In this report, we investigated a new rare earth based one-dimensional Ising spin chain magnet DyNi₅Ge₃ by means of magnetization, specific heat and powder neutron diffraction measurements. Due to the crystalline electrical field splitting, the magnetic Dy ions share an Ising like ground doublet state. Owning to the local point symmetry, these Ising moments form into two canted magnetic sublattices, which were further confirmed by the angle-dependent magnetization measurement. In zero fields, two successive antiferromagnetic phase transitions were found at temperatures $T_{\rm N1}=6$ K and $T_{\rm N2}=5$ K, respectively. Only part of the moments are statically ordered in this intermediate state between $T_{\rm N1}$ and $T_{\rm N2}$. Powder neutron diffraction experiments at different temperatures were performed as well. An incommensurate magnetic propagation vector of $\mathbf{k}_{\rm m}=(0.5,0.4,0.5)$ was identified. The refined spin configurations through the irreducible representation analysis confirmed that these Ising spins are canted in the crystal ab plane.

I. INTRODUCTION

One-dimensional quantum magnets have received extensive research interest because of the emerging collective behaviors and strong quantum fluctuations enhanced by the low dimensionality [1, 2]. Unique magnetic ground states and exotic spin dynamics, such as the fractional spinon excitations have been explored with thermal property studies and neutron scattering techniques [3–7]. In addition, an external magnetic field can be applied along the longitudinal and transverse directions, which plays another important role in exploring the new exciting physics in one-dimensional quantum magnets [8, 9]. Besides the experimental side of view, the most important part is that the one dimensional quantum spin systems provided a particular platform for testing various theoretical and numerical models [10, 11]. The possibility to compare the experimental results with the exact theoretical and numerical solutions allows very precise analysis of the exotic physics in one-dimensional systems, which makes it one of the most exciting topics in condensed matter physics in the last few decades [12–15].

The recent work on the one-dimensional antiferromagnetic Ising spin chain compounds BaCo₂V₂O₈ [16] and SrCo₂V₂O₈ [17–20] presents a nice example. Exotic spin excitations involve two and more consecutive magnetic moments, which were known as Bethe strings [21], have been experimentally observed and quantitatively characterized in SrCo₂V₂O₈ [22]. However, due to the large exchange interactions between the magnetic Co²⁺ ions, high magnetic field larger than 20 T is required for further investigation of these exotic quantum excitations near the quantum critical region. Few experimental techniques have access to such a large magnetic field. On the contrary, the critical fields in one-dimensional quantum magnets with rare-earth ions are much smaller due to the relatively weak exchange interactions and the large effective g-factors arising from the strong spin orbital coupling. Relatively little research has been done on these systems, so new f-electron based one-dimensional quantum spin chains with accessible upper critical fields are highly demanded.

The rare-earth based germanide system RT_5Ge_3 (R = Ce, Nd, Dy, Yb, and T = Ni, Pd, Pt) crystallizes in an orthorhombic structure, with well separated one-dimensional spin chains, composed of the rare earth ions. For these rare-earth systems, due to the large splitting of the crystalline electrical field (CEF), the low temperature magnetism is usually dominated by the low lying CEF states. For Kramers ions, such as Ce, Nd, Dy and

^{*} These authors have contributed equally to this work.

[§] shengjm@sustech.edu.cn

Yb, the CEF splitting normally leads to a doublet ground state described by pseudo-spin S=1/2 with anisotropic effective g-factors. The ground doublet state wave functions are determined by the surrounding charges and the local point symmetry. It is interesting to notice that, the crystal space group of RT_5Ge_3 and the local site symmetry of the rare-earth ions were identical to the rare earth based orthorhombic perovskite system RTO_3 (R=Ce-Lu, T=Fe, Al, Sc), where one dimensional quantum magnetism has been explored [23–25]. Similar CEF configurations and one-dimensional magnetism are expected in this germanide system as well.

