### Abstract

In systems biology and pharmacology, large-scale kinetic models are used to study the dynamic response of a system to a specific input or stimulus. While in many applications, a deeper understanding of the input-response behaviour is highly desirable, it is often hindered by the large number of molecular species and the complexity of the interactions. An approach that identifies key molecular species for a given input-response relationship and characterises dynamic properties of states is therefore highly desirable. We introduce the concept of index analysis; it is based on different time- and state-dependent quantities (indices) to identify important dynamic characteristics of molecular species. All indices are defined for a specific pair of input and response variables as well as for a specific magnitude of the input. In application to a

large-scale kinetic model of the EGFR signalling cascade, we identified different phases of signal transduction, the peculiar role of Phosphatase3 during signal activation and Ras recycling during signal onset. In addition, we discuss the challenges and pitfalls of interpreting the relevance of molecular species based on knock-out simulation studies, and provide an alternative view on conflicting results on the importance of parallel EGFR downstream pathways. We envision that index analysis will be beneficial in comparing different model scenarios (e.g., healthy and diseased conditions), in designing more informed model reduction approaches, and in translating large-scale systems biology models from early to late phase in drug discovery and development.

# Author summary

In systems biology, the response of signalling networks to various molecular stimuli is studied by use of large and complex kinetic models. Prominent examples include the epidermal growth factor receptor signalling cascade and its response to growth factors or therapeutic interventions by small molecules and therapeutic protein drugs. The design of targeted interventions requires a detailed understanding of the signalling cascade, the identification of key molecular constituents and their functional role in propagating the signal. A quantitative analysis of such systems, however, is challenging due the size of the model and the complexity of molecular interactions. We present an approach based on time- and state dependent quantities called indices that quantify different characteristic dynamic features of the molecular constituents. This allows for a more in-depth understanding of how the signal propagates through the network and elicits its response. Our findings for the epidermal growth factor receptor signalling cascade provide new insights on the dynamic interplay of key molecular players.

### Introduction

Large scale models of biochemical reaction networks are increasingly used to study the dynamical response of a system to a specific input. The response is often measured in terms of some output quantity of interest. Examples include the therapeutic inhibition of the epidermal growth factor receptor (EGFR) signalling cascade in cancer [\[1,](#page-38-0) [2\]](#page-38-1) or the development of anti-coagulant drugs targeting the blood coagulation network [\[3\]](#page-38-2). Understanding the input-response relationship for a given model, however, is a challenging task when the order (dimension) of the model is large and the interactions between its constituents are manifold.

We introduce a novel approach to characterise the dynamic property of state variables within signalling network by means of time- and state dependent quantities, called indices. All indices are specific for a given input-response relationship and a given magnitude of the input. The sensitivity-based input-response index allows to quantify the dynamical importance of states. It is based on the product of two local sensitivity coefficients; the first coefficient quantifies the impact of the input on a given state variable at a given time, while the second coefficient quantifies how a perturbation of a given state variable at a given time impacts the output on the remaining time interval. States having a large input-response index are considered dynamically important. To further characterise states with a low input-response index, we define the environmental and the partial steady state classification indices. They are based on a comparison of the original kinetic system to a modified kinetic system and allow to identify very slow state variables (environmental) or very fast state variables (partial steady state). Two additional state classification indices allow to study the impact of removing/neglecting state variables in the network.

Approaches to study complex systems biology models include sensitivity analysis [\[4\]](#page-38-3), and model reduction techniques, like lumping and time-scale separation [\[5–](#page-38-4)[9\]](#page-39-0) or profile likelihood based reduction [\[10\]](#page-39-1). Sensitivity analysis quantifies how a change in parameters and/or initial states influences the system output. Several different techniques have been developed such as local and global sensitivity analysis [\[4\]](#page-38-3), with only local sensitivity analysis focusing on a given inputresponse relationship. Based on sensitivity coefficients, the parameters/initial states are ranked as important or unimportant for the model output [\[11\]](#page-39-2), but in particular appropriate scaling of the coefficients for comparability remains a challenge, see also Discussion. For model reduction techniques, a common interpretation is to classify state variables that are part of the reduced model as important and those that are not part of the reduced model as unimportant. Different model reduction techniques such as time-scale separation or balanced truncation exploit different

underlying characteristics of the system. In time scale separation, the system dynamics needs to present different time scale, where a partitioning into slow and fast states and a subsequent quasi-steady state approximation of the fast variables results in the reduced model [\[12\]](#page-39-3). In balanced truncation [\[13\]](#page-39-4), the basic idea is to transform the system into its principal components and neglect the least important components while still maintaining the same input-response behaviour as the original system. Balanced truncation has seen limited application for signalling networks [\[5\]](#page-38-4). The authors conclude that there is no "one size fits all" model reduction technique as each approach exploits different model characteristics, consequently there have been various attempt to combine different techniques [\[5\]](#page-38-4). Profile likelihood based model reduction utilises parameter identifiability to designate likely parameter candidates for reduction [\[10\]](#page-39-1). It is a powerful tool for model reduction, focussing on experimental data and parameters, rather than on states variables and time. There appear, however, some interesting links between their four scenarios and our proposed indices. In [\[14\]](#page-39-5), we introduced the concept of an empirical input-response index by building and expanding on concepts from control theory (empirical controllability and observability gramians). Given some input and response, the empirical index quantifies the relevance of a state variable for the given input-response relationship by some finite set of perturbations. We illustrated in a clinically relevant setting, how the empirical index can guide us to reduce a large systems biology model of the blood coagulation network by eliminating states variables, either by completely removing them from the system or by assuming them to be constant.

In the present article, we substantially extend the concept of an index and at the same time focus on understanding a given signal transduction network rather than reducing it. This index analysis is first introduced based on a number of simple model systems to ease understanding of the different index types and their application. We finally illustrate the power of index analysis in application to a large-scale model of the EGFR signalling cascade [\[1,](#page-38-0) [15\]](#page-39-6). This signalling network has been intensively studied in the context of tumour genesis and tumour progression as well as for anti-cancer treatment strategies, e.g., to overcome drug resistance in non-small cell lung cancer [\[16\]](#page-39-7). From a signal transduction point of view, the EGFR network remains a challenging system due to the large number of interacting molecular species and its multiple

parallel pathways.

