We find that a quantum device having an accessory involving precision measurement can have an enhancement of its metrological precision in estimating an unknown parameter of the quantum system by insertion of glassy disorder, accidental or engineered. We clearly mention how an unbiased estimator can also be identified in a disordered situation, and how the precision thereof can be bounded by the quantum Crámer-Rao inequality. We compare the Fisher information-based lower bound of the minimum standard deviation of an unbiased estimator, in presence of glassy disorder in the system, with the same of an ideal, viz. disorder-free, situation. The phenomenon can boost the efficiency of certain measuring devices, such as atomic clocks. The precision of these clocks, when measuring time, hinges on the precise determination of the frequency of a two-level atom. In cases where impurities are present in the atom, and can be modeled as a disorder parameter, it is possible for the measurement of frequency to be more accurate than in an ideal, disorder-free scenario. Moreover, disorder insertion can reduce the requirement of entanglement content of the initial probes, which are copies of two-qubit states, along with providing a disorder-induced enhancement.

I. INTRODUCTION

In the last few decades, quantum metrology $[1-3]$ $[1-3]$ has become an important area of research and its application in various arenas of physics has been delved into [\[4–](#page-12-1)[47\]](#page-13-0). For optimal choice of encoded probes and decoding schemes, the error in measurement can be minimized, and that minimum error is achievable by repeating the experiment a large number of times [\[42,](#page-12-2) [48\]](#page-13-1).

Imperfections, modelled as disorder, are ubiquitous in all practical implementations of a physical process [\[18,](#page-12-3) [49](#page-13-2)[–129\]](#page-14-0). For example, let us consider the measurement of time or frequency using Ramsey interferometry in quantum devices, like atomic clocks [\[130–](#page-14-1)[133\]](#page-14-2). These clocks are known for their high precision in measuring time. However, even the most well-designed quantum systems have minor flaws that influence their performance. These imperfections and flaws can be characterized as disordered parameters inherent to the system. Specifically, one notable source of disorder in atomic clocks arises from the regulated probing of atoms. This controlled interaction with atoms, while critical for precise measurements, can change the energy difference between the two energy levels of a two-level system. This variation, in turn, can affect the clock's accuracy and stability. Therefore, response to disorder in measurement precision for such measuring devices is of prime significance in parameter estimation protocols, and yet is hitherto unexplored. We consider disorder present in the scale of the parameter to be estimated.

We construct disorder models for measuring devices, especially for atomic clocks, by introducing disordered parameters - more precisely, effective glassy disordered parameters into the ideal system Hamiltonian, where the disorder distributions are chosen from a clutch of paradigmatic continuous and discrete distributions. In such a disordered system, we find scenarios where the presence of disorder provides an improvement in the efficiency of estimation of an unknown system parameter, over the ideal situation. These situations of attaining better efficiency of measurement in presence of disorder over the ideal scenario can be termed as "disorder-induced enhancements of metrological precision" or instances of "order from disorder". Therefore, a quantum device containing an accessory that involves estimating a parameter, such as an atomic clock measuring time or frequency, can attain a better precision when a system parameter is inflicted - accidentally or intentionally - by disorder. Moreover, we find scenarios where for an ideal system, the best metrological precision is obtained for maximally entangled initial probes, whereas insertion of disorder into the system provides a *double advantage*: an enhancement of metrological precision over the ideal one, and lower entanglement content in the probe state.

For dealing with metrological precision in disordered scenarios, we analyze how an unbiased estimator can be identified in a disordered situation. We go on to further show that the precision thereof can be bounded by a quantum Crámer-Rao inequality.

It is important to mention here that our work falls within the general category of imperfections in the encoding process. Until now, this has been considered using noisy quantum operations [\[18,](#page-12-3) [19,](#page-12-4) [30,](#page-12-5) [134,](#page-14-3) [135,](#page-14-4) [137](#page-15-0)[–164\]](#page-15-1). We however analyze its implementation by considering disorder present in the encoding unitary. Moreover, while the results such as in [\[144\]](#page-15-2) pertain to arbitrary multi-party inputs - which may include entangled ones - and non-unitary encodings, our work uses copies of single-qubit states and unitary encoding, but in presence of glassy disorder. We consider arbitrary multi-party inputs only when the encoding Hamiltonian contains interaction terms.

The rest of the paper is presented as follows. In Sec. [II,](#page-1-0) we briefly discuss certain aspects of quantum metrology. The concept and origin of glassy disorder and disorder averaging are discussed in Sec. [III.](#page-2-0) The disorder distributions, that provide disorder-induced enhancement of metrological precision, are also presented in this section. In Sec. [IV,](#page-5-0) we identify an unbiased estimator for the disordered situation considered, and show that the precision thereof can be bounded by the Crámer-Rao inequality. Sections V and VI constitute evidence of order from disorder scenarios for copies of uncorrelated and two-qubit maximally entangled initial probes, for different glassy disorder models. The reduction of the requirement of entanglement content of the initial probes in presence of glassy disorder, thus providing the "double advantage", is shown in Sec. [VII.](#page-10-0) A conclusion is presented in Sec. [VIII.](#page-10-1)

II. ESTIMATION OF AN UNKNOWN PARAMETER

The enhancement of measurement precision in the frequency estimation protocol using the concepts of quantum metrology has been studied some time back in [\[18,](#page-12-3) [19\]](#page-12-4). The problem initiated with a single-qubit system described by the Hamiltonian \mathcal{H}_1 , given by

$$
\mathcal{H}_1 = -\hbar\omega\left|1\right\rangle\left\langle1\right|,\tag{1}
$$

where ω is the frequency to be estimated. For an *n*-qubit system, the dynamics is governed by the n -qubit Hamiltonian,

$$
\mathcal{H}_n = \mathcal{H}_1 \otimes \mathcal{I}_2 \otimes \mathcal{I}_3 \cdots \otimes \mathcal{I}_n + \mathcal{I}_1 \otimes \mathcal{H}_1 \otimes \mathcal{I}_3 \cdots \otimes \mathcal{I}_n + \cdots + \mathcal{I}_1 \otimes \mathcal{I}_2 \cdots \otimes \mathcal{I}_{n-1} \otimes \mathcal{H}_1.
$$
 (2)

For the evolution of n -qubit initial probes by the unitary $U_n = e^{-\frac{i}{\hbar} \mathcal{H}_n t}$, the minimum standard deviation in the estimation of ω , is less for two-qubit maximally entangled probes than for copies of uncorrelated ones. This enhancement of metrological precision by introducing quantumness in the initial states is a key idea of quantum metrology.

The minimum deviations in frequency estimation are not due to imprecise measurements of the parameter in an experiment. It is a fundamental lower bound on the standard deviations of estimators of the parameter to be estimated, where the outcomes of measurements - on which the estimators depend - are distributed according to the probabilities dictated by the Born rule. This is the quantum Cramér-Rao bound $[40-$ [47\]](#page-13-0), which is attainable for a large number of repetitions of an experiment corresponding to an optimal strategy. Below we discuss the prescription of obtaining this bound.

Suppose an unknown parameter, θ , is encoded in a state, $\rho(\theta)$, of a physical system. To estimate θ , a measurement of elements $\{\Pi_x\}$ is done on the system, and let the probability distribution for a measurement outcome x be $f(x|\theta)$. Now, let us take the outcome of a single measurement to be x_1 . Based on this outcome, the predicted value of θ can be represented by the estimator function $\hat{\theta}(x_1)$ [\[19,](#page-12-4) [48\]](#page-13-1). For a large number of measurements, our prediction is assumed to be correct on an average for a fixed θ . Therefore,

$$
\langle \hat{\theta}(x) \rangle_{\theta} = \int dx f(x|\theta) \hat{\theta}(x) = \theta.
$$
 (3)

Such a $\hat{\theta}(x)$ is called an unbiased estimator. So, for a given θ, we get a distribution of the estimate $\hat{\theta}(x)$ with probability $f(x|\theta)$. The variance of the estimator function, while estimating θ , is lower bounded by the Cramér-Rao inequality given by

$$
\Delta^2 \theta \ge \frac{1}{F(\theta)},\tag{4}
$$

where $F(\theta)$ is the Fisher Information (FI) [\[42,](#page-12-2) [48\]](#page-13-1). Here we use the traditional notation $\Delta^2 \theta$ for $\Delta^2 \hat{\theta}(x)|_{\theta}$ as the variance of the distribution of the estimator function $\hat{\theta}(x)$. The Fisher information for a single measurement is defined in terms of the probability distribution $f(x|\theta)$, through the relation

$$
F(\theta) = \int dx \left[\frac{\partial}{\partial \theta} \log f(x|\theta)\right]^2.
$$
 (5)