Previous studies on the isostructure compounds CePd₅Ge₃ and CePt₅Ge₃ reveal an antiferromagnetic ground state with significant spin fluctuations arising from the one dimensionality [26–29]. On the other hand, ferromagnetic like behaviors were observed for NdPd₅Ge₃ and NdPt₅Ge₃ [30]. Here, in this paper, we choose the Dysprosium (Dy) based germanide compound DyNi₅Ge₃, whose magnetic properties have not been explored yet. Single crystalline DyNi₅Ge₃ samples have been grown by the flux method, and thermal properties under field have been measured. An antiferromagnetic ground state is found. The zero field magnetic structure has been refined with the powder neutron diffraction measurements, and an incommensurate magnetic ground state is identified.

II. EXPERIMENTAL DETAILS

The single crystalline samples, used for thermal property measurements, were grown by the metallic flux method. High purity starting elements of Dysprosium (Dy), Nickel (Ni) and Germanium (Ge) were placed in alumina crucibles with excessive Bismuth (Bi) as flux. The assembly was sealed in evacuated quartz tubes, and heated up to 1050 °C until all the starting materials were completely melted. The assembly was then slowly cooled down to 650 °C at a rate of 3°C/h, at which temperature the extra Bi flux was mechanically removed by the centrifuge. Needle shaped DyNi₅Ge₃ single crystals of sizes about $0.1 \times 0.2 \times 5$ mm³ were left inside the growth crucibles. The crystal structure of DyNi₅Ge₃ was verified by the Bruker APEX-II CCD diffractometer. The magnetic susceptibility and specific heat measurements were performed by the commercial Quantum Design Magnetic Property Measurement System (MPMS) and the Physical Property Measurement System (PPMS).

To identify the zero field magnetic structure, an additional 3 g polycrystalline sample of $\mathrm{DyNi_5Ge_3}$ was synthesized by arc-melting a stoichiometric amount of the high purity starting elements under argon atmosphere. Powder neutron diffraction measurements were performed by the time-of-flight powder diffractometer, POWGEN, at Spallation Neutron Source (SNS), Oak Ridge National Laboratory [31]. An orange cryostat was used as the sample environment to cover a temperature region down to 1.8 K. High resolution neutron diffrac-

tion patterns were collected by two neutron frames with center wavelengths of 1.5 and 2.665 $\mathring{\rm A}$.

DyNi₅Ge₃ crystallized in an orthorhombic YNi₅Si₃type structure with the space group No.62. The crystal structure has been verified by the single crystal Xray diffraction measurement. The lattice parameters refined at 100 K are found to be $\alpha = \beta = \gamma = 90^{\circ}$, and a = 6.7934(3) Å, b = 19.0737(11) Å, c = 3.8549(2) Å,with the conventional Pbnm notation (Table I and II). We choose this traditional Pbnm notation for reasons. An advantage is that the one-dimensional Dysprosium (Dy^{3+}) spin chain is able to be along the crystal c axis. The distance between the nearest neighbour ions along the chain direction is about 3.85 Å, while the inter-chain distance is about 5.61 Å, as indicated in Fig. 1. In addition, the crystal ab plane is exactly the mirror plane with this Pbnm notation. This will make the discussion about the crystal field more straightforward, and make these results obtained here comparable with other systems sharing the same local point symmetry.

In DyNi₅Ge₃, the magnetic Dysprosium Dy³⁺ atoms are surrounded by the nearby Ni and Ge charges, with a local point symmetry $C_{\rm s}(m)$. This low local point symmetry would then lift the 2J + 1 = 16 (L = 5, S = 5/2, and J = 15/2) multiplet states of Dy³⁺ into eight doublet CEF states because of the strong spin-orbital couplings. The mirror symmetry in the crystal ab plane usually results in an Ising like ground state, with easy moment direction constrained either along the crystal c axis, which is perpendicular to the mirror plane, or lying within the ab mirror plane. In the latter case, the magnetic moments are likely to lie along the direction of an angle φ with respect to the a or b axis of the principle crystal, rather than strictly along them. This is because no additional rotational symmetry is preserved in this ab mirror plane. In addition, the local charge environments of the ${\rm Dy}^{3+}$ ions from nearby chains are connected by an inversion symmetry operation. This inversion symmetry operation relates the Ising moments of nearby chains with canted angles $\pm \varphi$ from the crystal a or b axis symmetrically. This situation is identical to that in the rare-earth orthorhombic perovskite oxides such as DyScO₃ and YbAlO₃ [23–25]. However, different from those perovsike oxides, the compound DyNi₅Ge₃ is metallic, and it is hard to assign an accurate charge to the surrounding Ni and Ge ions, due to the screen effect of the conducting electrons. Thus, the CEF calculations based on the point charge model can only give qualitative guide, rather than an accurate prediction as in rare earth oxides [23–25]. Therefore, to examine the magnetic ground state, further experimental characterizations with the anisotropic magnetization and neutron diffraction experiments are required.

