## Abstract

The triangular lattice antiferromagnet (TLAF) has been the standard paradigm of frustrated magnetism for several decades. The most common magnetic ordering in insulating TLAFs is the  $120^\circ$  structure. However, a fundamentally new triple-**Q** chiral state can emerge in metallic TLAFs, representing the short wavelength limit of magnetic skyrmion crystals. We report the metallic TLAF  $\text{Co}_{1/3}\text{TaS}_2$  as the first example of tetrahedral triple-**Q** ordering with the associated topological Hall effect (non-zero  $\sigma_{xy}(\mathbf{H}=0)$ ). Our measurements of the inelastic neutron scattering cross section are also consistent with the calculated dynamical structure factor of the tetrahedral triple-**Q** state.

Discovering magnetic orderings with novel properties and functionalities is one of the main goals of condensed matter physics. While ferromagnets are still the best examples of functional materials due to their vast spectrum of technological applications, antiferromagnets are creating a paradigm shift for developing new spintronic components<sup>1,2</sup>. A more recent case is the discovery of Skyrmion crystals induced by a magnetic field in different classes of materials. These chiral states, which result from a superposition of three spirals with ordering wave vectors that differ by a  $\pm 120^\circ$  rotation about a high-symmetry axis, can produce a huge synthetic magnetic field that couples only to the orbital degrees of freedom of conduction electrons.

The triangular lattice Heisenberg model is a textbook example that can host a diverse spectrum of quantum states with small variations of short-range exchange interactions. For any spin value, the generic ground state for nearest-neighbour (NN) antiferromagnetic interactions is the three-sublattice  $120^\circ$  structure shown in Fig. 1a. This spiral structure is characterized by an ordering wave vector located at  $\pm K$ -points of the hexagonal Brillouin zone (Fig. 1d). Adding a relatively small second NN antiferromagnetic interaction gives rise to the two-sublattice collinear stripe spin configuration shown in Fig. 1b, whose ordering wave vector is one of the three M-points of the Brillouin zone (see Fig. 1e). Remarkably, for  $S = 1/2$ , these two phases seem to be separated by a quantum spin liquid state<sup>3-9</sup> whose nature is not yet fully understood.

However, small effective four-spin interactions can induce a fundamentally different chiral antiferromagnetic order in triangular lattice antiferromagnets. This state is the “triple-Q” version of the stripe order, where the three different M-ordering wave vectors (see Fig. 1f) coexist in the same phase giving rise to a noncoplanar four-sublattice magnetic ordering (see

Fig. 1c). The spins of each sublattice point along the all-in or all-out principal directions of a regular tetrahedron. Theoretical studies suggest that this state can appear naturally in metallic TLAFs, where effective four-spin interactions arise from the magnetic exchange interactions between conduction electrons and localized spin degrees of freedom<sup>10,11</sup>. This state was predicted to appear in the Mn monolayers on Cu(111) surfaces by density functional theory,<sup>12</sup> and it was observed in the hcp Mn monolayers on Re(0001) using spin-polarized scanning tunnelling microscopy<sup>13,14</sup>. However, it has not been reported yet in bulk systems.

The tetrahedral ordering is noteworthy for its topological nature, as it can be viewed as the short-wavelength limit of a magnetic skyrmion crystal<sup>15</sup>. The three spins of each triangular plaquette span one-quarter of the solid angle of a sphere, implying that each skyrmion (one flux quantum) is confined to four triangular plaquettes. As illustrated in Fig. 1c, the two-dimensional (2D) magnetic unit cell of the tetrahedral ordering consists of eight triangular plaquettes, meaning there are two skyrmions per magnetic unit cell. In other words, the tetrahedral triple- $\mathbf{Q}$  ordering creates a very strong effective magnetic field of one flux quantum divided by the area of 4 triangular plaquettes in the adiabatic limit. Notably, this ordering does not have any net *spin* magnetization. However, the emergent magnetic field couples to the orbital degrees of freedom of the conduction electrons, giving rise to a uniform *orbital* magnetization and a large topological Hall effect characterized by scalar spin chirality ( $\chi_{ijk} = \langle \mathbf{S}_i \cdot \mathbf{S}_j \times \mathbf{S}_k \rangle$ )<sup>16,17</sup>. Thus, this spin configuration is the simplest textbook example where non-trivial band topology is induced in the absence of *relativistic* spin-orbit coupling (the noncoplanar configuration generates the large spin-orbit coupling). Moreover, the tetrahedral ordering can provide a potential route to realize the antiferromagnetic Chern insulator by properly adjusting the Fermi level of the system, as suggested in Refs.<sup>10,11,18</sup>.

This work reports the four-sublattice tetrahedral triple- $\mathbf{Q}$  ordering as the only viable scenario for the metallic triangular antiferromagnet  $\text{Co}_{1/3}\text{TaS}_2$ . Our key observations are the coexistence of long-range antiferromagnetic ordering with wave vector  $\mathbf{q}_m = (1/2, 0, 0)$ , non-zero AHE ( $\sigma_{xy}(\mathbf{H} = 0)$ ), and weak ferromagnetic moment ( $M_z(\mathbf{H} = 0)$ ) below  $T_{N2}$ , which rule out the possibility of single- $\mathbf{Q}$  ordering. Based on the crystalline and electronic structure of  $\text{Co}_{1/3}\text{TaS}_2$ , we also provide a theoretical conjecture about the origin of the observed ordering, which is further corroborated by our ARPES (angle-resolved photoemission spectroscopy) data. Moreover, the calculated magnon spectra of the tetrahedral ordering agree with the low-energy spectra measured by inelastic neutron scattering. Finally, we discuss the robustness of the tetrahedral ordering against an applied magnetic field in  $\text{Co}_{1/3}\text{TaS}_2$ .