From the additivity of FI, for ν measurements, or ν copies of the input probe, we have the FI, $F^{\nu}(\theta) = \nu F(\theta)$, where $F(\theta)$ represents the Fisher information corresponding to each probe. Therefore for ν measurements, [\(4\)](#page-1-1) has the general form

$$
\Delta^2 \theta \ge \frac{1}{\nu F(\theta)},\tag{6}
$$

which attains the equality for large ν . The choice of measurement strategy has been fixed so far. To make the FI independent of such a choice, one has to maximize the Fisher information with respect to all possible measurements. As a consequence of the maximization, the Cramér-Rao bound becomes

$$
\Delta \theta \ge \frac{1}{\sqrt{\nu \left(\max_{\Pi_x} F(\theta) \right)}} = \frac{1}{\sqrt{\nu F_Q(\theta)}}. \tag{7}
$$

 F_Q is the quantum Fisher information corresponding to a single probe, obtained by maximizing the Fisher information $F(\theta)$ with respect to all possible $\{\Pi_x\}$, where $f(x|\theta) =$ $Tr[\Pi_x \rho(\theta)]$. Here ${\Pi_x}$ is a positive operator valued measurement and $\rho(\theta)$ is the quantum state where θ is enoded. The quantum Fisher information can also be directly calculated for a given $\rho(\theta)$ as

$$
F_Q(\theta) = \text{Tr}\Big[\rho(\theta)L_s\big[\rho(\theta)\big]^2\Big].\tag{8}
$$

 $L_s[\rho(\theta)]$ is known as the symmetric logarithmic derivative (SLD) [\[19,](#page-12-4) [42\]](#page-12-2) of $\rho(\theta)$. If the eigen-decomposition of $\rho(\theta)$ is $\rho(\theta) = \sum_i \lambda_i(\theta) |e_i(\theta)\rangle \, \langle e_i(\theta)|$, the SLD is given by

$$
L_s[\rho(\theta)] = \sum_{i,j} \frac{2 \langle e_i(\theta) | \frac{\partial \rho(\theta)}{\partial \theta} | e_j(\theta) \rangle}{\lambda_i(\theta) + \lambda_j(\theta)} |e_i(\theta) \rangle \langle e_j(\theta) |, \tag{9}
$$

with the sum being over all pairs of i and j for which $\lambda_i(\theta) + \lambda_j(\theta) \neq 0$. The maximum of $F(\theta)$ in [\(5\)](#page-1-2) is obtained by considering the projective measurement in the eigenbasis of the SLD [\[42,](#page-12-2) [43,](#page-12-7) [136,](#page-15-3) [137\]](#page-15-0). For the parameter θ encoded in a pure state $|\psi(\theta)\rangle$, QFI simplifies to

$$
F_Q(\theta) = 4 \left[\langle \dot{\psi}(\theta) | \dot{\psi}(\theta) \rangle - | \langle \dot{\psi}(\theta) | \psi(\theta) \rangle |^2 \right], \quad (10)
$$

where $|\psi(\theta)\rangle$ refers to the derivative of $|\psi(\theta)\rangle$ with respect to θ [\[137,](#page-15-0) [151\]](#page-15-4).

The minimum uncertainty in measuring a parameter, obtained so far, is optimal with respect to all possible measurements, but still depends on initial choice of inputs $\rho_0^{\otimes \nu}$. So, an optimization over the initial states also has to be done in order to possibly increase the accuracy of the measurement [\[19,](#page-12-4) [48\]](#page-13-1).

Hence, the minimum deviation in the estimation of θ takes the form

$$
\Delta \theta_{opt} = \min_{\rho_0^{\otimes \nu}} \frac{1}{\sqrt{\nu F_Q(\theta)}}.
$$
\n(11)

Here $F_Q(\theta)$ refers to the quantum Fisher information for a single copy of the input probe, which can be either product or entangled, and ν is the number of copies of that probe. The number of times the whole estimation is repeated is considered to be one.

In some situations, the optimal state is easy to determine. For example, let the parameter θ be encoded in the state through a unitary operator of the form $U(\theta) = e^{-i\tilde{H}\theta}$, with \tilde{H} being the generator of the unitary, independent of θ . In this situation, it can be shown that the best input state for attaining the minimum error in θ is of the form

$$
|\psi(\theta)\rangle_{opt} = (|\lambda_{\text{max}}\rangle + |\lambda_{\text{min}}\rangle)/\sqrt{2},
$$
 (12)

where $|\lambda_{\text{max}}\rangle$ and $|\lambda_{\text{min}}\rangle$ are the respective eigenvectors associated with the highest and lowest eigenvalues of the genera-tor H [\[19,](#page-12-4) [48,](#page-13-1) [185\]](#page-16-0). Additionally, for the unitary $U(\theta, \phi) =$ $e^{-i(\tilde{H}_1\theta + \tilde{H}_2\phi)}$, where $[\tilde{H}_1, \tilde{H}_2] = 0$, while estimating θ or ϕ independently, the best choice of input states remains the same as in Eq. (12) , with the eigenvectors corresponding to \tilde{H}_1 and \tilde{H}_2 respectively. For a situation where \tilde{H}_1 and \tilde{H}_2 do not commute, the best input state cannot be obtained following this scheme.

In this paper, we focus on the minimum error, as given by the right hand side of (11) , in the estimation of a parameter, say θ , by obtaining the QFI directly from Eq. [\(8\)](#page-1-3) and choosing the optimal input states following the prescription around Eq. (13) of the same. This actually presents the Fisher information-based lower bound for the deviation in estimation of an unknown parameter θ , where the measurement basis is taken to be the eigenbasis of SLD, which is the optimal choice of basis. In further discussions, we will only concentrate on this Fisher information-based lower bound, with optimal choice of basis and inputs, and this quantity will be denoted as $\Delta\theta$, for the parameter θ .

III. GLASSY DISORDER: ORIGINS, MODELS AND AVERAGING

For acquiring better precision in metrological estimations, an experiment should be repeated a large number of times to attain the Cramér-Rao lower bound. The high number of repetitions of the measurements, in turn, can cause some fluctuations or imperfections in the system parameters which may drive the system some "distance" away from its ideal nature. Also, as a consequence of the failure to construct an ideal experimental setup, disorder can appear in a system while tuning the parameters of the setup. Irrespective of the origin of the disorder, it may affect the efficiency of a measurement scheme, while estimating an unknown parameter. In this paper, we consider scenarios, where some types of disorder are present in a system in the form of randomness, incorporated into the parameters of the system. We take the disorder parameter to be glassy, which means that the equilibration time of the disorder in the system is several orders of magnitude larger than the relevant observation time. For a specific realization (configuration) of the disorder, the disordered parameters virtually do not alter during the time of investigation [\[172,](#page-15-5) [176–](#page-15-6) [181\]](#page-16-1). They may change after a long time, but that time span is not in our range of interest. Such "glassy" systems have also been called "quenched" disordered systems [\[111,](#page-14-5) [114,](#page-14-6) [116\]](#page-14-7). In such scenarios, the disorder averaging must be performed after evaluation of the relevant physical quantity, which, in our case, is the Fisher information-based lower bound of the minimum uncertainty in measuring the parameter to be estimated, in presence of glassy disorder in the system. A similar averaging is performed for calculating quantities like magnetization and entanglement in glassy systems [\[113,](#page-14-8) [114\]](#page-14-6). Further details of the origin of disorder in physical systems, the different disorder models and the disorder-averaging method for glassy disorder are provided in the succeeding subsections.