# Methods

Many dynamical models in systems biology/pharmacology are of the form

$$
\frac{dx}{dt}(t) = f(x(t);p), \quad x(t_0) = x_0 + u_0 \tag{1}
$$

<span id="page-4-0"></span>
$$
y(t) = h(x(t))
$$
\n<sup>(2)</sup>

with  $x(t) \in \mathbb{R}^n$  denoting the vector of state variables at time  $t \in [t_0, T]$ , and  $p \in \mathbb{R}^m$  denoting the vector of parameters. The function  $f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$  represents the reaction kinetic model, and is typically of the form

$$
f(x; p) = \sum_{\mu=1}^{M} \nu_{\mu} \alpha_{\mu}(x; p)
$$
\n(3)

with stoichiometric vectors  $\nu_{\mu} \in \mathbb{R}^{n}$  and reaction rates  $\alpha_{\mu} \in \mathbb{R}$  of the reactions  $\mu = 1, \ldots, M$ . The function  $h : \mathbb{R}^n \to \mathbb{R}^q$  maps  $x(t)$  to the output  $y(t)$  of interest, often only a single state variable. The initial condition  $x(t_0)$  comprises two parts: (i) the state  $x_0 \in \mathbb{R}^n$  of the system prior to the stimulus, and (ii) an input or stimulus  $u_0 \in \mathbb{R}^n$  at time  $t_0$ . The solution of the ordinary differential equations (ODEs) in eq. [\(1\)](#page-4-0) is written as

$$
x(t) = \Phi^{t,t_0}(x_0 + u_0)
$$
\n(4)

with state transition function  $\Phi^{t,t_0}$ . The output then takes the form

$$
y(t) = h\left(\Phi^{t,t_0}(x_0 + u_0)\right). \tag{5}
$$

The assumptions on f (time-independence) and h (independent on parameters  $p$ ) can be relaxed.

In the sequel, we used both,  $z_k$  and  $[z]_k$  to denote the kth entry of a vector  $z = (z_1, \ldots, z_n)$ ; the

choice depended on whatever was deemed easier to read. An analogous notation was used for matrices.

Input-response index. The (sensitivity-based) input-response index quantifies the dynamic importance (to be defined below) of state variables. The input-response index for a state  $x_k$  at time  $t^* \in [t_0, T]$  is based on two factors that characterise to what extent

- (i) perturbations in the input  $u_0$  impact the state variable  $x_k$  at time  $t^*$
- (ii) perturbations in the state  $x_k$  at time  $t^*$  impact the output y on the remaining time interval  $[t^*,T].$

It is well-known that signalling cascades might respond differently to different magnitudes of the same input variable. Consequently, we defined the input-response index relative to some reference input  $u_{\text{ref}}$ . It defines a reference trajectory

$$
x_{\text{ref}}(t) = \Phi^{t,t_0}(x_0 + u_{\text{ref}}); \qquad t \in [t_0, T]
$$
\n(6)

according to eq. [\(1\)](#page-4-0). To quantify the extent to which a perturbation of the input impacts a given state variable, we considered a perturbed input  $u_{\text{per}} = u_{\text{ref}} + \Delta u_{\text{per}}$  and quantified the impact using a first-order Taylor approximation (indicated by the dot on top of the "=" sign)

$$
x_{\text{per}}(t^*) = \Phi^{t^*,t_0}(x_0 + u_{\text{per}}) \doteq \Phi^{t^*,t_0}(x_0 + u_{\text{ref}}) + J_u(t^*,t_0)\Delta u_{\text{per}} \tag{7}
$$

with Jacobian

$$
J_u(t^*, t_0) = \frac{\partial}{\partial u} \Phi^{t^*, t_0}(x_0 + u) \Big|_{u = u_{\text{ref}}} = \frac{\partial x_{\text{ref}}(t^*)}{\partial u}.
$$

Relative to the reference input, this resulted in a perturbation

$$
\Delta x_k(t^*) = \left[ x_{\text{per}}(t^*) - x_{\text{ref}}(t^*) \right]_k \doteq \left[ J_u(t^*, t_0) \Delta u_{\text{per}} \right]_k
$$

of the kth state variable at time  $t^* \in [t_0, T]$ . The larger  $[J_u(t^*, t_0)]_{k,i}$  the stronger the *i*th input

impacts the k<sup>th</sup> state variable at time  $t^*$ . If  $[J_u(t^*, t_0)]_{k,i} = 0$ , then the *i*th input has no impact on the  $k$ th state variable at time  $t^*$ . This quantification alone, however, is not sufficient to infer the importance of state variables for a specific input-response relationship, since it only quantifies the first aspect (i) above.

Thus, we next quantified the extent to which a perturbation of the  $k$ th state variable at  $t^*$  impacts the output y on the remaining time interval. The key idea is to reinterpret the perturbation  $\Delta x_k(t^*)$  as an input

$$
u_{\Delta x_k}(t^*) = (0,\ldots,0,\Delta x_k(t^*),0,\ldots,0) \in \mathbb{R}^{k-1} \times \mathbb{R} \times \mathbb{R}^{n-k}
$$

to the model system in eq. [\(1\)](#page-4-0) with (unperturbed) initial condition  $x_{\text{ref}}(t^*)$  at initial time  $t^*$ . This resulted in the perturbed output (to first order Taylor approximation):

$$
y_{\text{per}, \Delta x_k(t^*)}(t) = h\Big(\Phi^{t, t^*}\big(x_{\text{ref}}(t^*) + u_{\Delta x_k}(t^*)\big)\Big) \doteq h\Big(\Phi^{t, t^*}\big(x_{\text{ref}}(t^*)\big)\Big) + J_y(t^*, t_0)u_{\Delta x_k}(t^*)\tag{8}
$$

with  $t \in [t^*, T]$ . Realising that

$$
y_{\rm ref}(t) = h\Big(\Phi^{t,t_0}(x_0 + u_{\rm ref})\Big) = h\Big(\Phi^{t,t^*}(x_{\rm ref}(t^*))\Big),\tag{9}
$$

we thus quantified the resulting perturbation on the jth output component as

$$
\Big[y_{\text{per},\Delta x_k(t^*)}(t)-y_{\text{ref}}(t)\Big]_j\doteq\Big[J_y(t^*,t_0)u_{\Delta x_k}(t^*)\Big]_j
$$

with Jacobian

$$
J_y(t, t^*) = \frac{\partial h(\Phi^{t, t^*} x)}{\partial x}\bigg|_{x = x_{\text{ref}}(t^*)}.
$$

Analogously as above, the larger  $[J_y(t, t^*)]_{j,k}$  the stronger the kth state variable at time  $t^*$ impacts the jth output during the remaining time interval. If  $[J_y(t, t^*)]_{j,k} = 0$ , then the kth state variable has at time  $t^*$  no impact on the *j*th output.

We finally defined the sensitivity-based input-response index  $ir_k(t^*)$  of the k<sup>th</sup> state variable at time  $t^*$  as

<span id="page-7-0"></span>
$$
\left[\text{ir}_k(t^*)\right]_{ji} = \left(\frac{1}{T} \int_{t^*}^T \left( \left[J_y(t, t^*)\right]_{j,k} \right)^2 dt\right)^{\frac{1}{2}} \cdot \left[J_u(t^*, t_0)\right]_{k,i}.
$$
 (10)

The definition is motivated from control theory (see also below). The first factor represents the time-average integrated impact of an (infinitesimal) state perturbation over the time span  $[t^*, T]$  on the output; the integral form guarantees that a transient impact during the time span is taken into account, even if it occurs only during some short time span in the interval  $[t^*,T]$ . If, however, only the output at a single event time  $t_{\text{event}}$  is of interest, then  $[J_y(t_{\text{event}}, t^*)]_{j,k}$ rather than the integral should be considered. For time-dependent inputs, also the second factor becomes an integral; for delta-type inputs as in our case it reduced to a single value at the initial time.