$\text{Co}_{1/3}\text{TaS}_2$  is a Co-intercalated metal comprising triangular layers of magnetic  $\text{Co}^{2+}$  ions (Fig. 1g). While most studies from the 1980s focused on the typical bulk properties of a metallic antiferromagnet<sup>19,20</sup>, a previous neutron diffraction study reported the ordering wave vector  $\mathbf{q}_m = (1/3, 1/3, 0)$  characteristic of  $120^\circ$  ordering<sup>21</sup>. In contrast, the latest experimental study of the single-crystal  $\text{Co}_{1/3}\text{TaS}_2$  reported two antiferromagnetic phase transitions at  $T_{N1} = 38$  K and  $T_{N2} = 26.5$  K (Fig. 1h), as well as a significant anomalous Hall effect (AHE) comparable to that of ferromagnets below  $T_{N2}$ <sup>22</sup>. The authors of Ref. <sup>22</sup> interpreted the observed AHE as being based on the ferroic order of cluster toroidal dipole moments, which is the only scenario that gives rise to finite  $\sigma_{xy}(\mathbf{H} = 0)$  for the single- $\mathbf{Q}$   $120^\circ$  ordering reported in Ref. <sup>21</sup>. However, our latest neutron scattering data reported in this work reveals an entirely different picture:

Co<sub>1/3</sub>TaS<sub>2</sub> has a magnetic structure with ordering wave vectors of the M-points ( $\mathbf{q}_m = (1/2, 0, 0)$  and symmetry-related vectors) instead of  $\mathbf{q}_m = (1/3, 1/3, 0)$ .

Figs. 2a and 2b show the neutron diffraction patterns of powder and single-crystal Co<sub>1/3</sub>TaS<sub>2</sub> for  $T < T_N$ . Magnetic reflections appear at the M-points of the Brillouin zone for both  $T < T_{N2}$  and  $T_{N2} < T < T_{N1}$ , implying that the ordering wave vector is  $\mathbf{q}_m = (1/2, 0, 0)$  or its symmetrically equivalent wave vectors. It is worth noting that this observation is inconsistent with the previously reported wave vector  $\mathbf{q}_m = (1/3, 1/3, 0)$ <sup>21</sup>; *i.e.*, Co<sub>1/3</sub>TaS<sub>2</sub> does not possess a 120° magnetic ordering. The magnetic Bragg peaks at the three different M points connected by the three-fold rotation along the c-axis ( $C_{3z}$ ) have equivalent intensities within the experimental error (Fig. 2c). This result suggests either single-**Q** ordering with three equally weighted magnetic domains or triple-**Q** ordering.

First, we analyzed the neutron diffraction data based on group representation theory and Rietveld refinement, assuming a single-**Q** magnetic structure:  $\mathbf{M}_i^v = \Delta_v \cos(\mathbf{q}_m^v \cdot \mathbf{r}_i)$  with  $v = 1, 2, \text{ and } 3$  (see Supplementary Text and Supplementary Table 3–4). As a result, we found that the spin configurations for  $T < T_{N2}$  and  $T_{N2} < T < T_{N1}$  correspond to Figs. 2g and 2h, respectively, where each configuration corresponds to  $\Gamma_2 + \Gamma_4$  ( $\alpha \mathbf{V}_{22} + \beta \mathbf{V}_{41}$ , see Supplementary Table 4) and the  $\Gamma_2$  ( $\mathbf{V}_{22}$ ) representations (see Supplementary Notes). The refinement result yielded an ordered moment of  $1.27(1)\mu_B/\text{Co}^{2+}$  at 3 K.

However, a single-**Q** spin configuration with  $\mathbf{q}_m = (1/2, 0, 0)$  possesses time-reversal symmetry (TRS) combined with lattice translation ( $\equiv \tau_{1a}T$ , see Fig. 2g or 2h), which strictly forbids the finite  $\sigma_{xy}(\mathbf{H} = 0)$  and  $M_z(\mathbf{H} = 0)$  observed at  $T < T_{N2}$  (Fig. 2e–f). Triple-**Q**

ordering is, therefore, the only possible scenario that can resolve this contradiction since it allows for finite  $\sigma_{xy}(\mathbf{H} = 0)$  and  $M_z(\mathbf{H} = 0)$  due to broken  $\tau_{1a}T$  symmetry<sup>23-25</sup>. In general, determining whether the magnetic structure of a system is a single- $\mathbf{Q}$  phase with three magnetic domains or a triple- $\mathbf{Q}$  ordering requires advanced experiments. However,  $\mathbf{q}_m = (1/2, 0, 0)$  is a special case where a triple- $\mathbf{Q}$  state can be easily distinguished from a single- $\mathbf{Q}$  state by probing non-zero TRS-odd quantities that are incompatible with  $\tau_{1a}T$  symmetry.

The triple- $\mathbf{Q}$  ordering that produces the same neutron diffraction pattern as that of Fig. 2h is illustrated in Fig. 2i. This is precisely the four-sublattice tetrahedral ordering shown in Fig. 1c, except that  $\text{Co}_{1/3}\text{TaS}_2$  has an additional 3D structure with an AB stacking pattern. Such a triple- $\mathbf{Q}$  counterpart can be obtained through a linear combination of three symmetrically-equivalent single- $\mathbf{Q}$  states ( $\mathbf{M}_i^\nu = \Delta_\nu \cos(\mathbf{q}_m^\nu \cdot \mathbf{r}_i)$  with  $\nu = 1, 2, 3$ ) connected by three-fold rotation about the  $c$ -axis<sup>26</sup>. More mathematical descriptions are provided in Supplementary Notes. However, an arbitrary linear combination yields a triple- $\mathbf{Q}$  spin configuration with a site-dependent magnitude of ordered moments on the Co sites, *i.e.*,  $|\mathbf{M}_i^{\text{tri}}|$  depends on  $i$  (see Supplementary Fig. 7). A uniform  $|\mathbf{M}_i^{\text{tri}}|$  is obtained only when the Fourier components  $\Delta_\nu$  of the three wave vectors  $\mathbf{q}_m^\nu$  are orthogonal to each other<sup>10</sup>, *i.e.*,  $\mathbf{M}_i^{\text{tri}} = \sum_{\nu=1,3} \Delta_\nu \cos(\mathbf{q}_m^\nu \cdot \mathbf{r}_i)$  with  $\Delta_\nu \perp \Delta_{\nu'}$  for  $\nu \neq \nu'$ .