B. Magnetization and Single Ion Anisotropy

The temperature-dependent magnetic susceptibility χ with field along different directions is shown in Fig. 2a. We can see that these measured susceptibility begin to

FIG. 2. (a) Temperature-dependent DC magnetic susceptibility χ (measured at B=0.1 T) with external magnetic fields applied along different principle axis. (b) The temperature-dependent magnetic susceptibility and the temperature derivative of the susceptibility $(d\chi/dT)$ at temperatures lower than 8 K, measured with field applied along the b axis. Two antiferromagnetic transitions at temperatures $T_{\rm N1}=6{\rm K}$ and $T_{\rm N2}=5{\rm K}$ were observed, as indicated by the vertical dashed lines.

deviate from each other below about 200 K. This single ion anisotropy is probably due to the CEF effect. When the measuring temperatures are lower than the excited CEF states, the magnetic properties will be dominated by the ground doublets. Depending on the wave functions of the ground doublets, strong single ion anisotropic behaviors start to build up. In Fig. 2a, we found that the measured magnetic susceptibility in the ab plane becomes larger than that along c axis as the temperature decreases. This suggests that these Dy moments are lying in the ab-mirror plane, as in systems like DyScO₃ [23]. In addition, the magnetization along b axis seems to be the dominant one, indicating that the local easy axis is close to the crystal b axis. Additional broad peaks are observed around 40 K for $B \parallel a$ and $B \parallel c$. These are

FIG. 3. (a) The field-dependent magnetization, measured at $T=1.8~\rm K$, with the field applied along b (within the mirror plane), (b) and c axis (perpendicular to the mirror plane). (c) The angle-dependent magnetization measured at $T=5~\rm K$ with the magnetic field applied in the ab mirror plane. The blue line represents the fitting assuming two canted Ising magnetic lattices.

probably due to the contributions of the excited CEF levels, which may locate at the energy scale of about 40 K to 200 K (or roughly $4\sim20$ meV).

It is the magnetic properties at the lowest temperatures that matter here, which are dominated by the ground doublet states. Thus, to avoid the complexity, we focus on the magnetization within the temperature region below about 10 K. As shown in Fig. 2b, the low temperature magnetization for $B \parallel b$ is measured in 0.1 T. A broad maximum like feature around 9 K was observed in $\chi(T)$, indicating short range correlations already start to build up. Following this broad maximum like feature, a significant drop at $T_{\rm N1}=6$ K is observed, indicating a long range antiferromagnetic order. In addition, in the temperature derivative of the susceptibil-

ity $(d\chi/dT)$ (blue line in Fig. 2b), an additional peak like anomaly shows up at $T_{\rm N2}$ = 5 K. Similar phenomena have been observed in other low dimensional frustrated metallic systems before [32]. In the case here, if next near neighbor interactions between chains are included, these one dimensional spin chains actually form two dimensional anisotropic triangular lattices (gray lines in Fig. 1). In this anisotropic triangular lattice, Dy spin chains are connected into bulked layers, composed of isosceles triangles. Considering that DyNi₅Ge₃ is a metallic system with large Ising moments, neither the long range Ruderman-Kittel-Kasuva-Yosida (RKKY) interaction nor the dipolar interaction can be neglected. Thus, the spin frustration is induced by these long range inter-chain interactions. In the mean time, part of the frustration is released with the establishment of a long range statical order. As proposed in HoAgGe [32], a possible scenario is that the antiferromagnetic ordering at $T_{\rm N1} = 6$ K is not a complete phase transition, and the system is in a partially ordered state in between $T_{\rm N1}$ and $T_{\rm N2}$. This scenario will be further discussed together with the specific heat and neutron scattering results.