In general,  $ir_k(t^*)$  is a matrix of dimension (number of outputs)×(number of inputs). For the common situation of a single state input (i.e.,  $u_0$  has only a single, say ith non-zero entry) and a single response state (i.e.,  $y(t) = h(x(t)) = x_r(t) \in \mathbb{R}$  for some state index  $r \neq i$ ), the input-response index is real-valued and can be written in terms of two local sensitivity coefficients

<span id="page-7-1"></span>
$$
\text{ir}_k(t^*) = \left(\frac{1}{T} \int_{t^*}^T \mathcal{S}_{r,k}(t,t^*)^2 dt\right)^{\frac{1}{2}} \cdot |\mathcal{S}_{k,i}(t^*,t_0)|\tag{11}
$$

with sensitivity coefficients

$$
\mathcal{S}_{m,j}(t_2,t_1) = \left[ \mathcal{S}(t_2,t_1) \right]_{m,j} = \left[ \frac{\partial \Phi^{t_2,t_1} x}{\partial x} \bigg|_{x = x_{\text{ref}}(t_1)} \right]_{m,j} . \tag{12}
$$

It is a distinct feature of the input-response index that it combines both, the impact of the input on a state variable as well as the impact of the state variable on the output. Neither one nor the other on its own is in general informative to quantify the relevance of a state variable for a given input-response relationship. In a control theoretical setting, the factors

$$
\mathcal{O}_k(t^*) = \left(\frac{1}{T} \int_{t^*}^T \mathcal{S}_{r,k}(t,t^*)^2 \mathrm{d}t\right)^{\frac{1}{2}} \quad \text{and} \quad \mathcal{C}_k(t^*) = \mathcal{S}_{k,i}(t^*,t_0) \tag{13}
$$

can be interpreted as a controllability index  $c_k$  and an observability index  $\mathcal{O}_k$ .

To ease comparison of the ir-indices for different points in time, we normalised each index by the sum of all indices, resulting in the normalised ir-indices (nir):

<span id="page-8-0"></span>
$$
\text{nir}_k(t^*) = \frac{\text{ir}_k(t^*)}{\text{sum-ir}(t^*)}; \qquad \text{sum-ir}(t^*) = \sum_{j=1}^n \text{ir}_j(t^*). \tag{14}
$$

As a result, the nir-index takes only values between 0 and 1. The sum of ir-indices is also of interest, as it gives some indication on the overall magnitude of the ir-values. Details on the computation and the extension to time-dependent input or fixed output time of the ir-indices can be found in the Supplementary Material S2&3 Text.

We classified a state variable as dynamically important, if its input-response index is above a (user-defined) threshold at some point in time. A threshold of 10% was successfully used in all examples of the results section. The relevance of the input-response index is two-fold: (i) it allows to characterise the dynamic pattern of importance of a state variable: When is a state variable important for the input-response relationship? At which times is it less important? And (ii) it allows to identify state variables that are not dynamically important and to further characterise them.

State classification indices. The motivation of additional state classification indices is to further characterise states with a small input-response index. In such a case, the impact of the input on a state variable is insufficient to see a marked change in the output. This includes the two extreme cases, that the input has no impact on that state variable, or that the state variable has no impact on the output. The former would typically be considered an environmental state

variable, the latter be considered negligible. It can be shown that also state variables with very fast dynamics have a low input-response index.

We introduced four state classification indices:  $env_k$ ,  $pss_k$ ,  $pneg_k$  and  $cneg_k$  (for definition, see below). For the kth state variable, they all take the common form

<span id="page-9-0"></span>
$$
\left[\text{ind}_k(t^*)\right]_j = \left(\frac{1}{Z_j(t^*)} \int_{t^*}^T \left( \left[y_{\text{ref}}(s) - y_{\text{mod}}^{(k)}(s)\right]_j \right)^2 ds\right)^{1/2} \tag{15}
$$

with  $t^* \in [t_0, T]$  and normalisation constant  $Z_j(t^*) = \int_{t^*}^T |[y_{\text{ref}}(s)]_j|$  $^{2}$  ds. The definition of the state classification indices has some similarity with the first factor of the  $ir_k$  index in eq. [\(10\)](#page-7-0). However, rather than perturbing the  $k$ <sup>th</sup> state variable at  $t^*$  and simulating with the original system of ODEs, now the state variable is unperturbed and the system of ODEs is modified (details below). In both cases, the difference to the reference solution is quantified on the remaining time interval  $[t^*,T]$ . Up to time  $t^*$ , the modified system coincides with the reference system, so no additional factor appears in the definition in eq. [\(15\)](#page-9-0) (in contrast to the second factor in eq. [10\)](#page-7-0). We finally note that the normalised indices can take values larger than 1.

We defined four state classification indices; they aim at classifying a state from the perspective of their effect on the output.

- The environment index  $(\text{env}_k)$  quantifies to what extent the kth state variable can be classified as an environmental state, defined as being constant in time. Thus, the modification of the system of ODEs at time  $t^*$  is to set the right hand side (RHS) of the kth ODE to zero.
- The partial steady state index  $(\text{pss}_k)$  quantifies to what extent the kth state variable can be classified as being instantaneous in steady state; since this only affects the kth state variables, it is a partial steady state of the system. Its dynamics is characterised by an algebraic equation rather than on ODE—the kth state variable is simply a function of other state variables. Thus, the modification of the system of ODEs at time  $t^*$  is to set

the left hand side of the kth ODE to zero, resulting in a system of differential-algebraic equations (DAEs). Many numerical solvers can integrate this type of equations. Of note, we used the term 'partial steady state' to differentiate it from a quasi-steady state, which typically involves the exploitation of additional conservation laws. For further illustration and clarification, see the analysis of the enzyme kinetics model given in the Supplementary Material S4 Text.

• The partially and completely neglected indices ( $\text{pneg}_k$ , cneg) quantify to what extent the kth state variable can be neglected and thus removed from the system. This can be done in two different ways: Consider the reaction A  $\rightleftharpoons$  B  $\rightarrow$  C. When neglecting C, we might either want to partially remove C from the system and maintain its 'producing' reaction (thus maintaining the degrading reaction of B), resulting in A  $\rightleftharpoons$  B  $\rightarrow$  \*, or we might want to completely remove  $C$  and all reactions involving it, resulting in  $A \rightleftharpoons B.$ 

Thus, for the *partially neglected index*  $\{text{preg}_k\}$ , the modification to the system of ODEs is to set all reaction rate constants to zero that involve the kth state variable as reactant species. In many reaction kinetic systems, this can easily be realised by setting  $x_k(t) = 0$ for all  $t \in [t^*, T]$ . For the *completely neglected index* cneg<sub>k</sub>, the modification to the system of ODEs is to set all reaction rate constants to zero that involve the kth state variable as reactant or product species.