In this context, the triple- $\mathbf{Q}$  ordering that yields a neutron diffraction pattern identical to that in Fig. 2g would give rise to nonuniform  $|\mathbf{M}_i^{\text{tri}}|$ , as illustrated in Supplementary Fig. 7. This is not realistic, and therefore, the single- $\mathbf{Q}$  ordering shown in Fig. 2g is more plausible for  $T_{N2} < T < T_{N1}$ , which is in line with the absence of  $M_z(\mathbf{H} = 0)$  and  $\sigma_{xy}(\mathbf{H} = 0)$  in this temperature range. This suggests that a transition from single- $\mathbf{Q}$  to triple- $\mathbf{Q}$  ordering occurs at

$T_{N2}$ . Interestingly, as we will see below, our theoretical analysis precisely captures this two-step transition process at  $T_{N1}$  and  $T_{N2}$ .

We now examine the feasibility of the tetrahedral triple-**Q** ground state in  $\text{Co}_{1/3}\text{TaS}_2$ . Notably, this state occurs spontaneously in  $\text{Co}_{1/3}\text{TaS}_2$  without requiring an external magnetic field, in contrast to typical triple-**Q** orderings reported in other materials<sup>27-29</sup>. It was suggested theoretically that this state could arise in a 2D metallic TLAf formulated by the Kondo lattice model<sup>10,11,18,30</sup>:

$$H = -t \sum_{\langle i,j \rangle} c_{i\alpha}^\dagger c_{j\alpha} - J \sum_i \mathbf{S}_i \cdot c_{i\alpha}^\dagger \boldsymbol{\sigma}_{\alpha\beta} c_{i\beta}. \quad (1)$$

$\text{Co}_{1/3}\text{TaS}_2$  is an ideal candidate for this model from a crystal structure perspective. The nearest Co-Co distance (5.74 Å) is well above Hill's limit, and the  $\text{CoS}_6$  octahedra are fully isolated ((Fig. 3a). This observation suggests that the Co 3d bands would retain their localized character, while itinerant electrons mainly arise from the Ta 5d bands. Our density functional theory (DFT) calculations confirm this picture and reveal that the density of states near the Fermi energy has a dominant Ta 5d orbital character (Supplementary Fig. 12). In this situation, a magnetic  $\text{Co}^{2+}$  ion can interact with another  $\text{Co}^{2+}$  ion only via the conduction electrons in the Ta 5d bands. Thus, in a first approximation, the  $\text{Co}^{2+}$  3d electrons can be treated as localized magnetic moments interacting via exchange with the Ta 5d itinerant electrons<sup>19,21</sup> (see Fig. 3b). Indeed, the Curie-Weiss behaviour observed in  $\text{Co}_{1/3}\text{TaS}_2$  provides additional support for this picture;

the magnitude of the fitted effective magnetic moment indicates  $S \sim 1.35$ , close to the single-ion limit of  $\text{Co}^{2+}$  in the high spin  $S = 3/2$  configuration<sup>22</sup>. However, neutron diffraction measurements indicate a significant suppression of the ordered magnetic moment  $S \sim 0.64$  (assuming that a  $g$ -factor is 2). Similar reductions of the ordered moment have been reported in other metallic magnets comprising 3d transition metal elements, and it is generally attributed to a partial delocalization of the magnetic moments. More specifically, in  $\text{Co}_{1/3}\text{TaS}_2$ , interactions between Co local moments and itinerant electrons from Ta 5d band can lead to a partial screening of the local moments. Another possible origin of the reduction of the ordered moment is strong quantum spin fluctuations arising from the frustrated nature of the effective spin-spin interactions.

Tetrahedral ordering can naturally emerge when the Fermi surface (FS) is three-quarters ( $3/4$ ) filled<sup>10,11,18,31</sup> because the shape of the FS is a regular hexagon, whose vertices touch the M-points of the first Brillouin zone (Fig. 3c). In this case, there are three nesting wave vectors connecting different M points, leading to a diverging magnetic susceptibility of the conduction electrons ( $\chi(\mathbf{q}, E_F)$ ) at  $\mathbf{q} \in \text{M-points}$ <sup>30</sup>. This naturally results in a magnetic order with ordering wave vectors corresponding to the three M points (*i.e.*, triple- $\mathbf{Q}$ ). While perfect nesting conditions are not expected to hold for real materials,  $\chi(\mathbf{q}, E_F)$  is still likely to have a global maximum at the three M points for Fermi surfaces with the above-mentioned hexagonal shape<sup>18</sup>. As shown on the right side of Fig. 3c, our ARPES measurements reveal that this is indeed the case of the FS of  $\text{Co}_{1/3}\text{TaS}_2$ , indicating that the filling fraction is close to  $3/4$  and that the effective interaction between the  $\text{Co}^{2+}$  magnetic ions is mediated by the conduction electrons.