The field-dependent magnetization is measured as presented in Fig. 3. Significant anisotropic behaviors are observed when an external field is applied in the ab plane and along the crystal c axis. Plateau like anomalies at 1/3and 1/2 are observed at 1.8 K as $B \parallel b$. These fractional plateau phases are also evident by the dip like features in the field derivative magnetic susceptibility (dM/dB)(green line in Fig. 3a). As discussed previously, these plateau like states are induced by the spin frustration. These observations further confirm that multiple interchain interactions are playing important roles in this system. On the other hand, linear like field-dependent magnetization is observed as $B \parallel c$ (Fig. 3b). The highfield saturation moment is about 9.2 $\mu_{\rm B}/{\rm Dy}$ for $B \parallel b$, which is one order larger than the measured magnetic moment along the c axis. These behaviors confirm that these Dy^{3+} magnetic moments are lying in the *ab*-mirror plane.

As expected from the CEF analysis based on the point symmetry, these moments are likely to be canted from the crystal a or b axis. To verify this, we performed the measurements of the angle-dependent magnetization with field rotating in the ab plane and the result is shown in Fig. 3c. These angles at $90^{\circ}(270^{\circ})$ and $0^{\circ}(180^{\circ})$ correspond to $B \parallel a$ and $B \parallel b$, respectively. We find that diplike features appear symmetrically around 90° and 270° . With the assumption of two canted magnetic sublattice of Dy³⁺ Ising moments, the measured angle dependence can be described as:

$$M = \frac{M_{\rm s}}{2}(|\cos(\varphi - \theta)| + |\cos(\varphi + \theta)|). \tag{1}$$

Here $M_{\rm s}$ is the saturation moment, φ is the local easy direction of these Ising Dy³⁺ moments from the b axis, and θ is the angle between the external field and crystal b axis. The fitting is represented as the blue line shown

in Fig. 3c. The extracted saturation moment is $M_{\rm s} = 9.7 \, \mu_{\rm B}/{\rm Dy}$, with titling angle $\varphi = 18.7^{\rm o}$. These values are well consistent with the field-dependent magnetization shown in Fig. 3a, where the saturation moments for $B \parallel b$ equal to $M_{\rm s}(B \parallel b) = 9.7 \times \cos\varphi \simeq 9.2 \, \mu_{\rm B}/{\rm Dy}$.

C. Specific Heat and Integrated Entropy

FIG. 4. (a) The temperature-dependent specific heat C of DyNi₅Ge₃(black line) and LuNi₅Ge₃ (green line) in zero fields. (b) The corrected magnetic specific heat and (c)the integrated temperature-dependent entropy. Vertical dashed lines indicate the two successive phase transitions at $T_{\rm N1}=6$ K and $T_{\rm N2}=5$ K.

The temperature-dependent specific heat C is measured in zero field and presented in Fig. 4a. The non-magnetic isostructural compound LuNi₅Ge₃ is synthesised as well, and the specific heat of LuNi₅Ge₃ is used as the estimation of the lattice contributions (green circles in Fig. 4a). The corrected magnetic specific heat $C_{\rm M}$

is then shown in Fig. 4b. Two subsequent phase transitions were observed at $T_{\rm N1}=6$ K and $T_{\rm N2}=5$ K in the temperature-dependent specific heat. These transition temperatures are well consistent with the observations in the magnetization derivatives dM/dT, as presented in Fig. 2b.