The state classification indices only measure the impact (of a specific change of the system of ODEs) on the output. For a final classification of a state variable, it is, however, important to also measure the impact on the state variable itself. Thus, for the state classification indices  $env_k$  and  $qss_k$ , we additionally defined a corresponding relative state approximation error

$$
\text{rel-state-err}_k(t^*) = \left(\frac{1}{Z(t^*)} \int_{t^*}^T \left| \left[x_{\text{ref}}(s) - x_{\text{mod}(k)}(s)\right]_k \right|^2 \,\mathrm{d}s\right)^{1/2} \tag{16}
$$

with  $t^* \in [t_0, T]$  and normalisation  $Z(t^*) = \int_{t^*}^T \left| [x_{\text{ref}}(s)]_k \right|$ <sup>2</sup> ds. Note that for the indices  $\text{pneg}_k$ and  $\text{cneg}_k$ , the relative state approximation error is not meaningful, since it equals 1 by definition. We classified a state variable as environmental or in partial-staedy state, if the corresponding state classification index and the state approximation error are both below a (user-defined) threshold for all times  $t \in [t_0, T]$ . We classified a state variable as partially or completely negligible, if the partially/completely neglected index is below a (user-defined) threshold for all times  $t^* \in [t_0, T]$ . In all examples, we successfully used a threshold of 0.1, consistent with the threshold of 10% for the ir-index. Fig. [1](#page-11-0) summaries the strategy we used to classify states.

#### **all indices refer to the** *k***-th state variable**

## Material

We chose a number of simple model systems to illustrate the application, interpretation and usefulness of the indices, of which one is included in the Results section and the remaining are included in the Supplementary Material S4 Text.

We then studied the epidermal growth factor (EGF) receptor signalling network [\[1,](#page-38-0)15,17] to illustrate how the indices allow to obtain detailed insights into the dynamic behaviour of complex, large-scale systems biology/pharmacology models. The EGFR system is an an important pathway in cell division, death, motility and adhesion [\[1,](#page-38-0) [18,](#page-40-2) [19\]](#page-40-3). In addition, it is of key interest in the development of anti-cancer therapies, as the pathway is often dysfunctional in tumour cells. We used a detailed model of the EGFR reaction network [\[15\]](#page-39-6) consisting of 106 state variables and 148 reactions. We followed [\[15\]](#page-39-6) regarding the abbreviations of state variable names. The original model includes a lumped pseudo state of degradation products that serves as a substitute for various individual degradation products. To allow for a more refined analysis of receptor degradation, we modified the original model by separating the degraded receptor species (EGF-EGFR<sup>\*</sup>)<sub>2</sub>-deg into six separate degradation products, increasing the number of state variables by six to 112. This extension does not change the remaining system dynamics. All initial conditions and parameter values for the model were taken from [\[15,](#page-39-6) Suppl. Table 2]. In addition, all corrections reported in [\[20\]](#page-40-4) were taken into account.

The model was implemented in Matlab 2021b and will be uploaded to the permanent and open-access repository zenodo. In contrast to our expectations, the system published in [\[15\]](#page-39-6) is not in steady state in the absence of EGF, i.e., the stimulus of the system. Some state variables do change, including EGFR, EGFRi, Grb2, Sos and Grb2-Sos; see Supplementary Material S2 Fig. To ensure comparison to the original publication in [\[15\]](#page-39-6), however, we did not make any further changes.

### Results

#### Index analysis for illustrative model system

To illustrate the index analysis in application, we first considered a simple reaction cycle model sketched in Figure [2.](#page-13-0) In the model, the signal A transforms B into C, which in turn activates D. In addition, A, C and D may be subject to degradation. In this example, A is considered the input and D the response variable. We distinguished three different scenarios defined by the parameter values in Table ??. These were chosen to illustrate how the indices allow to analyse and differentiate between the scenarios. We use Scenario 1 to introduce the indices in detail and build on this in Scenarios 2 and 3. We used the decision-tree in Figure [1](#page-11-0) to guide the analyses.

<span id="page-13-0"></span>

Figure 2. Simple reaction cycle model and scenario-specific parameter values. (A) Reaction network, and (B) parameter values for the three scenarios, for which the model system was studied. The time span was  $t \in [0, 0.1]$  min, the input A, and the response variable D. The initial conditions were identical in all three scenarios:  $(A_0, B_0, C_0, D_0) = (2, 100, 5, 0)$  nM. Units:  $k_{\text{on}}$  in 1/nM/min; all other reaction rate constants in 1/min.

Figure [3A](#page-14-0) shows the time course of the state variables, while Figure [3B](#page-14-0) shows the normalised ir-indices. Here and in all other analyses, we empirically (as with many thresholds) used a threshold of 10%; this choice was supported a-posteriori by the results. One nicely observes from panel B that the dynamic importance of state variables changes substantially over time: Initially, the signal A has the largest dynamic importance; it decays, however, very quickly and below a threshold of 10%. This threshold has been chosen empirically (as for most thresholds). In contrast, the indices of all other state variables are negligibly small initially and increase

steeply. While B and D reach interim values of 45% around 2 min, C increases only up to 10%, before it starts to decays again. It stays below 10% for the entire time span. The dynamic importance of B and D continue to evolve with almost opposite behaviour. Eventually, B decays and D increases to its maximal value. For a classification of states, the particular features of the index are not considered relevant; the key feature considered is whether an index stays below the threshold for all times, or not. For the input-response index, we considered a state dynamically unimportant, if its ir-index stays below the threshold of 10% for the entire time span. Otherwise, we consider it as 'not unimportant', i.e., as dynamically important. Thus, we considered A, B and D as dynamically important, but not C.

<span id="page-14-0"></span>

Figure 3. Scenario 1 of the simple reaction cycle model: time course of state variables and normalised indices. Time course of state variables (left) and normalized ir-indices (right) for the model specified in Figure [2.](#page-13-0)

The top graphics of Figure [4](#page-15-0) show the state classification indices for two states, B (left) and C (right). These indices are designed to further analyse the characteristics of dynamically unimportant states, i.e, here state C. We also included state B, though dynamically important, for illustration only. A state classification index below the threshold for all times is considered indicative of the corresponding index classification type (environmental, in partial steady state, negligible).

<span id="page-15-0"></span>

Figure 4. Scenario 1 of the simple reaction cycle model: Relative state approximation error and modified dynamics. A: State classification indices for state B and B: for state. C: Relative state approximation errors for B and D: for C. E: Comparison of reference dynamics and modified dynamics from  $t^* = 0$  (dashed lines) for B as environmental state and F: for C in partial steady state. For details on the model, see Figure [2.](#page-13-0)

For a state classification as environmental or in partial-steady state, also the relative state approximation error (shown in Figure [4\)](#page-15-0) is taken into account. Since the normalised input-response indices for B was above the threshold, we would expect to see no further characteristics for state B. In contrast, give the below-threshold normalised input-response indices for C, we would hope to get further indications for its classification. In line with these expectations, none of the state classification indices for B is below the threshold, while for C a single index (the partial steady state index) is below the threshold for all times. This is an indication for C being in a partial steady state. This is finally confirmed by Figure [4D](#page-15-0). The middle panels show the relative state approximation errors for state B (left) and C (right). We infer that only the classification of C being in partial steady state (red dashed line) results in an approximation error below the threshold for all times. The bottom-right panel illustrates the impact of modifying the reaction system to enforce C being in partial steady state from time  $t^* = 0$  onwards. As can be seen, the solution of the modified system (dashed lines) is a very good approximation to the solution of the reference model (solid lines). For sake of illustration, the bottom left panel show the impact of modifying the system so that B is environmental (i.e. constant) from  $t^* = 0$  onwards. Clearly and in line with the large environmental index of B, the resulting approximation is very poor. Thus, we conclude for Scenario 1 that C can be considered in partial steady state, while all other states are considered as dynamically important.