A. How can glassy disorder appear in a physical system?

Let us begin by examining the origin of such disorders in certain physical measuring devices, specifically in the context of atomic clocks. The precision of time measurement in an atomic clock relies on accurately estimating the frequency of a two-level atom, employing the principle of Ramsey interferometry. An atomic clock functions essentially as an oscillator, where its frequency is tuned to match the transition frequency of a two-level atom. This tuning allows for the precise measurement of the number of oscillations of the atom, effectively defining one second. To delve deeper into this concept let us consider a beam of identical two-level atoms described by the Hamiltonian \mathcal{H}_1 , emerging from an oven [\[165\]](#page-15-7). The energy difference between their levels is $\hbar\omega$, with ω being an unknown parameter. This atom beam traverses between two points, A and B , within a waveguide, subject to two microwave pulses originating from a source with a frequency ω_f . During the interaction of the atom with the microwave pulse at point A, a coherent superposition of the excited $(|0\rangle)$ and ground $(|1\rangle)$ states is generated, each with equal weight. The atom then evolves freely up to point B in time t, creating a phase difference of $\delta \phi = (\omega - \omega_f)t$ between the atomic superposition and the field. At point B, a second microwave pulse is introduced, and the detector, placed after the point B , measures the probability of the atom being in the ground state of \mathcal{H}_1 , denoted as $p = (1 + \cos(\delta\phi))/2$. To achieve the maximum transition probability p, the oscillator frequency ω_f is adjusted to obtain the match, $\omega_f = \omega$. This procedure enables us to estimate the unknown frequency gap of the two-level system, which can, in turn, be used to determine the number of atomic oscillations, thus setting the standard for defining one second. However, due to controlled probing of atoms, there may exist tunable disorder within the atom, altering the energy gap between the two levels to $\hbar\omega(1+\epsilon)$ or $\hbar(\omega+\epsilon)$, so that the altered Hamiltonians are H_1 or H_2 respectively, where ϵ is a small parameter, which varies according to some known probability distribution. We consider the disorder parameter ϵ , to be fixed for a particular trial of experiment, but selected randomly from a known distribution. It varies unpredictably from one trial to another, but once realized, it is known and fixed for that trial, and is distributed according to a known probability density. In this paper, we show that, the presence of impurities modelled as H_1 , can, in certain instances, reduce the error in estimating ω , consequently enhancing the accuracy of frequency estimation. Consequently, the tuning of the frequency of the oscillator with the beam of atoms that have impurities, will be more precise. If we now connect this finely-tuned oscillator to an ideal, disorder-free beam of atoms, it will accurately count the oscillations, even though impurities were initially present in the atoms during the frequency estimating process. Such disordered systems can be effectively modeled in several physical systems [\[166,](#page-15-8) [167\]](#page-15-9). Let us consider the possibility of implementing it in ultracold gas systems [\[167–](#page-15-9)[170\]](#page-15-10), which also offers a variety of options, of which we utilize the choice of realizing it in composite fermions formed by fermions and bosonic holes [\[166,](#page-15-8) [170\]](#page-15-10). The effective Hamiltonian in this system contains nearestneighbor hopping and spin-spin interaction (of strengths d_{ij}) and K_{ij} respectively), and onsite energy terms (of strength μ_i). The d_{ij} and K_{ij} are proportional to J^2/V , where J and V are respectively the tunneling rate and onsite inter-particle interaction strength of the parent Bose-Fermi Hubbard model. In the limit of small J^2/V , one is left with an effective Hamiltonian of spinless fermions that is a sum of several decoupled single-particle Hamiltonians of the form in Eq. [\(29\)](#page-5-1), with the ϵ being independently and identically distributed from one site to the other. Performing interference experiments with each site of that physical system will potentially lead to the desired data required for obtaining a disorder-averaged minimum deviation in frequency estimation, and a potential demonstration of the disorder-enhanced precision in atomic clocks. Note that interferometry with systems of ultracold gas systems is a reality. See e.g. [\[171\]](#page-15-11) for a recent reference.

B. Models of disorder

We enumerate below the models of glassy disorder that we will consider in this paper. In each case, the "strength" of the disorder is ascertained by the standard deviation of the probability distribution. In the case of the Cauchy-Lorentz disorder, the mean and hence the standard deviation does not exist. The strength in such a case can be defined by using the semi-interquartile range of the distribution.

• G: *Gaussian disorder.* In this scenario, the disorder parameter, ϵ , is chosen from a Gaussian distribution with a mean of zero and a standard deviation of σ_G , and the corresponding probability density function is given by

$$
P(\epsilon) = \frac{1}{\sigma_G \sqrt{2\pi}} e^{-(\epsilon/\sigma_G \sqrt{2})^2}, \quad -\infty \le \epsilon \le \infty.
$$
 (13)

• CL: *Cauchy-Lorentz disorder.* This disorder is quite different from the others as the mean does not exist for this distribution. The disorder parameter ϵ is distributed as

$$
P(\epsilon) = \frac{1}{\gamma \pi} \left(\frac{\gamma^2}{\epsilon^2 + \gamma^2} \right), \quad \text{where} \quad -\infty < \epsilon \leq \infty. \tag{14}
$$

As mentioned above, the mean and standard deviation do not exist for this distribution. The strength of the disorder for this distribution is discussed in the succeeding subsection.

 \bullet \mathbf{D}_1 : *a discrete disorder*. For this instance, the disorder parameter ϵ is distributed as

$$
P(\epsilon) = \frac{(1-p)}{2} \quad \text{when} \quad \epsilon = \pm \alpha,
$$

= p \quad \text{when} \quad \epsilon = 0,
= 0 \quad \text{otherwise,} \tag{15}

with $\alpha > 0$ and $0 \le p < 1$. The standard deviation of the probability distribution is given by

$$
\sigma_{D_1} = \alpha \sqrt{1 - p}.\tag{16}
$$

• D_2 : *a discrete disorder*. This is another discrete distribution which is somewhat different from D_1 . Here the ϵ is distributed as

$$
P(\epsilon) = \frac{1}{2} \quad \text{when} \quad \epsilon = \pm \alpha,
$$

= 0 \quad \text{otherwise}, \tag{17}

for $\alpha > 0$. This distribution has a standard deviation $\sigma_{D_2} = \alpha$, which provides the strength of this disorder.

• G1: *a modulated Gaussian disorder.* This is a continuous distribution with mean zero. The corresponding probability distribution function is given by

$$
P(\epsilon) = \frac{1}{A_1} |\epsilon^2 - 1| e^{-(\epsilon^2/a^2)} \quad -\infty \le \epsilon \le \infty,
$$
 (18)

where

$$
A_1 = \int_{-\infty}^{\infty} |\epsilon^2 - 1| e^{-(\epsilon^2/a^2)} d\epsilon,
$$

and $a > 0$. The strength of this disorder is characterized by the standard deviation of the distribution,

$$
\sigma_{G_1} = \frac{1}{2} \Big[a^3 \Big(2\sqrt{\pi} (2 - 3a^2) \operatorname{erf} \Big(\frac{1}{a} \Big) + a e^{-\frac{1}{a^2}} \Big(\sqrt{\pi} \sqrt{\frac{1}{a^2}} e^{\frac{1}{a^2}} (3a^2 - 2) + 12 \Big) \Big) \Big]^{1/2}, \, (19)
$$

where $\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-y^2} dy$.

• G2: *a modulated Gaussian disorder.* Another continuous distribution with mean zero and a steeper gradient, in comparison to G_1 , is represented by the distribution function,

$$
P(\epsilon) = \frac{1}{A_2} |\epsilon^2 - 1|^2 e^{-(\epsilon^2/a^2)} \quad -\infty \le \epsilon \le \infty,
$$
 (20)

where

$$
A_2 = \int_{-\infty}^{\infty} |\epsilon^2 - 1|^2 e^{-(\epsilon^2/a^2)} d\epsilon,
$$

and $a > 0$. The standard deviation in this case is

$$
\sigma_{G_2} = \left[\frac{\sqrt{\pi}a^3}{8}\left(15a^4 - 12a^2 + 4\right)\right]^{1/2}.\tag{21}
$$

• G3: *a modulated Gaussian disorder.* This represents a distribution sharper than G_2 . The disorder parameter ϵ is, in this case, distributed as

$$
P(\epsilon) = \frac{1}{A_3} |\epsilon^2 - 1|^4 e^{-(\epsilon^2/a^2)} \quad -\infty \le \epsilon \le \infty, \quad (22)
$$

where

$$
A_3 = \int_{-\infty}^{\infty} |\epsilon^2 - 1|^4 e^{-(\epsilon^2/a^2)} d\epsilon,
$$

and $a > 0$. Again we define the strength of the disorder as the standard deviation of the probability distribution, given by

$$
\sigma_{G_3} = \left[\frac{\sqrt{\pi}}{32a^3} \left(945a^8 - 840a^6 + 360a^4 - 96a^2 + 16\right)\right]^{1/2}.
$$
\n(23)

These disorder models provide advantages in the precision of metrological estimation of the relevant quantities, over the same for the ideal scenario with uncorrelated initial probes, in case of evolution by the disordered Hamiltonian $H₁$. For uncorrelated initial probes, the disorder-averaged error in frequency estimation is non-existent for the Gaussian (G) and Cauchy-Lorentz (CL) distributions. The median, however exists in these cases, and the disorder-averaged median is found to be beneficial over that of the disorder-free scenario. Further, the Gaussian and uniform disorder models provide significant enhancement in measurement precision by incorporating some external fields and interaction between the system particles, when copies of two-qubit states are taken as initial probes. The uniform distribution function is also given below, for completeness.

• U: *Uniform disorder*. In this circumstance, ϵ is distributed as

$$
P(\epsilon) = \frac{1}{s}, \quad \text{when} \quad -\frac{s}{2} \le \epsilon \le \frac{s}{2}
$$

= 0 otherwise. (24)

The strength of the disorder, quantified by the standard deviation of the distribution, is given by $\sigma_U = \frac{s}{2\sqrt{3}}$ $rac{s}{2\sqrt{3}}$.

C. Disorder averaging

When the disorder parameters of a system are glassy, the relevant physical quantities are the glassy disorder-averaged versions of the corresponding quantities, which we will simply refer to as disorder-averaged quantities. For glassy disorder, the averaging must be done after the relevant physical quantity has been already computed. Suppose that we want to compute the Fisher information-based lower bound of the minimum uncertainty in measuring frequency, in presence of glassy disorder in the system. Then, we first need to evaluate the uncertainty in measuring frequency, $\Delta \tilde{\omega}_{\epsilon}(t)$, encoded in a physical system, for an arbitrary but fixed time t , and for an arbitrary but fixed configuration of the disorder. The disorderaveraged deviation in frequency is then given by

$$
\Delta \tilde{\omega}_{\mathcal{Q}}(t) = \int_{-\infty}^{\infty} \Delta \tilde{\omega}_{\epsilon}(t) P(\epsilon) d\epsilon,.
$$
 (25)

with $P(\epsilon)$ being the probability distribution of the disorder parameter ϵ . A similar averaging is performed for calculating physically relevant quantities like magnetization and entanglement in glassy systems. For discrete probability distributions, the integral is substituted by a summation.