The above-described stabilization mechanism based on the shape of the Fermi surface suggests

that the effective exchange interaction between the  $\text{Co}^{2+}$  magnetic ions and the conduction electrons is weak compared to the Fermi energy. Under these conditions, it is possible to derive an effective RKKY spin Hamiltonian by applying degenerate second-order perturbation theory in  $J/t$ <sup>30,31</sup>. Since the RKKY model includes only bilinear spin-spin interactions, the single-**Q** (stripe) and triple-**Q** (tetrahedral) orderings remain degenerate in the classical limit. Moreover, by tuning the mutually orthogonal vector amplitudes  $\Delta_\nu$  while preserving the norm  $|\Delta_1|^2 + |\Delta_2|^2 + |\Delta_3|^2$ , it is possible to continuously connect the single-**Q** (stripe) and triple-**Q** (tetrahedral) orderings via a continuous manifold of degenerate multi-**Q** orderings. The classical spin model's accidental ground state degeneracy leads to a gapless magnon mode with quadratic dispersion centred at the three M points. The accidental degeneracy is broken by effective four-spin exchange interactions that make the quadratic magnon mode gapped<sup>12,15,30,31</sup>. The simplest example of a four-spin interaction favouring the triple-**Q** ordering is the bi-quadratic term  $K_{\text{bq}}(\mathbf{S}_i \cdot \mathbf{S}_j)^2$  with  $K_{\text{bq}} > 0$ . This was explicitly demonstrated by using a simplified  $J_1$ - $J_2$ - $J_c$ - $K_{\text{bq}}$  model (see Figs. 3a and 3e), as shown in Supplementary Fig. 8. This model successfully captures the tetrahedral ground state and the two-step transition process at  $T_{\text{N2}}$  and  $T_{\text{N1}}$  observed experimentally, which is attributed to thermal fluctuations generally favouring the collinear spin configuration. In addition, previous DFT studies on  $\text{TM}_{1/3}\text{NbS}_2$  (TM = Fe, Co, Ni), which is isostructural to  $\text{Co}_{1/3}\text{TaS}_2$ , also revealed that a noncoplanar state could be energetically more favourable than collinear and co-planar states<sup>32</sup>.

Before analyzing the magnon spectra in detail, it is worth considering the inter-layer network of  $\text{Co}_{1/3}\text{TaS}_2$  with AB stacking. Along with the refined magnetic structure (Fig. 2g-i), the steep magnon dispersion shown in Fig. 3d indicates non-negligible antiferromagnetic NN interlayer

exchange:  $J_c S^2 \sim 2.95$  meV (see Fig. 3e). However, the finite value of  $J_c$  does not change the qualitative features of the 2D stripe and tetrahedral orderings. More importantly, the antiferromagnetic exchange  $J_c$  forces the tetrahedral spin configuration of the B layer to be the same as that of the A layer (see Supplementary Fig. 8a). Therefore, all triangular layers have the same sign of the scalar chirality  $\chi_{ijk}$  (or skyrmion charge), resulting in the realization of 3D ferro-chiral ordering. In this 3D structure, each magnetic unit cell of  $\text{Co}_{1/3}\text{TaS}_2$  includes four skyrmions, implying that the resultant fictitious field has an extremely high density.

The low-energy magnon spectra ( $< 3$  meV) of  $\text{Co}_{1/3}\text{TaS}_2$  measured by INS are presented in Fig. 3f. In addition to the linear (Goldstone) magnon modes, which appear as bright circular signals centred at the M points, a quadratic mode appears with weaker intensity as a line-shaped hexagon connecting six M points (see Supplementary Fig. 9). This signal is only present for  $E > 1.5$  meV, indicating that the quadratic mode is slightly gapped. We used linear spin-wave theory to compare the measured INS spectra with the theoretical spectra of both single-**Q** and triple-**Q** orderings. Despite the simplicity of the  $J_1$ - $J_2$ - $J_c$ - $K_{bq}$  model, the calculated magnon spectra of the tetrahedral ordering (Fig. 3g) successfully describe the measured INS spectra. The magnon spectra of the stripe order are also presented in Fig. 3h for comparison. The intensity of the quadratic magnon mode is much stronger than that of the triple-**Q** spectra, in apparent disagreement with our INS data. A complete comparison between our data and the two calculations is shown in Supplementary Fig. 10. Additionally, the linear magnon modes of  $\text{Co}_{1/3}\text{TaS}_2$  are slightly gapped ( $\sim 0.5$  meV, see Fig. 3i). This feature can be explained for tetrahedral ordering by including the higher-order single-ion anisotropy  $O_6^6$  (see Supplementary Fig. 11). Moreover,  $O_6^6$  can describe the tetrahedral spin configuration obtained from the Rietveld refinement (Fig. 2i), where one of the four spins is parallel to the  $c$ -

axis and the in-plane components of the other three spins are parallel to the  $a^*$ -axis (see Supplementary Fig. 11).

Finally, we discuss the behaviour of the tetrahedral ordering in  $\text{Co}_{1/3}\text{TaS}_2$  in response to out-of-plane and in-plane magnetic fields. Fig. 4c illustrates the field dependence of the measured anomalous Hall conductivity ( $\sigma_{xy}^{\text{AHE}}$ ) and  $M_z$  for  $\mathbf{H} // \mathbf{c}$ , showing evident hysteresis with a sign change at  $\pm H_{c1}$ . Indeed,  $M_z$  cannot characterize the observed  $\sigma_{xy}^{\text{AHE}}$  as already discussed in Ref. <sup>22</sup>. Instead, as explained in the introduction, it is  $\chi_{ijk}$  that characterizes  $\sigma_{xy}^{\text{AHE}}$  for the tetrahedral ordering. Therefore, the sign change at  $\pm H_{c1}$  represents the transition between tetrahedral orderings with positive and negative  $\chi_{ijk}$  values (see Figs. 4a–b). In addition, the coexistence of weak ferromagnetic moment and large  $\sigma_{xy}(\mathbf{H} = 0)$  is expected since the real-space Berry curvature of the tetrahedral triple- $\mathbf{Q}$  ordering should generate both the orbital ferromagnetic moment and spontaneous Hall conductivity (see the introduction section). However, the experimental techniques used in this study cannot discriminate between the spin and orbital contributions to  $M_z(\mathbf{H}=0)$ . While it will be interesting to identify the nature of this weak ferromagnetic moment, this is left for future studies.