For Scenarios 2+3, Figure [5](#page-18-0) shows the time course of all state variables and the normalised input-response indices. For Scenario 2 (left column), we conclude from Figure [5C](#page-18-0) that all states are classified as dynamically important, since no nir-index is below the threshold for all times. In contrast, for Scenario 3, we conclude from Figure [5D](#page-18-0) that only states A and D are dynamically important, while states B and C are not. Figure  $6$  (top) shows the state classification indices for B (left) and C (right). Two indices are below the threshold for all times: the env-index for B and the pss-index for C. The bottom panel finally confirms this classification. The relative state approximation errors for B as environmental state (left, solid blue line) and C as in partial steady state (right, dashed red line) are below the threshold for all times.

For Scenario 2, we conclude that all states are dynamically important. For Scenario 3, in

contract, only A and D are dynamically important, while B is an environmental state and C is in partial steady state.

The input-response index classifies whether or not a state variable is considered dynamic for a particular set of parameters and given input-output relationship. The four state classification indices provide further understanding in which way the state variable with a low input-response index (below 10%) impact the output either as a constant (environmental), in partial steady state or whether it can be neglected (partially or completely). Further simple model system to help guide understanding and use of the index analysis can be found in the Supplementary Material S4 Text.

# Input-response indices of the EGFR signalling pathway guide subsequent analysis of the key molecular species

To illustrate applicability and usefulness to large-scale systems, we next performed an index analysis of the epidermal growth factor receptor (EGFR) signalling cascade. The EGFR pathway is activated by binding of EGF to EGFR. Dimerised EGF-EGFR autophosphorylates and recruits a series of adaptor molecules called GAP, Grb2 and Sos. Signal transduction may occur via membrane-bound or internalised species; in addition it occurs via two major pathways: the Shc-dependent and the Shc-independent pathway. The two pathways, however, do not act independently from each other, since there are many molecules involved in both pathways. Both pathways eventually activate Ras-GDP, a well-known oncogene and the merging point of both pathways. Subsequent activation of Raf transduce the signal to the MAP kinase cascade and finally to ERK. The output signal is double-phosphorylated ERK, which transiently increases as a response to the input stimulus. In view of the input (EGF) and the output (ERK-PP), the signalling cascade is sometimes termed the EGF–ERK-PP system. A graphical representation can be found in the Supplementary Material S1 Fig.

While the principal transduction of the signal is well known, the relative importance of the different pathways (Shc-dependent and Shc-independent, membrane-bound vs. internalised forms) and its molecular constituents is still not well understood.

<span id="page-20-0"></span>

Figure 7. Output signal and sum of ir-indices evolving over time A: Transient increase of ERK-PP (output) in response to the EGF (input) stimulus. Inset zoom: signal activation occurs within 3 min. B: Sum of ir-indices over time, showing three phases: initial peak (0-0.3 min), high plateau (0.3-3 min), and low plateau including decay (3-100 min)

To index-analyse the EGFR signalling cascade, we chose a constant extra-cellular EGF stimulus of 50 nM and a time interval [0, 100] min, as in [\[15\]](#page-39-6). Figure [7A](#page-20-0) shows the temporal response of the ERK-PP output signal; the peak of the signal is reached within 3 min. The sensitivity-based indices were determined according to eq. [\(11\)](#page-7-1). Figure [7B](#page-20-0) shows the sum of the ir-indices over

time. We clearly identify three different phases: an initial peak (0-0.3min), a short high plateau (until 3min); followed by an extended and finally decaying low plateau. While the extended low plateau corresponds to the decay phase of the output, the initial peak and the short high plateau correspond to signal onset and steep increase

Figure [8](#page-22-0) shows all normalised ir-indices that exceed a threshold of 10% at least once during the time span—20 out of a total of 112. The threshold value was chosen empirically, but also matched a gap in the decay of the maxima of the normalised input-response indices (see Figure [8D](#page-22-0)). In broad terms, Figure [8](#page-22-0) shows an ordered appearance and disappearance of states, as might be expected. A closer examination reveals that at any point in time there exist often 3–5 states with a normalised ir-index above 10%, but always at least one index (see Supplementary Material S14 Fig). At any point in time, there are thus only a few dynamically important states responsible for the transduction of the input to the output. For further analysis, the 20 states with a maximal normalised ir-index exceeding 10% are coloured in light blue in the EGFR model cartoon in Figure [9.](#page-23-0) Interestingly, the 20 states all belong either to the membrane-bound and Shc-dependent receptor species (as opposed to the internalised or Shc-independent species), or the free cytosolic Ras, Raf, MEK and ERK species (as opposed to the internalised species).

<span id="page-22-0"></span>

Figure 8. Normalised ir-indices over time and ordered maximal value. A, B and C: Normalised ir-indices for the three phases  $(0-0.3 \text{ min}, 0.3-3 \text{ min}, 3-100 \text{ min})$ . Shown are all 20 indices with a maximal value exceeding 10%. D: Order of decay of maximum value of the normalised ir-indices. All 20 states above the threshold of 10% are membrane-bound or free cytosolic forms and (as far as applicable) belong to the Shc-dependent pathway—as opposed to internalised forms and the Shc-independent pathway; see Supplementary Material S3 Table. The state just below the threshold is  $(EGF-EGFR^*)_2$ -GAP-Shc<sup>\*</sup>-Grb2-Sos.

Further observations can be gained from Figure [8:](#page-22-0) First, not all species that are absolutely necessary to transmit EGF to ERK-PP have a normalised ir-index exceeding 10%, including adaptor proteins Shc, Grb2, Sos as well as Raf and MEK. Second, while Phosphatase3 is known to be involved in signal deactivation, its nir-index already peaks around 1.4 min and thus during

signal activation. Phosphatase 1 and 2, however, do not seem to have a similar role during the activation phase. Finally, MEK-P and ERK-P-MEK-PP seem to be relevant during the deactivation phase (see Figure [8C](#page-22-0)), while we would rather associate them with the activation phase. The analyses below are guided by these observations.

#### <span id="page-23-0"></span>(A) membrane EGFR signalling (B) internalised EGFR signalling

Figure 9. Schematic with state classification of the signal transduction network focussing on the Shc dependent pathway, including the 20 state variables with largest maximum input-response index (light blue, see Figure [8D](#page-22-0)), environmental state variables (purple), state variables in quasi-steady state (green) and further state variables (dark blue). States being part of the membrane-bound and internalised pathway are coloured orange in panel (B). The red boxes mark the input and output state variables; coloured dots as part of reaction arrows indicate intermediate complexes. A similar graphic for the Shc-independent pathway is given Supplementary Material S13 Fig.