The mean of a probability distribution gives a measure of its central tendency. The mean, however, is non-existent in certain cases. In those cases, or otherwise, it may be useful to use the median, which is the middlemost value of the distribution, and it exists for all probability distributions. If we arrange the functional values of a distribution in increasing (equivalently decreasing) order, and move from the lowest (or highest) value towards the middle, then the middlemost point where one arrives is the median. Since our relevant function is $1/|1+\epsilon|$, which has its maximum at $\epsilon = -1$, we move from the maximum functional value towards the middle. Therefore, to obtain the median, $x_{M_{\epsilon}}$, in this case, the following equation can be solved:

$$
\int_{-1-x_{M_{\epsilon}}}^{-1+x_{M_{\epsilon}}} P(\epsilon)d\epsilon = \frac{1}{2}.
$$
 (26)

The solution gives $x_{M_{\epsilon}}$ corresponding to the probability distribution $P(\epsilon)$, from which one can calculate the median $M_{\epsilon} = 1/|1 + x_{M_{\epsilon}}|$. In a similar fashion, the first and third quartiles, Q_1 and Q_3 respectively, can be obtained by first solving

$$
\int_{-1-x_{Q_1}}^{-1+x_{Q_1}} P(\epsilon)d\epsilon = \frac{1}{4} \quad \text{and} \quad \int_{-1-x_{Q_3}}^{-1+x_{Q_3}} P(\epsilon)d\epsilon = \frac{3}{4},\tag{27}
$$

for x_{Q_1} and x_{Q_3} respectively, and then using $Q_i = 1/|1 + \frac{1}{2}$ x_{Q_i} , for $i = 1, 3$. The semi-interquartile range is then given by $Q = (Q_3 - Q_1)/2$.

In presence of disorder, a system naturally undergoes disorder-induced fluctuations. As a result, there may occur oscillations in the variance, Δ , of the estimated parameter, about a mean value with a standard deviation. Now, if the "advantage", $\beta = \Delta \tilde{\omega}_0(t) - \Delta \tilde{\omega}_Q(t)$, of the disordered model over the ideal scenario in a parameter estimation protocol is greater than the standard deviation, $\tilde{\sigma}$, in $\Delta \tilde{\omega}_{\epsilon}(t)$, due to the disorder-induced distribution of the variance of the estimated parameter, then the situation can be referred to as a disorderinduced enhancement over the ideal situation. In cases when the mean and standard deviation of Δ do not exist, we use the median [\[182,](#page-16-2) [183\]](#page-16-3) and the semi-interquartile range of Δ . The semi-interquartile range, like the standard deviation, is a measure of dispersion of a data [\[182,](#page-16-2) [183\]](#page-16-3). Here, the disorderaveraged deviation in frequency is given by $\Delta\tilde{\omega}_Q(t)$, $\Delta\tilde{\omega}_0(t)$ represents the Fisher information-based lower bound of minimum error in estimating ω in an ideal scenario and $\Delta\tilde{\omega}_{\epsilon}(t)$ is the uncertainty in measuring frequency, encoded in a physical system, for an arbitrary but fixed time t and for an arbitrary but fixed configuration of the disorder. In this paper, in all cases, we consider the relative advantage and the corresponding standard deviation, and rechristen them as β and $\tilde{\sigma}$. This is attained by dividing the original quantities by $\Delta\tilde{\omega}_0(t)$. In particular, this has the effect of making the derived quantities dimensionless. Suffixes of the quantities will be used to refer to the different disorder distributions used.

We begin by finding the disorder-averaged minimum uncertainty in frequency ω , in presence of the disorder parameter ϵ , incorporated in the Hamiltonian H_1 . For a single-qubit system, with the encoding being effected by a unitary evolution with the unitary $U_1 = e^{-\frac{i}{\hbar}H_1t}$, the optimal input state for measuring ω is $|\psi_0\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$, where $|0\rangle$ and $|1\rangle$ are eigenvectors of H_1 . The QFI in this case is $F_Q^{\epsilon} = t^2(1+\epsilon)^2$. As Fisher information is additive, we can extend this situation to ν copies of $|\psi_0\rangle$, i.e., $|\psi_0\rangle^{\otimes \nu}$, and the disorder-averaged minimum deviation in the estimation of the frequency is given by

$$
\Delta \tilde{\omega}_{\mathcal{Q}}^{(p)}(t) = \int_{\text{lb}}^{\text{ub}} \frac{1}{|1 + \epsilon| t \sqrt{\nu}} P(\epsilon) d\epsilon, \tag{28}
$$

where lb and ub denote respectively the lower bound and upper bound of the corresponding probability distribution function from which ϵ is chosen. We compare the disorder-averaged quantities for the different probability distributions, with the ideal minimum uncertainty in ω , which is $\Delta \tilde{\omega}^{(p)}_0 = \frac{1}{t\sqrt{\nu}}.$

IV. UNBIASED ESTIMATORS AND THE QUANTUM CRAMER-RAO BOUND IN PRESENCE OF GLASSY ´ DISORDER

We consider the insertion of a disorder parameter, into a single-qubit system described by the Hamiltonian \mathcal{H}_1 = $-\hbar\omega$ |1⟩ \langle 1|, with ω being the parameter to be estimated. We incorporate the disorder in two ways into the "ideal" Hamiltonian. The altered forms of the Hamiltonian, with disorder, are taken as

$$
H_1 = -\hbar\omega(1+\epsilon)|1\rangle\langle 1| \tag{29}
$$

and $H_2 = -\hbar(\omega + \epsilon)|1\rangle\langle 1|$, where the disorder is modeled by the parameter ϵ . An unbiased estimator for ω can be found in this disordered situation, and the Cramer-Rao bound therein ´ can also be derived. An explicit derivation is provided below.

For a single-qubit system, with the encoding being effected by a unitary evolution, $U_1 = e^{-\frac{i}{\hbar}H_1t}$, the optimal input state for measuring ω is $|\psi_0\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$, with $|0\rangle$ and $|1\rangle$ being the eigenvectors of H_1 . We perform measurements with projectors from the eigenbasis of SLD of the encoded state, $|\psi_{\omega}\rangle = (|0\rangle + e^{i\omega t} |1\rangle)/\sqrt{2}$. Let these measurement operators belong to the set, $\{M, I_2 - M\}$. Suppose that for the measurement operator M , the corresponding eigenvalue is x_1 and it clicks with probability $p_1 = \text{Tr}(M|\psi_\omega\rangle\langle\psi_\omega|)$, while for $I_2 - M$, the eigenvalue is x_2 and clicks with probability $p_2 = \text{Tr}((I_2 - M)|\psi_\omega\rangle\langle\psi_\omega|)$. The explicit forms of these probabilities are $p_1 = \frac{1 + \cos(\omega t(1 + \epsilon))}{2}$, and $p_2 = \frac{1 - \cos(\omega t (1 + \epsilon))}{2}$. From these outcomes, we have to estimate the unknown parameter, ω . The time of the measurement is t (where the initial time is 0), which we assume to know exactly, and the disorder parameter ϵ , being glassy, is known to us, although can take arbitrary values within a given distribution that depends on the material used. The disorder parameter, therefore, varies unpredictably from one trial to another, but once realized, it is known and fixed for all measurements performed in that trial, and is distributed according to a known probability density. A suitable estimator in our case is $\hat{\omega}(x)$: $\{x_1, x_2\}$ $\rightarrow \mathbb{R}^+ \cup \{0\}$, given by

$$
\hat{\omega}(x_1) = \frac{\cos^{-1}(2p_1 - 1)}{t(1 + \epsilon)}, \quad \hat{\omega}(x_2) = \frac{\cos^{-1}(1 - 2p_2)}{t(1 + \epsilon)}.
$$
 (30)

The values of t and ϵ are pre-determined or determined from an analysis of the glassy material, and p_1 and $p_2(= 1 - p_1)$ are obtained after the measurements, and can be utilized in Eq. [\(30\)](#page-5-2) to estimate the unknown parameter, ω . It may be noted that for the scenario at hand, the estimators are not explicitly dependent on the values of the random variables, x_1 and x_2 . We now try to see whether this estimator is unbiased. The average of the estimator function is given by

$$
\langle \hat{\omega}(x) \rangle = \hat{\omega}(x_1) p_1 + \hat{\omega}(x_2) p_2. \tag{31}
$$

If we substitute the expressions of p_1 and p_2 in Eq. [\(31\)](#page-5-3), then we obtain, $\langle \hat{\omega}(x) \rangle = \omega(p_1 + p_2) = \omega$. This proves that the estimator function is indeed unbiased.