We also compared the field dependence of the measured  $\sigma_{xy}^{\text{AHE}}$  and  $\chi_{ijk}$  calculated from our  $M_z(\mathbf{H})$  data based on the canting expected in the tetrahedral order of  $\text{Co}_{1/3}\text{TaS}_2$  (blue and orange arrows in Fig. 4). As shown in Fig. 4d,  $\sigma_{xy}^{\text{AHE}}$  decreases slightly in response to both positive and negative magnetic fields, consistent with the calculated  $\chi_{ijk}$  of the tetrahedral ordering with mild canting. However, such a model cannot capture the sudden decrease of  $\sigma_{xy}^{\text{AHE}}$  due to a meta-magnetic transition at  $\pm H_{c2}$ , indicating that this transition entirely

changes the spin configuration. Additional neutron diffraction is required to identify the new ordering for  $|\mathbf{H}| > H_{c2}$ .

The effect of an in-plane magnetic field was investigated using single-crystal neutron diffraction. Fig. 4e shows field-dependent ( $\mathbf{H} // \mathbf{q}_m^1 = (1/2, 0, 0)$ ) intensities of the three magnetic Bragg peaks, each originating from three different  $\mathbf{q}_m^v$  of the tetrahedral ordering. Interestingly, the equal intensity of the three peaks remains almost unchanged by a magnetic field up to 10 T, implying the robustness of the tetrahedral ordering against an in-plane magnetic field. This is in contrast to triple- $\mathbf{Q}$  states in other materials, which are induced by a finite magnetic field and occupy narrow regions of the phase diagram due to the ferromagnetic nature of the dominant exchange interaction<sup>27-29</sup>.

In summary, we have discovered a tetrahedral triple- $\mathbf{Q}$  ordering in  $\text{Co}_{1/3}\text{TaS}_2$ . Our study provides a complete picture of how this exotic phase can be stabilized in the triangular metallic magnet  $\text{Co}_{1/3}\text{TaS}_2$  and opens avenues for exploring chiral magnetic orderings with the potential for spontaneous integer quantum Hall effect<sup>30</sup>.

## Methods

**Sample preparation and structure characterization.** Polycrystalline  $\text{Co}_{1/3}\text{TaS}_2$  was synthesized by the solid-state reaction. A well-ground mixture of Co (Alfa Aesar, > 99.99 %), Ta (Sigma Aldrich, > 99.99%), and S (Sigma Aldrich, > 99.999%) was sealed in an evacuated quartz ampoule and then sintered at 900 °C for 10 days. A molar ratio of the three raw materials was  $\alpha:3:6$  with  $1.05 < \alpha < 1.1$ , which is necessary to obtain the resultant stoichiometric ratio of Co close to 1/3. Single-crystal  $\text{Co}_{1/3}\text{TaS}_2$  was grown by the chemical vapour transport method with an  $\text{I}_2$  transport agent (4.5 mg  $\text{I}_2/\text{cm}^3$ ). The pre-reacted polycrystalline precursor and  $\text{I}_2$  were placed in an evacuated quartz tube and then were heated in a two-zone furnace with a temperature gradient from 940 to 860 °C for 10~14 days.

We measured the powder X-ray diffraction (XRD) pattern of  $\text{Co}_{1/3}\text{TaS}_2$  using a high-resolution (Smartlab, Rigaku Japan) diffractometer, which confirmed the desired crystal structure without any noticeable disorder (Supplementary Fig. 1). In particular, the intercalation profile of Co atoms was carefully checked by the (10L) superlattice peak pattern in the low- $2\theta$  region. See Supplementary Table 1 for the refinement results. The powder neutron diffraction experiment further corroborated this result (see the relevant subsection below). Finally, single crystals were examined by Raman spectroscopy (XperRam Compact, Nanobase Korea), confirming their high quality based on the sharp Raman peak at  $137\text{ cm}^{-1}$ <sup>22</sup>.

The composition  $x$  of  $\text{Co}_x\text{TaS}_2$  single crystal was confirmed primarily by energy-dispersive X-ray (EDX) spectroscopy (Quantax 100, Bruker USA & EM-30, Coxem Korea). We measured 12 square areas of  $300\text{ }\mu\text{m} \times 300\text{ }\mu\text{m}$  wide for every single piece, yielding homogeneous  $x$  centred at  $\sim 0.320$  with a standard deviation of  $\sim 0.004$ . The homogeneity of  $x$  was further verified by the spatial profile ( $\sim 1.5\text{ }\mu\text{m}$  resolution) of the EDX spectra, which is very uniform, as shown in Supplementary Fig. 2. The obtained  $x$  from EDX was again cross-checked by the composition measured by inductively coupled plasma (ICP) spectroscopy (OPTIMA 8300, Perkin-Elmer USA), which is almost the same within a measurement error bar<sup>22</sup>.

**Bulk property measurements.** We measured the magnetic properties of  $\text{Co}_{1/3}\text{TaS}_2$  using MPMS-XL5 and PPMS-14 with the VSM option (Quantum Design USA). To measure the spontaneous magnetic moment (Figs. 3d and 5a), a sample was field-cooled under 5 T and then measured without a magnetic field. Transport properties of  $\text{Co}_{1/3}\text{TaS}_2$  were measured by using four systems: our home-built set-up, PPMS-9 (Quantum Design, USA), PPMS-14 (Quantum Design, USA), and CFMS-9T (Cryogenic Ltd, UK). To observe the temperature dependence of the anomalous Hall effect (Figs. 3d and 5b), we field-cooled the sample under  $\pm 9$  T and then measured the Hall voltage without a magnetic field. The measured Hall voltage was anti-symmetrized to remove any longitudinal components. Hall conductivity ( $\sigma_{xy}$ ) was derived using the following formula:

$$\sigma_{xy} = \frac{\rho_{xy}}{\rho_{xx}^2 + \rho_{xy}^2}. \quad (1)$$

Anomalous Hall conductivity  $\sigma_{xy}^{\text{AHE}}$  was derived by first subtracting a normal Hall effect from measured  $\rho_{xy}$  and then using Eq. (1).