The integrated magnetic entropy is presented in Fig. 4c. A full entropy of Rln2 is realized around 10 K, confirming a doublet ground state at lower temperatures. Generally speaking, for classical magnets, the critical fluctuations are weak, and the full entropy or at least 80-90\% of the full entropy will be released at the transition temperature [33]. Here, in contrast, we found that only about 25% of the full entropy is released at $T_{\rm N2} = 5$ K and about 60% of the full entropy is released at $T_{\rm N1} = 6$ K for DyNi₅Ge₃. There are still about 40% of the full entropy left above the ordered state, indicating the existence of strong spin fluctuations. It is also noticed that the entropy of $60\%R\ln 2$ related to the ordered state is released successfully through the two transitions. These observations suggest that the magnetic Dy^{3+} moments are not completely ordered at $T_{\rm N1}$. The coexistence of a great amount of fluctuations suggest that these moments are likely only partially frozen in the intermediate ordered state between $T_{\rm N1}$ and $T_{\rm N2}$. What's more, the additional magnetic contributions larger than Rln2 is observed at temperatures higher than 10 K, even with the lattice contribution removed. The magnetic entropy may be contributed from the excited CEF levels, which may locate at energy levels around a few milli-electronvolts.

D. Neutron Scattering and Magnetic Ordering

To determine the magnetic structure of DyNi₅Ge₃, powder neutron diffraction measurements have been performed with the time-of-flight powder diffractometer POWGEN [31]. Fig. 5a-c present the powder diffraction patterns measured at 10 K, 5.5 K and 1.8 K. Consistent with our single crystal X-ray diffraction results, the Rietveld refinement of the neutron diffraction data at 10 K confirms the orthorhombic structure of DyNi₅Ge₃ with the space group Pbnm (No.62). These powder samples for neutron scattering were prepared separately by the arc-melt method. Besides the main phase of DyNi₅Ge₃, about $15.57 \pm 0.18\%$ DyNi₂Ge₂ and $7.12 \pm 0.22\%$ Ni are identified as additional impurity phases inside the powder sample. For T = 1.8 K, a new set of reflections emerged around the low-Q region, indicating the magnetic origin. By applying the K-search program of the FullProf Suite, an incommensurate magnetic propagation vector, $\mathbf{k}_{\mathrm{m}} = (0.5, 0.4, 0.5)$, can be determined for DyNi₅Ge₃. We also found that there was an extra weak magnetic peak around $Q = 0.499 \text{ Å}^{-1}$, which could be indexed by the magnetic propagation vector $\mathbf{q}_{\mathrm{m}} = (0,0,0.779)$ for the impurity DyNi₂Ge₂ phase. This propagation vector is consistent with the previously reported powder neutron diffraction results of DyNi₂Ge₂ [34, 35].

FIG. 6. The magnetic structure of $\mathrm{DyNi}_5\mathrm{Ge}_3$ below the ordering temperature refined from the neutron data. The arrows indicate the ordered Dy^{3+} spins, which are found to lie in the ab plane.

Representation analysis is applied to find the possible magnetic structures for $DyNi_5Ge_3$ [36]. For Dy^{3+} site at (0.877,0.355,0.250) and the magnetic propagation vector $\mathbf{k_m} = (0.5, 0.4, 0.5)$, the possible spin configurations can be described by four different irreducible representations (IRs). Table IIID lists the basis vectors for IRs Γ_1 , Γ_2 , Γ_3 and Γ_4 , respectively. For Γ_1 and Γ_3 , the moments are constrained along the c axis, which are in contrast to the magnetization measurement results. For Γ_2 and Γ_4 , the moments are allowed to lie in the ab plane. By Rietveld refinement, we found that Γ_4 could give the best fit with $R_{\rm F}=8.09\%$ and $R_{\rm wp}=9.29\%$ for the powder neutron diffraction data at 1.8 K, as shown in Fig. 5c. The determined magnetic structure is presented in the Fig. 6a and b. All the moments are lying in the ab plane. The spins on site Dy₁ and Dy₃, Dy₂ and Dy₄ are aligned in parallel, with a tilting angle $\pm 13.95(5)^{\circ}$ from the b axis. The tilting angle 13.95° refined from neutron diffraction experiments is slightly different from the angle of 18.7° determined through the previous angle-dependent magnetization measurement. However, considering that these are two independent measurements with their own systematic errors, we think these two values are still in good agreement with each other. Based on the propagation vector $\mathbf{k_m} = (0.5, 0.4, 0.5)$, each spin of Dy³⁺ in the crystal unit cell is antiferromagnetically aligned along the a and c axis, and the amplitude of the spins is modulated by $\mathbf{k_y} \cdot \mathbf{r}$ along the b axis. The amplitude moment for each Dy ion is about 9.41(39) $\mu_{\rm B}$.