We now derive the quantum Cramér-Rao bound involving the standard deviation of the estimator, for the disordered scenario. We begin with the identity given in Eq. (31) , which can be rewritten as

$$
\sum_{i=1}^{2} \Delta \omega_i p_i = 0, \tag{32}
$$

where $\Delta \omega_i = \hat{\omega}(x_i) - \langle \hat{\omega} \rangle$. Now if we take the derivative of the left hand side of Eq. [\(32\)](#page-5-4), we obtain

$$
\sum_{i=1}^{2} \Delta \omega_i (p_i \frac{\partial \ln p_i}{\partial \omega}) = -\sum_{i=1}^{2} \frac{\partial (\Delta \omega_i)}{\partial \omega} p_i
$$

$$
= \frac{\partial \langle \hat{\omega} \rangle}{\partial \omega}.
$$
(33)

The second equality follows from the fact that $\hat{\omega}(x_i)$ is independent of ω . Now, an use of the Cauchy-Schwartz inequality in Eq. (33) yields

$$
\left(\sum_{i=1}^{2} \Delta \omega_{i}\right)^{2} \left(\sum_{i=1}^{2} p_{i} \frac{\partial \ln p_{i}}{\partial \omega}\right)^{2} \ge \left|\frac{\partial \langle \hat{\omega} \rangle}{\partial \omega}\right|^{2}
$$

$$
\implies \left(\sum_{i=1}^{2} \Delta \omega_{i}\right)^{2} \ge \left(\sum_{i=1}^{2} p_{i} \frac{\partial \ln p_{i}}{\partial \omega}\right)^{-2}, \qquad (34)
$$

which is the Cramer-Rao bound. The second inequality [\(34\)](#page-6-1) follows from the unbiased nature of the estimator, i.e., $\langle \hat{\omega}(x) \rangle = \omega$ in our case. Finally, if we evaluate the quantity on the right hand side of inequality [\(34\)](#page-6-1), using the expressions of p_1 and p_2 , we get

$$
\left(\sum_{i=1}^{2} \Delta \omega_i\right)^2 \ge \frac{1}{t^2 (1+\epsilon)^2},\tag{35}
$$

where t denotes the time duration for which the unitary operator, U_1 , acts on the probe, and ϵ is the disorder parameter. The parameter t is also the time at which the SLD measurement is performed. Since this bound $(Eq. (35))$ $(Eq. (35))$ $(Eq. (35))$ corresponds to an optimal measurement, it actually gives the QFI, and the bound is the quantum Cramér-Rao inequality in this case. Therefore, the QFI, in this scenario, is given by $F_Q^{\epsilon} = t^2(1+\epsilon)^2$, for a single copy of the probe.

V. RESPONSE TO GLASSY DISORDER DISTRIBUTIONS IN ESTIMATING FREQUENCY

In this section, we present specific instances of "order from disorder" scenarios, which can be viewed as a valuable aspect in the design of a highly precise atomic clock. We consider the disordered Hamiltonians H_1 and H_2 (see Eq. [\(29\)](#page-5-1)), where the disorder parameter ϵ is selected randomly from several paradigmatic distributions, both discrete and continuous. While considering single-qubit systems, we have utilized the Gaussian (G) , Cauchy-Lorentz CL), two discrete $(D_1$ and D_2) and three modulated Gaussian (G_1, G_2 and G_3) probability distributions for uncorrelated initial probes. We will find that the metrological estimation provides order from disorder for certain cases.

Gaussian glassy disorder G

We calculate the disorder-averaged median, $M_G = 1/|1 + \epsilon|$ x_{M_G} , by solving x_{M_G} from $\tilde{erf}(x_{M_G}) = (\text{erf}(1 + x_{M_G})$ erf $(1 - x_{M_G})$) $/\sqrt{2\sigma_G}$ corresponding to the probability distribution G. Note that the mean does not exist in this case. Fig. [1](#page-6-3) depicts that the advantage, $1 - M_G$, is positive and is significantly higher than the semi-interquartile range, Q_G , with the standard deviation, σ_G , of G plotted along horizontal axis. Thus the presence of disorder is advantageous over the disorder-free scenario, hence displaying order from disorder.

FIG. 1. Disorder-induced enhancement in frequency estimation for uncorrelated initial probes. Here we depict the difference between the true value of the median with the disorder-averaged median in the estimation of ω (blue dashed curve), and compare with its semiinterquartile range (orange curve). The subscript, G, denotes that the disorder parameter ϵ is chosen randomly from a Gaussian distribution G. All quantities plotted are dimensionless.

FIG. 2. Disorder-induced enhancement in frequency estimation for uncorrelated initial probes. Here we depict the difference between the true value of the median and the disorder-averaged median in the estimation of ω (blue dashed curve), and compare with its semiinterquartile range (orange curve). The subscript, CL, denotes that the disorder parameter ϵ is chosen randomly from a Cauchy-Lorentz distribution. All quantities plotted are dimensionless.

B. Cauchy-Lorentz glassy disorder CL

In this case, the disorder-averaged median, $M_{CL} = 1/11 +$ x_{MCL} , can be evaluated by solving [\[184\]](#page-16-4)

$$
\frac{1}{\pi} \left[\tan^{-1} \left(\frac{x_{M_{CL}} + 1}{\gamma} \right) + \tan^{-1} \left(\frac{x_{M_{CL}} - 1}{\gamma} \right) \right] = \frac{1}{2}, \tag{36}
$$

which gives $x_{MCL} = \sqrt{1 + \gamma^2}$. Note that the mean does not exist in this case also, and hence we have looked at the median. The relative advantage, $1 - M_{CL}$, is always positive. We have also compared this advantage with the semiinterquartile range, which, in this case, is given by Q_{CL} = $(1 + \sqrt{1 + 2\gamma^2})/((1 + \sqrt{1 + 2\gamma^2})^2 - \gamma^2)$, which is less than the relative advantage, $1 - M_{CL}$, in a certain range of γ (re-

FIG. 3. Disorder-induced enhancement in frequency estimation for uncorrelated initial probes. Here we depict the effect of discrete glassy disorder on the minimum deviation of estimation of ω , encoded in each of the initial states by evolving them with the Hamiltonian H_1 . The disorder parameter ϵ is chosen randomly from the discrete distribution D_1 in (a) and from D_2 in (b). The blue surface (dashed line) in panel (a) ((b)) depicts the quantity β_{D_1} (β_{D_2}) and the corresponding yellow surface (solid line) presents the standard deviation $\tilde{\sigma}_{D_1}$ ($\tilde{\sigma}_{D_2}$). All qunatities plotted are dimensionless.

fer to Fig. [2\)](#page-6-4). Thus we again obtain the phenomenon of order from disorder.

C. Discrete glassy disorder of type D_1

For the disorder parameter ϵ chosen from the discrete distribution, D_1 , the disorder-averaged frequency deviation, for ν copies of uncorrelated probes, is given by

$$
\Delta \tilde{\omega}_{\mathcal{Q}_{D_1}}^{(p)}(t) = \frac{1}{t\sqrt{\nu}} \left[\frac{1-p}{2} \left(\frac{1}{|1-\alpha|} + \frac{1}{1+\alpha} \right) + p \right]. \tag{37}
$$

At $\alpha = 1$, the function $\Delta \tilde{\omega}_{Q}^{(p)}$ $\mathcal{Q}_{D_1}(t)$ diverges. We find that for $\alpha \geq \frac{1+\sqrt{5}}{2} \approx 1.618$, the error in frequency in presence of glassy disorder of type D_1 , has an advantage over the ideal scenario i.e., $\Delta \tilde{\omega}_{Q_r}^{(p)}$ $\mathcal{Q}_{D_1}(t) < \Delta \tilde{\omega}_0^{(p)}(t)$, $\forall t$. The blue surface of Fig. [3-](#page-7-0)(a) presents the relative advantage, β_{D_1} = $\Delta\tilde{\omega}_{0}^{(p)}(t) - \Delta\tilde{\omega}_{\mathcal{Q}_{D_1}}^{(p)}(t)$ $\frac{\omega_{D_1}}{\Delta \tilde{\omega}_0^{(p)}(t)}$, with respect to α and p . β_{D_1} exhibits positive values, which signifies a possibility of obtaining an order from disorder situation for the discrete glassy disorder D_1 . But, for further assurance, we have to compare β_{D_1} with the standard deviation in $\Delta \tilde{\omega}_{\epsilon_{D_1}}^{(p)}(t)/\Delta \tilde{\omega}_0^{(p)}(t)$. Suppose, the standard deviation is denoted as $\tilde{\sigma}_{D_1}$. The behavior of $\tilde{\sigma}_{D_1}$ is shown by the yellow surface of the said figure, which is much smaller than β_{D_1} across a wide range of the $\alpha - p$ space for $\alpha \gtrsim 1.618$. This implies that we can have disorder-induced enhancements in efficiency of the frequency measurement for $\alpha \gtrsim 1.618$ for the disorder model D_1 .