### Phosphatases1–3 show very different behaviours and functions

Phosphatase3 (abbreviated P'ase3, when part of a complex) is involved in de-phosphorylation of ERK-P and ERK-PP (see also Figure [9\)](#page-23-0). Figure [10A](#page-25-0) depicts the time course of key molecular species involved in the local Phosphatase3 network during signal activation. Once the kinase MEK-PP is present, it phosphorylates ERK via ERK-P to ERK-PP. Rather than observing an increase in ERK-P followed by ERK-PP, however, we first see a steep increase of ERK-P:P'ase3, indicating that Phosphatase3 immediately binds ERK-P to form a complex and subsequently de-phosphorylates it. Only when the level of Phosphatase3 decreases sufficiently, ERK-P levels increase markedly. As with ERK-P, double-phosphorylated ERK-PP is immediately bound by Phosphatase3 and subsequently de-phosphorylated, as can be inferred from the step increase of ERK-PP:P'ase3. Again, only when the Phosphatase3 level further decreases, the output signal ERK-PP increases to high levels. Thus, Phosphatase3 delays signal onset by sequestering ERK-P and ERK-PP; moreover, it controls the ERK-PP peak concentration as well as signal deactivation. This is confirmed by simulating the model with no Phosphatase3, as shown in Figure [10B](#page-25-0). In summary, the described action of Phosphatase3 can be understood as a protection mechanism against activation of ERK-PP by spurious or random phosphorylation of ERK or ERK-P in the absence of a signal.

For Phosphatase1, Figure [11A](#page-26-0) show the normalised state classification indices. Since both, the env-index and the corresponding relative state error (not shown) are below the threshold, we classify Phosphatase1 as environmental. A further look at the Phosphatase1 levels of the reference model (see Figure [11B](#page-26-0)) is confirmatory. In addition, the prediction of the modified model with constant Phosphatase1 levels from  $t = 0$  on (i.e., as environmental state) are shown; the differences to the original model predictions are very minor.

We coloured all state variables classified as environmental in pink in the model scheme in Figure [9.](#page-23-0) We infer that only one other species—Prot, a coated pit protein that mediates receptor internalisation—is classified as environmental.

<span id="page-25-0"></span>

Figure 10. Relevance of Phosphatase3. A: concentration-time profiles of Phosphatase3 and relevant cytosolic ERK species during signal activation. B: comparison of the output ERK-PP for the reference simulation (solid lines) and a modified model (dashed lines) with no Phosphatase3. As a result, signal activation speeds up by roughly 1 min, in addition to lack of signal deactivation.

For Phosphatase2, none of the normalised state classification indices are below the threshold for all times; as shown in Figure [11C](#page-26-0). A closer look at important species related to Phosphatase2 (not shown) revealed that a noticeable fraction of Phosphatase2 is bound to internalised MEK, e.g., MEKi-P and MEKi-PP (10-12% for a substantial amount of time). This suggests that internalised MEK plays an important role in sequestering Phosphatase2. Figure [11D](#page-26-0) further supports this hypothesis: it shows the predictions of the reference model and a modified model with no internalised MEK species (all MEK i-species classified as cneg). Due to increased availability of free Phosphatase2, free MEK-PP levels are lower, and ERK-P bound MEK-PP levels are higher, the preceding species of ERK-PP. As a consequence, the signal is attenuated. This might indicate that the pool of *internalised* MEK plays a role in signal prolongation by sequestering Phosphatase2.

<span id="page-26-0"></span>

Figure 11. Analyses of Phosphatase1 (top)  $\&$  2 (bottom) A: State classification indices for Phosphatase1; B: comparison of the output ERK-PP and Phosphatase1 for the reference simulation (solid lines) and a modified model (dashed lines) with constant Phosphatase1 levels. C: State classification indices for Phosphatase2; D: comparison of the output ERK-PP, Phosphatase2 and two MEK-PP species for the reference simulation (solid lines) and a modified model (dashed lines) without MEK internalisation. Absence of internalised MEK increases free Phosphatase2 levels and thereby deactivates the signal more quickly.

<span id="page-27-0"></span>

Figure 12. Analyses of Raf<sup>\*</sup>, Ras-GTP<sup>\*</sup>. A: State classification indices for Raf<sup>\*</sup>; B: comparison of the output ERK-PP and Raf<sup>∗</sup> for the reference simulation (solid lines) and a modified model (dashed lines) with Raf<sup>∗</sup> in partial-steady state. C: State classification indices for Ras-GTP<sup>\*</sup>; D: comparison of the output ERK-PP and Ras-GTP<sup>\*</sup> for the reference simulation (solid lines) and a modified model (dashed lines) with partially neglected Ras-GTP<sup>\*</sup> (pneg).

#### Raf<sup>∗</sup> dynamics is fast throughout activation and deactivation

The maximal value of the ir-index of Raf<sup>\*</sup> is  $0.17\% \ll 10\%$  (see Supplementary Material S3 Table), a surprisingly small number given the relevance of Raf<sup>\*</sup> in signal transduction. Figure  $12A \& B$  show the normalised state classification indices and the corresponding relative state

approximation errors for Raf<sup>∗</sup> . Since both, the pss-index and the corresponding relative state error are below the threshold, we classified Raf<sup>∗</sup> as partial-steady state. The C panel shows the prediction of the reference model and a modified model with Raf<sup>∗</sup> in partial-steady state from  $t = 0$ ; the profiles are indistinguishable. Thus, signal propagation through Raf<sup>\*</sup> is 'instantaneous'.

We coloured all state variables classified as partial-steady state in light green in the model scheme in Figure [9.](#page-23-0) We infer that several other species, including a large fraction of internalised species, act on an instantaneous time scale.

### Ras-GTP<sup>\*</sup> recycling is important for signal prolongation

The cycle of Ras-GDP activation and Ras-GTP inactivation is a central motif of the signalling cascade (see Figure [9\)](#page-23-0). While Ras-GDP and -GTP have nir-indices above the threshold, the inactivated form Ras-GTP<sup>∗</sup> has a nir-indices below the threshold for all times. Figure [12A](#page-27-0) shows the state classification indices for Ras-GTP<sup>∗</sup> . Since none of them is below the threshold for all times, no further classification is possible (see also Figure [1\)](#page-11-0). Figure [12B](#page-27-0) shows the prediction of the reference model and a modified model with Ras-GTP<sup>∗</sup> partially neglected (pneg) from  $t = 0$ , i.e., removed from the network. The result is a response attenuation; the Ras-GDP profile clearly shows that the re-activation of Ras-GTP<sup>∗</sup> to Ras-GDP does play an important role in signal prolongation by replenishing the pool of Ras-GDP molecules—starting already from 1 min onwards and remaining important even during signal decline.

<span id="page-29-0"></span>

Figure 13. Analyses of receptor degradation. Comparison of the output ERK-PP and Raf<sup>∗</sup> for the reference simulation (solid lines) and a modified model (dashed lines) with no degradation from six internalised receptor species (those with degradation reaction in Figure [9,](#page-23-0) realised by classifying the degradation products as cneg).