**Powder neutron diffraction.** We carried out powder neutron diffraction experiments of  $\text{Co}_{1/3}\text{TaS}_2$  using the ECHIDNA high-resolution powder diffractometer ( $\lambda = 2.4395 \text{ \AA}$ ) at ANSTO, Australia. To acquire clear magnetic signals of  $\text{Co}_{1/3}\text{TaS}_2$ , which are weak due to the small content of Co and its small ordered moment, we used 20 g of powder  $\text{Co}_{1/3}\text{TaS}_2$ . The quality of the sample was checked before the diffraction experiment by measuring its magnetic susceptibility and high-resolution powder XRD. The neutron beam at ECHIDNA contains weak  $\lambda/2$  harmonics ( $\sim 0.3 \%$ ), yielding additional nuclear Bragg peaks (Supplementary Fig. 4). We also performed Rietveld refinement and magnetic symmetry analysis using Fullprof software<sup>33</sup>. The results are summarized in Supplementary Table 2-5 and Supplementary Fig. 3-4.

**Single-crystal neutron diffraction.** We carried out single-crystal neutron diffraction under a magnetic field using ZEBRA thermal neutron diffractometer at the Swiss spallation neutron source SINQ. We used one single-crystal piece ( $\sim 16 \text{ mg}$ ) for the experiment, which was aligned in a 10 T vertical magnet (Oxford instruments) with (*HHL*) horizontal (Supplementary Fig. 5a). The beam of thermal neutrons was monochromatic using the (220) reflection of germanium crystals, yielding a neutron wavelength of  $\lambda = 1.383 \text{ \AA}$  with less than 1% of  $\lambda/2$  contamination. Bragg intensities as a function of temperature and magnetic field were measured using a single  $^3\text{He}$ -tube detector in front of which slits were appropriately adjusted.

**Angle-resolved photoemission spectroscopy (ARPES) measurements.** The ARPES measurements were performed at the 4A1 beamline of the Pohang Light Source with a Scienta R4000 spectrometer<sup>34</sup>. Single crystalline samples with a large AHE were introduced into an ultra-high vacuum chamber and were cleaved in situ by a top post method at the sample temperature of  $\sim 20 \text{ K}$  under the chamber pressure of  $\sim 5.0 \times 10^{-11} \text{ Torr}$ . A liquid helium cryostat maintained the low sample temperature. The photon energy was set to 90 eV to obtain a high photoelectron intensity for the states of Co 3d characters. The total energy resolution was  $\sim 30 \text{ meV}$ , and the momentum resolution was  $\sim 0.025 \text{ \AA}^{-1}$  in the measurements.

**Single-crystal inelastic neutron scattering.** We performed single-crystal inelastic neutron scattering of  $\text{Co}_{1/3}\text{TaS}_2$  using the 4SEASONS time-of-flight spectrometer at J-PARC, Japan<sup>35</sup>. For the experiment, we used nearly 60 pieces of the single crystal with a total mass of 2.2 g, which were co-aligned on the Al sample holder with an overall mosaicity of  $\sim 1.5^\circ$  (Supplementary Fig. 5b). We mounted the sample with the geometry of the

(*HOL*) plane horizontal and performed sample rotation during the measurement. The data were collected with multiple incident neutron energies (3.5, 5.0, 7.9, 14.0, and 31.6 meV) and the Fermi chopper frequency of 150 Hz using the repetition-rate-multiplication technique<sup>36</sup>. We used the Utsusemi<sup>37</sup> and Horace<sup>38</sup> software for the data analysis. Based on the crystalline symmetry of  $\text{Co}_{1/3}\text{TaS}_2$ , the data were symmetrized into the irreducible Brillouin zone to enhance statistics.

**Classical Monte-Carlo Simulations.** To investigate the magnetic phase diagram of our spin model, we performed a classical Monte-Carlo (MC) simulation combined with simulated annealing. We used Langevin dynamics<sup>39</sup> for the sampling method of a spin system. To search for a zero-temperature ground state, a large spin system consisting of  $30 \times 30 \times 4$  unit cells (7200 spins) with periodic boundary conditions was slowly cooled down from 150 K to 0.004 K. The thermal equilibrium was reached at each temperature by evolving the system through 5000 Langevin time steps, with the length of each time-step defined as  $dt = 0.02/(J_1 S^2)$ . Finally, we adopted the final spin configuration at 0.004 K as the magnetic ground state, which was further confirmed by checking whether the same result was reproduced in the second trial.

For finite-temperature phase diagrams, we used a  $30 \times 30 \times 6$  supercell (10,800 spins). After waiting for 600 ~ 2,000 Langevin time steps for equilibration, 600,000 ~ 2,000,000 Langevin time steps were used for the sampling. Since thermalization and decorrelation time strongly depend on the temperature, the length of equilibration and sampling time steps were set differently for different temperatures. From this result, we calculated heat capacity ( $C_V$ ), staggered magnetization ( $M_{\text{stag}}$ ), and total scalar spin chirality ( $\chi_{ijk}$ ) using the following equations:

$$C_V = \frac{\langle \epsilon^2 \rangle - \langle \epsilon \rangle^2}{k_B T^2}, \quad (2)$$

$$M_{\text{stag}} = \frac{g\mu_B}{N} \sum_i (-1)^{2\pi(\mathbf{q}_m^v \cdot \mathbf{r}_i)} \langle \mathbf{S}_i \rangle, \quad (3)$$

$$\chi_{ijk} = \frac{1}{S^3} \frac{\sum_{\Delta} \langle \mathbf{S}_{\Delta 1} \cdot (\mathbf{S}_{\Delta 2} \times \mathbf{S}_{\Delta 3}) \rangle}{N_t}, \quad (4)$$

where  $\langle A \rangle$  is an ensemble average of  $A$  estimated by the sampling,  $\epsilon$  is the total energy per  $\text{Co}^{2+}$  ion,  $g$  is the Lande  $g$ -factor,  $\mathbf{q}_m^v$  ( $v = 1, 2, 3$ ) is the ordering wave vector of two-sublattice stripe order (see Supplementary Text),  $\Delta$  is the index for a single triangular plaquette on a Co triangular lattice consisting of three sites ( $\Delta_1, \Delta_2,$