D. Discrete glassy disorder of type D_2

If ϵ is chosen randomly from the discrete distribution D_2 , the disorder-averaged minimum deviation in estimation of frequency, for ν copies of uncorrelated probes, is given by

$$
\Delta \tilde{\omega}_{\mathcal{Q}_{D_2}}^{(p)}(t) = \frac{1}{2t\sqrt{\nu}} \Big[\frac{1}{|1-\alpha|} + \frac{1}{1+\alpha} \Big].
$$
 (38)

Like in the case of D_1 , here also $\Delta \tilde{\omega}_{Q}^{(p)}$ $\mathcal{Q}_{D_2}(t)$ diverges for $\alpha =$ 1 and the advantage, i.e., $\Delta \tilde{\omega}_{Q_r}^{(p)}$ $\mathcal{Q}_{D_2}^{(p)}(t) < \Delta \tilde{\omega}_0^{(p)}(t)$, is obtained only for the region, $\alpha \geq \frac{1+\sqrt{5}}{2} \approx 1.618$ The behavior of the relative advantage, $\beta_{D_2} = \frac{\Delta \tilde{\omega}_0^{(p)}(t) - \Delta \tilde{\omega}_{Q_{D_2}}^{(p)}(t)}{\Delta \tilde{\omega}_0^{(p)}(t)}$ $\frac{\mathcal{L}_{D_2}}{\Delta \tilde{\omega}_0^{(p)}(t)}$, along with the standard deviation in $\Delta \tilde{\omega}_{\epsilon_{D_2}}^{(p)}(t)/\Delta \tilde{\omega}_0^{(p)}(t)$, represented by $\tilde{\sigma}_{D_2}$, with respect to α are depicted in Fig. [3-](#page-7-0)(b), for $\alpha \gtrsim$ 1.618. It should be noted that $\tilde{\sigma}_{D_2}$ is significantly lower than β_{D_2} . This suggests that there occurs the order from disorder effect using this distribution for $\alpha \gtrsim 1.618$.

E. Modulated Gaussian glassy disorder of type G_1

For the modulated Gaussian disorder of type G_1 , the minimum error in estimation of frequency, ω , of the Hamiltonian H_1 of Eq. [\(29\)](#page-5-1), for ν uncorrelated initial probes, is

$$
\Delta \tilde{\omega}_{\mathcal{Q}_{G_1}}^{(p)} = \frac{1}{t\sqrt{\nu}} \frac{2a + e^{1/a^2} \sqrt{\pi} + 2e^{1/a^2} \sqrt{\pi} \operatorname{erf}(\frac{1}{a}) - 1}{\left[-4a + \sqrt{\pi}e^{1/a^2} (2 - a^2)(1 - 2\operatorname{erf}(\frac{1}{a})) \right]},
$$
\n(39)

FIG. 4. Disorder-induced enhancement in frequency estimation for uncorrelated initial probes. Here we present the effect of modulated Gaussian glassy disorders on the minimum deviation of estimation of ω , encoded in each of the initial states by evolving them with the Hamiltonian H_1 . This figure depicts the quantity $\tilde{\beta}_{G_i} = \frac{\Delta \tilde{\omega}_{G_i}^{(p)}(t)}{\Delta \tilde{\omega}_{G_i}^{(p)}(t)}$ $\frac{\partial G_i}{\partial \Delta \tilde{\omega}_0^{(p)}(t)}$ for $i = 1, 2, 3$, denoting the three modulated Gaussian distributions G_1, G_2 and G_3 respectively. The quantities $\{\beta G_1, \tilde{\sigma} G_1\}$, $\{\beta G_2, \tilde{\sigma} G_2\}$ and $\{\beta G_3, \tilde{\sigma} G_3\}$ are plotted with respect to the parameter a in case of the distributions G_1 , G_2 and G_3 respectively in panels (a), (b) and (c). The quantities β_{G_i} are is presented by the blue dashed lines and the quantities $\tilde{\sigma}_{G_i}$ are demonstrated with yellow solid lines in all the panels. All quantities plotted along the horizontal and vertical axes are dimensionless.

where $\text{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-y^2} dy$. From the nature of the quantity $\frac{\Delta \tilde{\omega}_{\mathcal{Q}_{G_1}}^{(p)}(t)}{\Delta z^{(p)}(t)}$ $\frac{\mathcal{Q}_{G_1}}{\Delta \tilde{\omega}_0^{(p)}(t)}$, with the variation of a (see Fig. [4-](#page-8-0)(a)), it is evident that this glassy system allows $\Delta \tilde{\omega}_{Q}^{(p)}$ $\mathcal{Q}_{G_1}(t) < \Delta \tilde{\omega}_0^{(p)}(t).$ For this particular distribution, the standard deviation in $\Delta \tilde{\omega}_{\epsilon_{G_1}}^{(p)}(t) / \Delta \tilde{\omega}_0^{(p)}(t)$, given by $\tilde{\sigma}_{G_1}$, is also less than the corresponding $\tilde{\beta}_{G_1}$, hence exhibiting order from disorder.

F. Modulated Gaussian glassy disorder of type G_2

For this glassy disorder situation, the disorder parameter, ϵ , is chosen from the distribution G_2 . The disorder-averaged frequency deviation for this case for ν copies of initial uncorrelated probes is

$$
\Delta \tilde{\omega}_{\mathcal{Q}_{G_2}}^{(p)} = \frac{1}{t\sqrt{\nu}} \left[\frac{4\left[(a+a^3)\frac{1}{\sqrt{e}} - \frac{1}{2}(a^2 - 2)\sqrt{\pi} \operatorname{erf}(\frac{1}{a}) \right]}{(4 - 4a^2 + 3a^4)\sqrt{\pi}} \right].
$$
\n(40)

Fig. [4-](#page-8-0)(b) shows that the relative advantage, β_{G_2} = $\Delta \tilde{\omega}^{(p)}_0(t) - \Delta \tilde{\omega}^{(p)}_{{\cal Q}_{G_2}}(t)$ $\frac{Q_{G_2}}{\Delta \tilde{\omega}_0^{(p)}(t)}$, is much greater than $\tilde{\sigma}_{G_2}$, which is the standard deviation in $\Delta\tilde{\omega}_{\epsilon_{G_2}}^{(p)}(t)/\Delta\tilde{\omega}_0^{(p)}(t)$. So, the occurrence of an order from disorder situation is prominently present in this situation.

G. Modulated Gaussian glassy disorder of type G³

The disorder-averaged frequency deviation for ν copies of initial uncorrelated probes is given in this case by

$$
\Delta \tilde{\omega}_{Q_{G_3}}^{(p)} = \frac{1}{t\sqrt{\nu}} \frac{4 \left[2a(2 - 3a^2 + 4a^4)e^{-1/a^2} + (4 - 4a^2 + 3a^4)\sqrt{\pi} \operatorname{erf}(\frac{1}{a}) \right]}{(16 - 32a^2 + 72a^4 - 120a^6 + 105a^8)\sqrt{\pi}},\tag{41}
$$

for estimating the frequency ω of the Hamiltonian in Eq. [\(29\)](#page-5-1). Here the range of the distribution parameter a , providing an enhancement in frequency estimation, is better than the previous two continuous distributions, G_1 and G_2 . Compare the three curves of Fig. [4.](#page-8-0) To ensure that this advantage is a disorder-induced enhancement in precision of measurement, we have plotted the relative advantage, β_{G_3} $\Delta \tilde{\omega}^{(p)}_0(t)$ $- \Delta \tilde{\omega}^{(p)}_{{\cal Q}_{G_3}}$ $\frac{\epsilon_{G_3}}{\Delta \tilde{\omega}_0^{(p)}}$, and the standard deviation of $\Delta\tilde{\omega}_{\epsilon\alpha}^{(p)}$ $\frac{\sigma_{\epsilon_{G_3}}(t)}{(\epsilon_{G_3}(t)/\Delta\tilde{\omega}_0^{(p)}(t))}$, given by $\tilde{\sigma}_{G_3}$, in Fig. [4-](#page-8-0)(c). It can be seen that β_{G_3} is positive, and $\tilde{\sigma}_{G_3}$ is substantially lower than β_{G_3} . So here also, we attain the phenomenon of order from disorder.

We compare the disorder-induced advantages in frequency estimation for the distributions, G_1 , G_2 and G_3 as functions of the parameter a in Fig. [5.](#page-9-1) We find that the minimum error is obtained by G_3 , followed by G_2 and G_1 .