# Degradation of internalised receptors-complexes results in faster decrease of Ras-GTP levels

Prot-mediated internalization and subsequent degradation of internalised receptor species plays an important role in output signal shut-down. Figure [9B](#page-23-0) shows six internalised EGFR species including degradation (out of 16 degradation reactions in total). For these six receptor species, degradation has a large impact on the output signal. Figure [13](#page-29-0) shows the prediction of the reference model and a modified model with no degradation of these six species from  $t = 0$ (realised by classifying the corresponding degradation products, e.g., (EGF-EGFR<sup>∗</sup> )2-deg as completely negligible). Without degradation of these receptor species, the signal is strongly prolonged: An elevated concentration of internalised receptors increases the recycling rate to the membrane, impacting the total concentration of membrane-bound receptor species. While the cytosolic species Ras-GDP is hardly changed, elevated receptors levels eventually increase the activation rate from Ras-GDP to Ras-GTP via increased levels of (EGF-EGFR<sup>∗</sup>)<sub>2</sub>-GAP-Shc<sup>∗</sup> -Grb2-Sos. Increased levels of activated Ras-GTP, finally, result in a prolonged output signal.

### Discussion

We defined the sensitivity-based input-response index and four state classification indices that together can be used to analyse signal transduction networks. All indices are (i) time- and state-dependent; defined (ii) for a specific input-output relationship; and (iii) for a specific magnitude of the input. We have illustrated the approach for simple small-scale models and demonstrated for the EGFR signalling network, how index analysis can provide an in-depth view on the role and contribution of the different molecular species.

The sensitivity-based input-response index is defined in terms of two sensitivity coefficients. In sensitivity analysis, local sensitivity coefficients measure the impact of changes in parameters p or initial conditions (also seen as input parameters) on a response variable  $x_r$  as a function of time [\[4\]](#page-38-3). They are used, e.g., for parameter sensitivity analysis or to study the robustness of signal transduction pathways. A key challenge in sensitivity analysis is to account for scaledifference and to make them invariant to transformation of units and thus comparable. A common solution is to consider scaled sensitivity coefficients

<span id="page-30-0"></span>
$$
G_{r,i}(t) = \frac{\partial x_r(t)}{\partial p_i} \cdot \frac{p_i}{x_r(t)},\tag{17}
$$

resulting in a unitless quantity know as the logarithmic gain [\[21\]](#page-40-5), or as control or response coefficient in metabolic control analysis [\[22,](#page-40-6) [23\]](#page-40-7). In signalling cascades, signals are often propagated through a series of activation steps. Activated forms temporarily rise from zero/very low concentrations to their maximum, while inactive forms almost vanish. In such a situation, the scaling above is highly problematic, since  $x_r(t) \approx 0$  at initial times for active forms and  $x_r(t) \approx 0$ at later times for inactive forms, resulting in ill-defined coefficients or numerical problems. Of note, metabolic control analysis has mainly be applied to metabolic systems in steady state, where such problems are absent. The input-response index differs in two regards: (i) it considers the integral of the first factor in eq. [\(17\)](#page-30-0) rather than the evaluation at a single point in time; and (ii) it scales with the controllability index of the kth state variable (see eqs.  $(11)$  and  $(13)$ ), rather than the factor  $p/x_r(t)$  in eq. [\(17\)](#page-30-0). This makes a key difference and firmly links the

input-response index to a specific input, ensures invariance under internal unit transformations; and at the same time resolves the above scaling issue.

In signalling cascades, some state variables are important for very short periods of time. Therefore if a state variable is dynamically important at some point in time (even, if only for a very brief period of time), we consider it to be not dynamically irrelevant, i.e., dynamically relevant. This motivates the choice of the maximum of the input-response index as the relevant characteristic. For applications to chronic progressive diseases, longer time periods are of interest. Then, slow changes in endogenous or exogenous factors may determine the rate of change in the system, while such changes are likely to be irrelevant on short time intervals. In this case, the metric might need to be changed, e.g., to the integral over the input-response index.

While the sensitivity-based input-response index is a measure of importance based on the original (unmodified) system, the state classification indices are measures involving a modification of the system. It is important to realise that a small state classification index solely indicates that the corresponding modification has a low impact on the output. This might be due to different reasons:

- (i) the modification has a low impact on the concentration-time profile of the corresponding state—and as a consequence, also on the output;
- (ii) the system is able to compensate for the impact of the modification on the state variable and as a consequence, the impact on the output is low;
- (iii) the state is not relevant for the input-output relationship—so even a larger impact on the state variable does not impact the output.

By using the state classification index in combination with the relative state approximation error, we aim to distinguish between (i) and (ii) for environmental and partial-steady state classifications. The partially/completely neglected indices are defined to identify case (iii). It is, however, important to note that a low partially/completely neglected index may as well be indicative of case (ii). See the analysis and illustration of the parallel pathways model in the Supplementary Material S4 Text. This is also of relevance in EGFR signal transduction, where conflicting results have been reported concerning the importance of the Shc-dependent pathway [\[11,](#page-39-2) [24\]](#page-40-8). The authors in [\[24\]](#page-40-8) state that the Shc-dependent pathway only plays an important role for low EGF concentrations. Their statement was based on a simple in silico knock-out study of the system. In contrast, the authors in [\[11\]](#page-39-2) use sensitivity as well as flux analysis to conclude that signalling transduction proceeds primary through the Shc-dependent pathway. This contradiction was in part resolved in [\[25\]](#page-40-9) by analysing the reactions of the EGFR signalling cascade model. They found that the production of Ras-GTP is indeed mostly mediated by the Shc-dependent pathway, while in case of the Shc knock-out, the Shc-independent pathway takes over the full activation of Ras-GTP. This analysis is easily reproduced with the completely neglected index (cneg): a knock-out of either all Shc-dependent or all Shc-independent species result in both cases in low relative errors on the output ERK-PP  $(5.5\% \text{ and } 1.1\%$ , respectively). In light of the low relative errors (and without knowledge on the pathway), one would conclude that neither the Shc-dependent nor the Shc-independent pathway is important. This conclusion, however, is falsified by the joint knock-out resulting in a  $100\%$  relative error on the output ERK-PP (no output at all). The example clearly illustrates that care has to be taken when interpreting the importance of states or entire pathways from (in-silico, but also in-vitro/vivo) knock-out studies.

Index analysis approaches the question differently. The input-response indices clearly highlight the important dynamic role of the Shc-dependent species. Importantly, the ir-indices do not require a modification (e.g., knock-out) of the system—in a certain sence, they measure the dynamic importance of states non-invasively. At the same time, our analysis shows that many states of the Shc-independent pathway are classified as being in partial-steady state. Hence, it is the "dynamic nature of the state variables" that is the most prominent difference between the Shc-dependent or Shc-independent pathway.

The precise impact of receptor internalisation and the role of internalised species is still up to debate  $[1, 11, 15]$  $[1, 11, 15]$  $[1, 11, 15]$ . We infer from Figure [9](#page-23-0) that a prominent difference between the membranebound and internalised pathway is again the "dynamic nature of the state variables". No internalised species is classified as dynamic (large nir-index), while a large number is classified as partial-steady state. Using the partially/completely neglected index, we identified the relevance of receptor degradation from specific internalised receptor species (indicated by degradation reactions in Figure [9\)](#page-23-0). Absence of receptor degradation from these species increases the pool of internalised receptors and thus receptor recycling to the membrane; this eventually results in higher levels of activated Ras-GTP and finally in signal prolongation. At the same time, we identified the role of internalised MEK in sequestering Phosphatase2 in complexes, lowering the deactivation rate of Raf<sup>∗</sup> and thereby prolonging the signal.

