](#page-12-3), we use the standard formula to collectively fit the physical quantities from different lattice sizes and different couplings for data collapse:

$$
A(J_2, L) = L^{\kappa} (1 + aL^{-\omega}) F[L^{1/\nu} (J_2 - J_c) / J_c], \tag{4}
$$

where $A = \xi_m$, $\langle M_0^2 \rangle$, or $\langle D_x^2 \rangle$, and $\kappa = 1$ for $A = \xi_m$, $-(z + \eta_s^*)$
for $A = \langle M^2 \rangle$ and $-(z + \eta_s^*)$ for $A = \langle D^2 \rangle$. Eactors *a* and for $A = \langle M_0^2 \rangle$, and $-(z + \eta_d^*)$ for $A = \langle D_x^2 \rangle$. Factors *a* and ω_d are tuning parameters of the subleading term $E[1]$ is a ω are tuning parameters of the subleading term. $F[]$ is a polynomial function, and we here use a third-order expansion and find that the second-order fit already works well because the third-order coefficient is small. Generally, for the AFM– VBS transition, the subleading term is necessary for good data collapse, although this is not always the case, such as when $J_{1y}=0.4$. For AFM–QSL and QSL–VBS transitions, subleading terms seem unnecessary, and we set $a = 0$. The transition point J_c is always fixed unless otherwise specified. In the following, we focus on how to evaluate the critical exponents for AFM–QSL and QSL–VBS transitions, and similar analyses can be conducted for AFM–VBS transitions.

For a given J_{1y} , we can estimate the AFM–QSL transition point J_{c1} using the crossing of ξ_m/L . Taking account of possible finite-size effects, we can alternatively collectively fit J_{c1} and v_1 simultaneously using the values of ξ_m/L for different *J*² and *L* according to the above formula. Suppose that at J_{1y} = 0.85 we have J_{c1} = 0.352(5) and v_{1m} = 1.00(4). With this fixed $J_{c1} = 0.352$, we can then use a collective fit of *v* and $z + \eta^*$ for the AFM and VBS order
parameters respectively We thus obtain $y_1 = 1.00(3)$ parameters, respectively. We thus obtain $v_{1,s} = 1.00(3)$ and spin correlation exponent $z + \eta_{s1}^* = 1.18(1)$ by fitting
the AEM order parameters, and $y_{t+1} = 0.98(2)$ and dimenthe AFM order parameters, and $v_{1,d}$ = 0.98(2) and dimer correlation exponent $z + \eta_{1,d}^* = 1.86(2)$ by fitting the VBS order
parameters Δt the OSI -VBS transition, we mention again $1, d = 1,$ $1, d = 1,$ $1,$ $d = 1,$ $1,$ $d = 0,$ $d = 0,$ that the dimer correlation length cannot be obtained to locate the VBS phase boundary for open-boundary systems because the dimer structure factor in this case is not well defined [\[23](#page-12-13)?]. We here use the critical point J_{c2} obtained using the order parameter ratio $\langle D_x^2 \rangle / \langle M_0^2 \rangle$, which has very small finite-size effects. Through fixing J_{c2} , we similarly get $v_{2,s} = 0.97(5)$ and spin correlation exponent $z + \eta_{s2}^* = 1.50(1)$ by fitting AFM
order parameters, and $y_{t+1} = 1.04(3)$ and dimer correlation order parameters, and $v_{1,d} = 1.04(3)$ and dimer correlation exponent $z + \eta_{2,d}^* = 1.50(1)$ by fitting VBS order parameters.
We apply the same applyses to other cases of a fixed