Note that not all disorder distributions lead to benefits in measurement precision. A discussion on the response to such disorder models in frequency estimation is provided in Appendix [A.](#page-11-1) Also, an ideal system sometimes is not effected by some disorder models. The Hamiltonian H_2 is an example of this case. We now study whether there is an enhancement in the efficiency of measurement precision, in presence of glassy

FIG. 5. Disorder-induced enhancement in frequency estimation for uncorrelated initial probes. Here we present the effect of modulated Gaussian glassy disorders on the minimum deviation of estimation of ω , encoded in each of the initial states by evolving them with the Hamiltonian H_1 . We depict here the quantities $\tilde{\beta}_{G_i} = \frac{\Delta \tilde{\omega}_{G_i}^{(p)}(t)}{\Delta \tilde{\omega}_{G_i}^{(p)}(t)}$ $\frac{\infty G_i}{\Delta \tilde{\omega}_0^{(p)}(t)}$ for $i = 1, 2, 3$, corresponding to the three modulated Gaussian distributions G_1 , G_2 and G_3 respectively. All quantities plotted along both the axes are dimensionless.

disordered parameters, for ν copies of initial probes, where each copy is a two-qubit maximally entangled state. The results for cases when there is no interaction between the two probe qubits are discussed below.

VI. MEASUREMENT PRECISION IN PRESENCE OF GLASSY DISORDER FOR COPIES OF TWO-QUBIT MAXIMALLY ENTANGLED INITIAL PROBES

We now study whether there is an enhancement in the efficiency of measurement precision, in presence of glassy disordered parameters, for ν copies of initial probes, of which, each copy is a two-qubit maximally entangled state. Moreover, we study the effect on the precision of incorporating interaction between the system particles and external fields in a disordered system.

We consider a two-qubit system acted upon by the Hamiltonian,

$$
H_3 = -\hbar\omega\big[(1+\epsilon_1)|1\rangle\langle 1| \otimes \mathcal{I} + \mathcal{I} \otimes (1+\epsilon_2)|1\rangle\langle 1|\big], (42)
$$

where ϵ_1 and ϵ_2 are disorder parameters introduced in the ideal system. The optimal input state can be constructed using Eq. [\(12\)](#page-2-1) as $|\phi_0\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$ and the encoded final state after evolving with the unitary $U_3 = e^{-iH_3t}$, comes out to be $|\phi_f\rangle = (|00\rangle + e^{-i(2+\epsilon_1+\epsilon_2)\omega t} |11\rangle)/\sqrt{2}.$ The quantum Fisher information for this case has the form, $F_Q^{\epsilon_1,\epsilon_2} = t^2(2+\epsilon_1+\epsilon_2)^2$, obtained from [\(10\)](#page-1-4). The single-copy scenario of the two-qubit maximally entangled initial state can be extended to ν copies of the same initial probes and the error in frequency for that case turns out to be

$$
\Delta \tilde{\omega}_{\mathcal{Q}}^{(e)} = \int_{\mathrm{lb}_1}^{\mathrm{ub}_1} \int_{\mathrm{lb}_2}^{\mathrm{ub}_2} \frac{1}{t\sqrt{\nu}|2 + \epsilon_1 + \epsilon_2|} P_1(\epsilon_1) P_2(\epsilon_2) d\epsilon_2 d\epsilon_1,
$$
\n(43)

FIG. 6. Disorder-induced enhancement in frequency estimation for copies of two-qubit maximally entangled initial probes. Here we depict the nature of the projection of the quantity $\frac{\Delta \tilde{\omega}_{\mathcal{Q}_{\mathcal{D}}^{(e)}}^{(e)}}{\Delta \tilde{\omega}_{\mathcal{Q}_{\mathcal{D}}^{(p)}}^{(h)}}$ $\frac{Q_{D_1}}{\Delta \tilde{\omega}_0^{(p)}}$, with respect to α_1 and α_2 , for each single copy evolving with the Hamiltonian H_3 . Here we take $p_1 = p_2 = 0.05$. All the quantities plotted along both the axes are dimensionless.

where lb_i and ub_i , for $i = 1, 2$, refer to the lower and upper bounds of the probability distribution functions $P_i(\epsilon_i)$ respectively. Here $P_1(\epsilon_1)$ and $P_2(\epsilon_2)$ are independent of each other. In absence of disorder, the deviation in frequency estimation is $\Delta \tilde{\omega}_0^{(e)} = \frac{1}{2t\sqrt{\nu}} = \frac{1}{2}\Delta \tilde{\omega}_0^{(p)}.$ Therefore to attain an advantage over the ideal case, we need $\frac{\Delta \tilde{\omega}_{\mathcal{Q}}^{(e)}}{\Delta \tilde{\omega}_{0}^{(p)}} < \frac{1}{2}$.

Following the line pursued in case of uncorrelated initial probes, we now investigate the effect of discrete disordered systems by choosing ϵ_1 and ϵ_2 randomly from the discrete disorder of type D_1 . The corresponding probability distribution functions $P_i(\epsilon_i)$ are the same as in Eq. [\(15\)](#page-3-0), with the parameters α_i and probability p_i for $i = 1, 2$ respectively. The minimum deviation in estimation of ω is given by

$$
\Delta \tilde{\omega}_{\mathcal{Q}_{D_1}}^{(e)} = \frac{1}{t\sqrt{\nu}} \Big[\frac{1}{2} \sum_{i,j} p_i (1 - p_j) \left(\frac{1}{|\alpha_j + 2|} + \frac{1}{|2 - \alpha_j|} \right) + \frac{1}{4} \sum_{i,j} \left\{ p_i p_j + (1 - p_i) (1 - p_j) \left(\frac{1}{|\alpha_i - \alpha_j + 2|} + \frac{1}{|(-1)^j (\alpha_i + \alpha_j) + 2|} \right) \right\} \Big].
$$
 (44)

Here i and j both run from 1 to 2. In Fig. [6,](#page-9-2) we plot the projection of the dimensionless quantity $\frac{\Delta \tilde{\omega}_{\mathcal{Q}_{D_1}}^{(e)}}{\Delta z^{(p)}}$ $\frac{\mathcal{Q}_{D_1}}{\Delta \tilde{\omega}_0^{(p)}}$, with respect to α_1 and α_2 , and observe that there is a certain range of α_1, α_2 for a fixed p_1 and p_2 , in which there is an advantage in the measurement precision over the ideal scenario. The advantage is highest in two regions, viz. for small α_1 and high α_2 , and for small α_2 and high α_1 (see the light blue parts of Fig. [6\)](#page-9-2). We have also compared the standard deviation in $\frac{\Delta \tilde{\omega}_{(\epsilon_1)_{D_1}(\epsilon_2)_{D_1}}^{(e)}}{\Delta \tilde{\omega}_{(\epsilon_1)_{D_1}(\epsilon_2)_{D_1}}}$ $\frac{\Delta \tilde{\omega}_0^{(p)}}{\Delta \tilde{\omega}_0^{(p)}}$, with the relative advantage, $\frac{\Delta \tilde{\omega}_0^{(p)} - \Delta \tilde{\omega}_{\mathcal{Q}_{D_1}}^{(e)}}{\Delta \tilde{\omega}_0^{(p)}}$ $\frac{\mathcal{L}_{D_1}}{\Delta \tilde{\omega}_0^{(p)}}$, and notice that there exists a region in the (α_1, α_2) -plane for which the standard

deviation is less than the relative advantage, which tells that in this case also, we obtain a disorder-induced enhancement in the efficiency of measurement over the ideal one. Similar to the single-qubit case, the truncated Cauchy-Lorentz (TGL) and truncated Gaussian (TG) distributions never give an advantage over the disorder-free scenario.

VII. PRESENCE OF ISING INTERACTION BETWEEN THE PROBE QUBITS AND INTRODUCTION OF EXTERNAL FIELDS

We now apply an external field on each of the qubits of a two-qubit single copy of the initial probe, in which the two qubits are also interacting through an Ising interaction. The disorder parameters are introduced in the coupling strengths of the interaction and the fields. The Hamiltonian of the composite system takes the form

$$
H_4 = \overline{H}(\hat{A}, \epsilon) + H_I, \text{ where}
$$

\n
$$
H_I = \hbar J k [(1 + \epsilon_1)\sigma_z^1 + (1 + \epsilon_2)\sigma_z^2] + \hbar J \epsilon_3 (\sigma_z^1 \otimes \sigma_z^2),
$$

with k being a dimensionless constant and ϵ_1 , ϵ_2 and ϵ_3 are the disorder parameters. $\overline{H}(\hat{A}, \epsilon)$ is an arbitrary hermitian operator which may be dependent on some other operators like \hat{A} , or even some disorder parameter ϵ , but is independent of J , and also $[H(A, \epsilon), H_I] = 0$. The parameter J is encoded into the system by evolving each copy of the the initial states by the Hamiltonian H_4 and the best input state is evaluated using Eq. [\(12\)](#page-2-1). Then the Fisher information-based lower bound, $\Delta \tilde{J}_{\mathcal{Q}}^{(2)}$, in estimation of the parameter *J*, in presence of various types of glassy disorders in the system, is evaluated numerically. Here " (2) " in the superscript is to remind us that the copies of two-qubit initial probes, which can be entangled or product, are used for encoding. An important point to be noted here is that while measuring the parameter J of a similar Hamiltonian containing only the interaction term, the best input state becomes a product state, instead of an maximally entangled one [\[185\]](#page-16-0). In this situation also, the entanglement content of the initial probes depends on the relative values of disorder parameters. We will discuss about this matter after a while.