$\Delta_3$ ), and  $N(N_t)$  is the total number of  $\text{Co}^{2+}$  ions (triangular plaquettes). When calculating  $M_{\text{stagg}}$ , one should first identify which ordering wave vector the spin system chose among the three  $\mathbf{q}_m^v$  ( $v = 1, 2, 3$ ), and then use proper  $\mathbf{q}_m^v$  to calculate  $M_{\text{stagg}}$ . For all the simulations, we used  $S = 3/2$ . The results of the simulations are shown in Supplementary Fig. 8.

**Spin-wave calculations.** We calculated the magnon dispersion and INS cross-section of  $\text{Co}_{1/3}\text{TaS}_2$  using linear spin-wave theory. For this calculation, we used the SpinW library.<sup>40</sup> Since we did not align positive and negative  $\chi_{ijk}$  domains of the tetrahedral ordering in our INS experiments, we averaged the INS cross-section of both cases. For the INS cross-section calculation with including higher-order single-ion anisotropies (Supplementary Fig. 11 & Supplementary Table 5), we used the calculation package Su(n)ny which is based on Landau-Lifshitz dynamics (LLD)<sup>41,42</sup>. We used a  $100 \times 100 \times 10$  supercell and the Langevin time step of  $dt = 0.1/(J_1 S^2)$  for this calculation. After evolving the system over 5,000 Langevin time steps for equilibration, 1,800 time steps were used for sampling the spin dynamics based on LLD.

**Density functional theory (DFT) calculations.** We performed first-principles calculations using ‘Vienna *ab initio*’ simulation package (VASP)<sup>43-45</sup> based on projector augmented wave (PAW) potential<sup>46</sup> and within Perdew-Burke-Ernzerhof (PBE) type of GGA functional<sup>47</sup> (see Supplementary Fig. 12). DFT+ $U$  method<sup>48,49</sup> was adopted to take into account localized Co-3d orbitals properly, where  $U = 4.1$  eV and  $J_{\text{Hund}} = 0.8$  eV were used as obtained by the constrained RPA for CoO and  $\text{Co}^{50}$ . For the  $2 \times 2$  magnetic unit cell, we used the  $\Gamma$ -centered  $6 \times 6 \times 6$   $k$ -grid. We obtained and used the optimised crystal structure with the force criterion for the relaxation fixed at  $1 \text{ meV}/\text{\AA}$ . The plane-wave energy cutoff was set to 500 eV.

### **Author contributions**

J.-G.P. initiated and supervised the project. P.P. synthesized the polycrystalline and single-crystal samples. P.P. performed all the bulk characterizations. M.A. carried out the powder neutron diffraction experiment. P.P. and R.S. performed the single-crystal neutron diffraction experiment at ZEBRA. P.P. analyzed the neutron diffraction data together with M.A.. P.P., C.K., Y.A., K.I., and R.K. conducted the single-crystal inelastic neutron scattering experiment at 4SEASONS. W.J., E.-J.C. and H.-J.N. conducted the ARPES experiment. Y.-G.K. and M.J.H. performed the DFT calculations. P.P., W.H.C., S.-S.Z., and C.D.B. conducted spin model calculations. P.P., W.H.C., S.-S.Z., K.H.L., Y.-G.K., M.J.H, H.-J.N., C.D.B., and J.-G.P. contributed to the theoretical analysis and discussion. P.P. C.D.B. and J.-G.P. wrote the manuscript with contributions from all authors.

**Supplementary Information** is available for this paper at [website url].

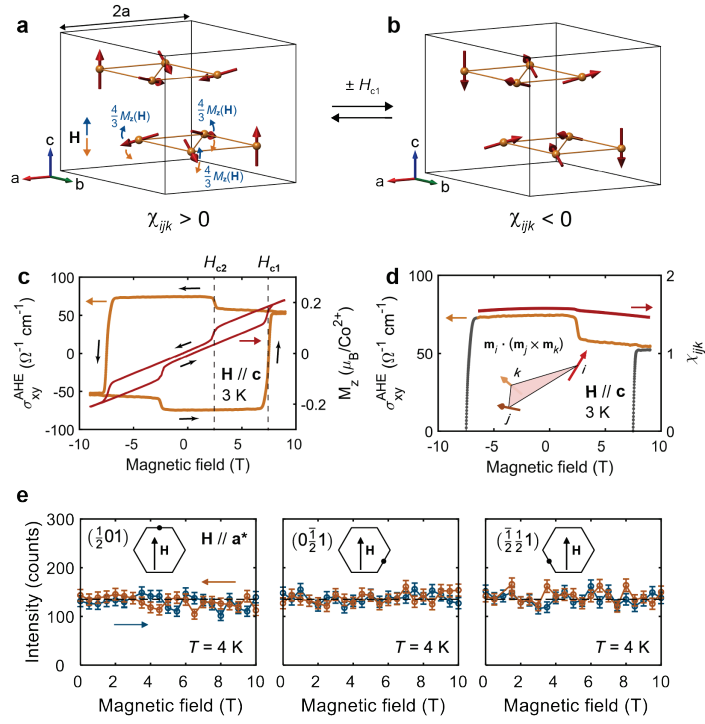

**Fig. 1 | The Tetrahedral triple-Q state and crystal structure of  $\text{Co}_{1/3}\text{TaS}_2$ .** **a–c**, Three fundamental antiferromagnetic orderings for a triangular lattice system. The red-shaded regions denote each magnetic unit cell. **d–f**, Positions of the magnetic Bragg peaks (red circles) in momentum space generated by **a–c**. A black (red) hexagon corresponds to a crystallographic (magnetic) Brillouin zone. The green and blue circles in **d–e** denote the magnetic Bragg peaks from the other two magnetic domains. **g**, A crystallographic unit cell of  $\text{Co}_{1/3}\text{TaS}_2$ . **h**, The temperature-dependent magnetization of single-crystal  $\text{Co}_{1/3}\text{TaS}_2$  with  $\mathbf{H}//\mathbf{c}$ .