Follow χ_1 , $\eta_{2,d}$ = 1.50(1) by htting v B5 other parameters.
We apply the same analyses to other cases of a fixed J_{1y} . With given J_{c1} obtained from ξ_m and J_{c2} obtained from $\langle D_x^2 \rangle / \langle M_0^2 \rangle$, by scaling order parameters, we get $v_{1,s}, v_{1,d}, v_{2,s}$,
and v_2 , and their corresponding $z + n^*$, $z + n^*$, $z + n^*$, and and $v_{2,d}$ and their corresponding $z + \eta_{s1}^*$, $z + \eta_{d1}^*$, $z + \eta_{s2}^*$, and $z + n^*$. Table III lists the fitted exponents y_{i} and y_{i} , obtained $z + \eta_{a2}^*$. Table [III](#page-11-0) lists the fitted exponents $v_{1,2}$ and v_{1m} obtained
by fitting ξ at the AFM-OSI, transition point, as well as by fitting ^ξ*^m* at the AFM–QSL transition point, as well as the spin and dimer correlation exponents $z + \eta_{s,d}^*$. Note that
the obtained *y*, and *y* are close, indicating *y*, $\approx y_0 \approx 1.0$ the obtained v_1 and v_2 are close, indicating $v_1 \approx v_2 \approx 1.0$.

Table III. Fitted critical exponents and errors from fittings. Fitting AFM order parameters gives $v_{1,s}$ and $z + \eta_{s1}^*$ at the AFM–QSL critical
point and gives v_2 and $z + \eta_{s1}^*$ at the OSL–VBS critical point. Fitting point, and gives $v_{2,s}$ and $z + \eta_{s2}^*$ at the QSL–VBS critical point. Fitting VBS order parameters gives $v_{1,s}$ and $z + n^*$ at the AFM–OSL critical VBS order parameters gives $\overline{v}_{1,d}$ and $z + \eta_{d1}^*$ at the AFM–QSL critical
point and gives v_2 , and $z + n^*$ at the OSL–VBS critical point. The point, and gives $v_{2,s}$ and $z + \eta_{a2}^*$ at the QSL–VBS critical point. The last column \bar{v} is an estimation made by directly averaging over v. last column \bar{v} is an estimation made by directly averaging over $v_{1,s}$,
 $v_{k+1}v_{2,k+1}$ and v_{s+1} $v_{1,d}$, $v_{2,s}$, $v_{2,d}$, and v_{1m} .

$J_{1v} = 0.95$	1.21(2)	1.87(2)	1.52(1)	1.53(2)		

Table IV. Critical exponents obtained using a single correlation length exponent \bar{v} at the AFM–QSL and QSL–VBS transition points. In each fit, $z + \eta^*$ is a free parameter, and \bar{v} is fixed. Errors are from fittings fittings.

Additionally, the spin and dimer correlation exponents are well consistent, $z + \eta_{s1}^* \sim 1.2$ and $z + \eta_{d1}^* \sim 1.8$ at the AFM–
OSL transition and $z + n^* = z + n^* \approx 1.5$ at the OSL–VBS QSL transition, and $z + \eta_{s2}^* = z + \eta_{d2}^* \sim 1.5$ at the QSL–VBS
transitions transitions.

The closeness of v_1 and v_2 indicates that the AFM–QSL and QSL–VBS transitions could have the same correlation length exponent ν and a single ν could scale all the quantities. To demonstrate this point, we use an value \bar{v} averaged over $v_{1,s}$, $v_{1,d}$, v_{1m} , $v_{2,s}$, and $v_{2,d}$ as a fixed parameter to fit $z + m^*$. The data collapse with the single \bar{v} for all the cases was shown in previous sections. Corresponding exponents *. The data collapse with the single $\bar{\nu}$ for all the cases are listed in Table [IV](#page-11-1) and only slightly differ from those in Table [III,](#page-11-0) which means that a single $v \sim 1.0$ indeed works well at the AFM–QSL and QSL–VBS transitions. We note that due to the imperfect optimization of wave functions, some obtained physical quantities may have slight unavoidable deviations from their exact values. However, this would not diminish the reasonability and correctness of the extracted critical exponents, because the large volumes of data from different (J_{1y}, J_2) reduce the uncertainty. Note that the physical quantities at different J_{1y} can be scaled well using smooth curves with similar critical exponents, which is an excellent characterization of the universal scaling functions.