For the interacting two-qubit probes, governed by H_4 , we study the effects of Gaussian and uniform disorder on the measurement precision of J. We evaluate the relative advantage in estimated J, viz. $\beta'_X = \frac{\Delta \tilde{J}_0^{(2)} - \Delta \tilde{J}_{QX}^{(2)}}{\Delta \tilde{J}_0^{(2)}}$, for X being G or U (for Gaussian and uniform disorders respectively), and compare β'_X with σ'_X , which is the standard deviation

in $\frac{\Delta \tilde{J}^{(2)}_{(\epsilon_1)} \times (\epsilon_2) \times (\epsilon_3) \times}{\Delta \tilde{J}_0^{(2)}}$. Here $\Delta \tilde{J}_0^{(2)}$ is the error in *J*, estimated in absence of any type of disorder in the interaction Hamiltonian H_I , i.e., for $\epsilon_1 = \epsilon_2 = \epsilon_3 = 0$. The standard deviation, σ'_X , for both $X = G$ and U, are significantly less than the corresponding β'_X . Precisely, σ'_G oscillates around an average value ≈ 0.33 , and the oscillation of β'_{G} is about ≈ 0.53 . For uniform distribution, σ'_U fluctuates around ≈ 0.27 , whereas the fluctuation of β'_U is around ≈ 0.44 . In these numerical investigations the strength of the Gaussian disorder, σ_G , is taken to be $\frac{1}{2}$ and for uniform distribution, $\sigma_U = \frac{1}{2\sqrt{2}}$ $\frac{1}{2\sqrt{3}}$, which corresponds to $s = 1$. We also set $J = 1.5$ and $k = 0.08$. So there are instances of order from disorder for both Gaussian and uniform glassy disorders.

Interestingly, the presence of various glassy disorders in the system provide advantages over the ideal scenario, also with respect to the entanglement content of the initial states. It can be easily checked using the optimal input state, described around Eq. (12) , that for the estimation of J, in absence of disorder in the fields and interaction term ($\epsilon_1 = \epsilon_2 = \epsilon_3 = 0$), the best choice of initial probes are maximally entangled states, viz. $|\phi_0\rangle$. But, in presence of disorder, depending upon the relative values of ϵ_1 , ϵ_2 and ϵ_3 , the optimal choice of the initial states may become a product one. It is observed that, the best initial inputs become copies of $|0+\rangle$ and $|+0\rangle$, when $\epsilon_3 < 1 + \epsilon_1$ and $\epsilon_3 < 1 + \epsilon_2$, respectively. Here $|0\rangle$ and $|1\rangle$ are eigenstates of σ_z , and $\ket{+} = (\ket{0} + \ket{1})/\sqrt{2}$. So, the optimal choice of input state may switch from a maximally entangled state to a product one, in presence of disorder. The explicit form of the Hamiltonian H_I shows that in absence of disorder, the Ising interaction between the two qubits disappear. This interaction comes into play in presence of disorder, which can be considered to be responsible for this peculiarity in the entanglement content of the two-qubit inputs. Thus, we find a situation when, even with a lower entanglement content of the initial probes, a certain metrological advantage may be obtained in glassy disordered systems over the ideal one. We numerically investigate the average entanglement of the optimal input states and see that it is much less the same of the ideal scenario. Since we take into account two-qubit pure states, the measure of entanglement considered is the von Neumann entropy of the local subsystem [\[186\]](#page-16-5). Precisely, the average entanglement for the Gaussian disorder is ≈ 0.09 , and the same for uniform disorder is ≈ 0.13 .

VIII. CONCLUSION

The response to disorder in a system is typically expected to be detrimental. Here we found instances in which the effect of glassy disorders is otherwise on the precision in quantum estimation of system parameters. This has potentially crucial implications for quantum devices having portions involving precision measurements, like measurement of time in atomic clocks.

We showed how an unbiased estimator can be identified in a disordered situation. We also found how the precision thereof can be bounded by the quantum Crámer-Rao inequality.

We considered copies of uncorrelated as well as twoqubit maximally entangled initial probes and identified instances where relative advantages in the efficiency of estimations are obtained in presence of glassy disorder in the system over the ideal cases. In looking for disorder-induced enhancement, we compared the disorder-averaged minimum Fisher information-based error with the corresponding quantity in the ideal, i.e., disorder-free, limit. We also examined whether the difference between the disorder-averaged and ideal cases is higher than the disorder-induced fluctuations in the disorder-average. Moreover, we identified cases where a glassy disorder, present in the system, reduces the requirement of initial quantum correlation - entanglement for attaining better precision in the estimation of a parameter over an ideal - disorder free - situation, providing us a "double advantage", viz. order-from-disorder in conjunction with resource reduction.

Appendix A: Models of disorder that offer no betterment in measurement precision over the ideal scenario

The disorder-averaged quantities for the Gaussian (G) and Cauchy-Lorentz (CL) distributions, represented as $\Delta \tilde{\omega}_{Q_C}^{(p)}$ \mathcal{Q}_G and $\Delta \tilde{\omega}_{Q_C}^{(p)}$ $Q_{CL}^{(p)}$ respectively, do not converge. Due to this difficulty, we try truncated Gaussian (TG) and truncated Cauchy-Lorentz (TCL) distributions. A truncated distribution is one, in which the domain of definition of the random variable is reduced to a finite range. These distribution functions and the corresponding disorder-averaged minimum error in estimation of a parameter are discussed below.

• TCL: *Truncated Cauchy-Lorentz disorder.* If we truncate the range of the parameter ϵ within a finite range in [\(14\)](#page-3-1), we get a truncated Cauchy-Lorentz distribution, given by

$$
P(\epsilon) = \frac{1}{\gamma \pi A_{TCL}} \left(\frac{\gamma^2}{\epsilon^2 + \gamma^2} \right), \text{ where } -a < \epsilon \le a,
$$

= 0 otherwise. (A1)

The normalisation constant $A_{TCL} = \frac{2}{\gamma} \tan^{-1} \frac{a}{\gamma}$. The disorder-averaged error in frequency estimation for ν copies of uncorrelated initial probes for this disorder is

$$
\Delta \tilde{\omega}_{Q_{TCL}}^{(p)} = \frac{1}{t\sqrt{\nu}} \frac{\gamma}{1+\gamma^2} \Big(\frac{\ln\left|\frac{1+a}{1-a}\right|}{2\tan^{-1}\frac{a}{\gamma}} + \frac{1}{\gamma} \Big). \tag{A2}
$$

This equation always gives $\Delta\tilde{\omega}_{Q_{\tau}}^{(p)}$ $\frac{p(p)}{Q_{TCL}}(t)/\Delta \tilde{\omega}^{(p)}_0(t) > 1$ for $\gamma > 0$ and $0 < a < 1$.

• TG: *Truncated Gaussian disorder.* In a similar way, a truncated Gaussian distribution can be defined as

$$
P(\epsilon) = \frac{1}{A_{TG}\sigma_{TG}\sqrt{2\pi}}e^{-(\epsilon/\sigma_{TG}\sqrt{2})^2}, \text{ when } -a \le \epsilon \le a,
$$

= 0 otherwise. (A3)

Here A_{TG} is the normalization constant given by A_{TG} = erf $(\frac{a}{\sqrt{2}\sigma_{TG}})$. The disorder-averaged deviation in frequency in presence of this disorder is evaluated numerically for ν copies of uncorrelated initial probes and the result does not provide advantage in the precision of measurement over the ideal situation.

• U: *Uniform disorder.* The uniform disorder mentioned in Eq. [\(24\)](#page-4-0) does not provide an advantage in the efficiency of measurement of a system parameter over the disorder-free situation when uncorrelated initial probes are taken. The disorder-averaged error in estimation of frequency for ν copies of uncorrelated initial states comes out to be

$$
\Delta \tilde{\omega}_{\mathcal{Q}_U}^{(p)} = \frac{1}{t\sqrt{\nu}} \frac{1}{s} \ln \left| \frac{2+s}{2-s} \right|,\tag{A4}
$$

which is always > $\Delta \tilde{\omega}_0^{(p)}$.

An important point to be noted is that while an introduction of disorder parameter in the scale of energy, as in H_1 , leads to a definite change in the frequency estimation, there is no change in the same if we introduce the same disorder parameter in the form of an energy shift (see H_2). The reason is the following. For a unitary evolution with the unitary $U_2 = e^{-iH_2t/\hbar}$, the variance in estimating ω is given by $\frac{1}{4\nu\Delta^2\mathcal{H}_1}$, where \mathcal{H}_1 is the ideal-system Hamiltonian. Hence, in this case, the error is independent of ϵ , and so there is no effect, on metrological precision of frequency estimation, of having this type of disorder in the system.