A detailed study of the EGFR signalling pathway is presented in [\[15\]](#page-39-6). The authors quantified the relevance of reactions based on the concept of impact control coefficients, and the importance of proteins based on a fractional change of their total concentration. The time-dependent output was described by three characteristics: the amplitude, duration and integral of the ERK-PP profile. Index analysis allows a complementary view on the system. It focusses on individual state variables and on time, in contrast to reactions and lumped total concentrations. In [\[26\]](#page-40-10) general principles that govern signal transduction are identified, with the central conclusion that collectively, kinases control amplitudes more than duration, whereas Phosphatases tend to control both. Our time-resolved index analysis of the Phosphatases of the EGRF signalling network, in particular Phosphatase3, supports this conclusion and adds an additional detail: Phosphatases might also control the time to signal onset. In addition, we identified mechanistic principles underlying the conclusion including, e.g., the stoichiometric ratio of the Phosphatases and their binding partners (see paragraph on Phosphatases1–3 in the Results). While free Phosphatase1 levels are hardly impacted by complex formation with Raf<sup>\*</sup>, free Phosphatase3 levels are reduced by three orders of magnitude; nearly 100 % of Phosphatase3 is sequestered in complex with ERK-PP for a long time.

Overall, the input signal EGF exerts its impact on the output ERK-PP only during a very small time window (see Supplementary Material S14 Fig, left); it does so by strongly impacting, i.e., controlling, state variables during this time frame. In combination with roughly seven orders of magnitude smaller observability indices (see Supplementary Material S15 Fig, right), this can be interpreted as some robustness property of the signalling cascade. Random fluctuations of constituents in the absence of an input signal are unlikely to span several order of magnitude needed to spontaneously activate the cascade.

Index analysis naturally links to model reduction. In [\[14\]](#page-39-5), we introduced an empirical inputresponse index by building and expanding on the concepts of controllability and observability from control theory. Based on the empirical index, we proposed an iterative model reduction scheme. In application to the blood coagulation network, we illustrated its usefulness in a clinically relevant setting. A key feature of the proposed model reduction technique is its reference to a local regime in the state space (by defining a reference input in addition to input/output state variables). We demonstrated the advantage of such a local approach by identifying different reduced models based on different reference inputs. For the given application, this allowed to understand the lack of impact of certain genetic modifications for the outcome of the standard blood coagulation test and the presence of impact for a modified test. In the present work, the focus is rather on understanding a given signal transduction network. At the same time, the index analysis provides new insights and opens new possibilities for future model reduction approaches. By introducing state classification indices jointly with corresponding relative state approximation errors, we clearly discriminate between the impact of an approximation on the output and on the state itself. The newly introduced state classification indices provide further options for the model reduction approach proposed in [\[14\]](#page-39-5).

Index analysis may contribute to the identification of promising new drug targets in the future by providing a deeper understanding of the pharmacologically targeted system. Moreover, we envision that index analysis will be beneficial to study the difference between a healthy and diseased state, e.g., by comparing the index analyses of the two conditions and identifying state variables that change their input-response index or state classification index.

All in all, we believe that the proposed index analysis approach substantially broadens our means to analyse and understand complex signal transduction models in systems biology.

S1 Table. Model specification for the parallel pathway model. For the two scenarios of the model in Figure , the parameter values are stated below. The time span was  $t \in [0, 0.05]$  min, the input A, and the response D. The initial conditions were  $(A_0, B_0, C_0, D_0) = (20, 0, 0, 0)$  nM, in addition to  $S_0$  (in nM) specified below. Units:  $k_{ab}$ ,  $k_{ac}$ ,  $k_{bd}$ ,  $k_{cd}$  in  $1/nM/min$ ; all other reaction rate constants in 1/min.

S4 Fig. Scenario 'with crosstalk' of the parallel pathways model: time course of state variables and normalised indices. A: Time course of state variables and B: normalized ir-indices. C: State classification indices for states B and D: for C.

S5 Fig. Scenario 'with crosstalk' of the parallel pathways model: Relative state approximation error and modified dynamics. A: Relative state approximation errors for C. B: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) for C in partial steady state or D: completely neglected. C: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) for B completely neglected.

S6 Fig. Scenario no crosstalk of the parallel-pathways model: A: Time course of state variables and B: normalised ir-indices. C: state classification indices for B and D: for C.

S7 Fig. Scenario no crosstalk of the parallel-pathways model: A: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) for B and B: for C being completely neglected. C: state classification indices and D: relative state approximation errors for S.

#### S8 Fig. Reaction network of the enzyme kinetics model.

S2 Table. Model specification for the enzyme kinetics model. For the two scenarios of the model in Figure , the parameter values are stated below. The time span was  $t \in [0, 30]$  min, the input A, and the response P. The initial conditions were  $(A_0, S_0, C_0, P_0) = (50, 0, 0, 0, 0, M,$  in addition to  $E_0$  (in nM) specified below. Units:  $k_{on}$  in  $1/nM/min$ ; all other reaction rate constants in 1/min.

S9 Fig. Scenario 1 of the enzyme kinetics model: time course of state variables and normalised indices . A: Time course of state variables and B: normalized ir-indices. C: State classification indices for state C and D: for state E.

S10 Fig. Scenario 1 of the enzyme kinetics model: Relative state approximation error and modified dynamics . A: Relative state approximation errors for C and B: for E. C: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) for C in partial steady state and D: for E as environmental state.

S11 Fig. Scenario 2 of the enzyme kinetic model: A: Time course of state variables and B: normalised ir-indices. C: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) for C in partial steady state. D: Comparison of reference dynamics (solid lines) and modified dynamics from  $t^* = 0$  (dashed lines) with conservation law E+C in addition to C in partial steady state.

#### S12 Fig. Decision tree for state classification based on indices including lumping

#### S5 Text. How to setup a new model for Index Analysis

S13 Fig. Schematic with state classification of the signal transduction network focussing on the Shc-independent pathway, including the state variables with large maximum input-response index (light blue, see Figure 4D), environmental state variables (purple), state variables in quasi-steady state (green) and further state variables (dark blue). States being part of the membrane-bound and internalised pathway are coloured orange in panel (B). The red boxes mark the input and output state variables. Note that the difference to the Shc-dependent pathway is the absence of Shc (adaptor protein between GAP and Grb2).

#### S14 Fig. Number of normalised ir-indices above the threshold of 10%.

S15 Fig. Sum of contr- and obs-indices evolving over time. Left: Sum of contr-indices over time, showing three phases: initial sharp peak (0-0.3 min), second prolonged peak (0.3- 3 min), and a slow, still uncomplete recovery period (3-100 min). Right: Sum of obs-indices over time, showing three phases: initial sharp decline (0-1.5 min), marginal increase (1.5-20 min), and a strong decline (20-100 min). Note the very different scales on the y-axis.

S3 Table. Normalised input-response indices for the EGFR system; sorted according to their maximum