**Fig. 2 | Magnetic ground state of  $\text{Co}_{1/3}\text{TaS}_2$  revealed by neutron diffraction.** **a**, The powder neutron diffraction pattern of  $\text{Co}_{1/3}\text{TaS}_2$ , measured at 60 K (Grey squares) and 3 K (Red circles). A weak  $\lambda/2$  signal is highlighted explicitly (see Methods). The solid black line is the diffraction pattern of  $\text{Co}_{1/3}\text{TaS}_2$  simulated with the spin configuration shown in **h**, or equivalently **i**. The full diffraction data can be found in Supplementary Fig. 4. **b**, The single-crystal neutron diffraction pattern at 5 K, demonstrating magnetic Bragg peaks located at the M points. **c**, The three magnetic Bragg peaks' intensities originate from three different ordering wave vectors. **d**, The temperature-dependent intensities of some magnetic Bragg peaks in single-crystal  $\text{Co}_{1/3}\text{TaS}_2$ . **e–f**, The temperature dependence of  $\sigma_{xy}(\mathbf{H} = 0)$  and  $M_z(\mathbf{H} = 0)$  in  $\text{Co}_{1/3}\text{TaS}_2$ , measured after field cooling under 5 T. **g–h**, The refined magnetic structures for **g**  $26.5 \text{ K} < T < 38 \text{ K}$  and **h**  $T < 26.5 \text{ K}$ . **i**, The triple-Q counterpart (tetrahedral) of the single-Q (stripe) ordering shown in **h**. Note that the spin configurations in **h** and **i** give the same powder diffraction pattern.

**Fig. 3 | Stabilization mechanism and dynamical properties of the tetrahedral order in  $\text{Co}_{1/3}\text{TaS}_2$ .** **a**, The in-plane crystal structure of  $\text{Co}_{1/3}\text{TaS}_2$  demonstrates isolated  $\text{CoS}_6$  octahedrons (purple-coloured) and a long NN Co-Co distance. **b**, The exchange interaction between Co local moments and conduction electrons from  $\text{TaS}_2$  layers leads to an effective RKKY interaction between the local moments. **c**, The Fermi surface of a 2D TLAF with  $3/4$  filling (shaded hexagons) and the Fermi surface of  $\text{Co}_{1/3}\text{TaS}_2$  measured by ARPES. **d**, The magnon spectra of  $\text{Co}_{1/3}\text{TaS}_2$  at 5 K along the (00L) direction.  $E_i = 7.9$  and 14 meV data are plotted. **e**, Antiferromagnetic NN interlayer coupling ( $J_c$ ) of  $\text{Co}_{1/3}\text{TaS}_2$ , which is necessary for explaining the data in (D) and the refined spin configuration (Fig. 2g–i). **f**, Const- $E$  cuts of the INS data measured at 5 K ( $< T_{N2}$ ). An energy integration range for each plot is  $\pm 0.2$  meV. The  $E = 1$  and 1.5 meV (2.0 ~ 3.0 meV) plots are based on the  $E_i = 5$  (7.9) meV data. In addition to bright circular spots centred at six M points (=linear modes), a weak line-shaped signal connecting the six M points (=the quadratic mode) appears for  $E > 1.5$  meV. **g**, The calculated INS cross-section of the tetrahedral triple-Q ordering with  $J_1 S^2 = 3.92$  meV,  $J_c S^2 = 2.95$  meV,  $J_2/J_1 = 0.19$ , and  $K_{\text{bq}}/J_1 = 0.02$  (see Supplementary Materials). **h**, The calculated INS cross-section of the single-Q ordering with three domains, using  $J_1 S^2 = 3.92$  meV,  $J_c S^2 = 2.95$  meV,  $J_2/J_1 = 0.1$ , and  $K_{\text{bq}}/J_1 = 0$ . The line-shaped signal in **h** has a much higher intensity than in **f** or **g**. The simulations in **g–h** include proper resolution convolution (see Supplementary Fig. 9), and their momentum and energy integration are the same as **f**. **i**, Low energy magnon spectra measured with  $E_i = 3.5$  meV at 5 K, showing the energy gap of the linear magnon mode.

**Fig. 4 | The effect of the out-of-plane and in-plane magnetic field on the tetrahedral triple-Q ordering in  $\text{Co}_{1/3}\text{TaS}_2$ .** **a-b**, A time-reversal pair of the tetrahedral spin configuration, having  $\chi_{ijk}$  opposite to each other. The blue and orange arrows in **a** depict the generic canting of the tetrahedral ordering in  $\text{Co}_{1/3}\text{TaS}_2$  by an out-of-plane magnetic field. **c**, Comparison between the measured  $\sigma_{xy}^{\text{AHE}}$  (orange) and  $M_z$  (red) under the out-of-plane field at 3 K. **d**, Comparison between the measured  $\sigma_{xy}^{\text{AHE}}$  (orange) at 3 K and  $\chi_{ijk}$  (red) calculated from the  $M_z$  data in **c**. **e**, Intensities of the three magnetic Bragg peaks in Fig. 2c under an external magnetic field along the  $\mathbf{a}^*$  direction.