Fig. 7a shows the contour plot of the measured neutron diffraction pattern as functions of temperatures. New set of magnetic reflections begins to develop below the antiferromagnetic ordering temperature $T_{\rm N1}=6$ K. However, no additional set of reflections is found below the second transition temperature at $T_{\rm N2}=5$ K. With further decreasing temperature, the intensity of all the magnetic peaks saturates below $T_{\rm N2}$. The temperature dependence of the refined moment of Dy³⁺ is shown in Fig. 7b, which is consistent with the evolution of the magnetic peaks. These neutron scattering results suggest that the Dy³⁺ moments in DyNi₅Ge₃ may share the

FIG. 7. (a) The contour plot of the measured neutron diffraction pattern collected at POWGEN in frame 3 as functions of temperature T and wave vector Q of the DyNi₅Ge₃ powdered sample. (b) Temperature evolution of the intensity of refined moment.

same ordering pattern in the intermediate temperature region between $T_{\rm N2}$ and $T_{\rm N1}$ and the lower temperature phase below $T_{\rm N2}$ (Fig. 5b and c). It is possible that the moments are only partially ordered in the intermediate temperature between $T_{\rm N2}$ and $T_{\rm N1}$, and then got further frozen in the phase below $T_{\rm N2}$. This is also consistent with the observations found in the specific heat and entropy measurements.

IV. CONCLUSION

In conclusion, we have performed a detailed investigation of DyNi₅Ge₃ through the specific heat, magnetization and powder neutron diffraction measurements. The crystal electrical field based on the crystal structure and local point symmetry suggests an Ising-like ground double state. Additional angle-dependent magnetization in the crystal ab plane reveals that these Ising Dy³⁺ moments are canted from the b axis by angle $\varphi \simeq 18.7^{\circ}$. The temperature-dependent magnetization and specific heat reveal two successive antiferromagnetic transitions at $T_{\rm N1}=6$ K and $T_{\rm N2}=5$ K. In the ordered state, fractional plateau phases at $M/M_s = 1/3$ and $M/M_s = 1/2$ are observed with magnetic field applied along the b axis. The measured specific heat and integrated magnetic entropy suggest that there exist a great amount of fluctuations persistent in the intermediate phase between $T_{\rm N1}$ and $T_{\rm N2}$. In addition, magnetic reflections are observed below $T_{\rm N1} = 6$ K in powder neutron scattering experiments. It is interesting to find that no additional magnetic peaks appeared below $T_{\rm N2}=5$ K. A possible scenario is that the intermediate phase and the lower temperature magnetic phase below $T_{\rm N2}=5~{\rm K}$ share a similar magnetic structure, but only partially ordered moments is observed in the former. The ground state magnetic structure has been presented as well with the irreducible representations analysis. The refined magnetic moments are found out to be tilted from the b axis by about $\varphi \simeq 13.95^{\circ}$. This value is close to the tilting angle $\varphi \simeq 18.7^{\circ}$ extracted from the angle-dependent magnetization measurements. In the future, single crystal neutron diffraction measurements with fields are needed, and the magnetic configurations with these fields induced plateau phases are worth further exploring.

ACKNOWLEDGMENTS

The research at SUSTech was supported by the National Natural Science Foundation of China (No. 12134020). Part of this work was also supported by the National Natural Science Foundation of China (No. 11974157, No. 11875265 and No. 12104255. This work was also supported by the Guangdong Basic and Applied Basic Research Foundation (No. 2021B1515120015), the Scientific Instrument Developing Project of the Chinese Academy of Sciences

(³He based neutron polarization devices), the Institute of High Energy Physics, the program for Guangdong Introducing Innovative and Entrepreneurial Teams (No. 2017ZT07C062), by Shenzhen Key Laboratory of Advanced Quantum Functional Materials and Devices

(No. ZDSYS20190902092905285). The authors acknowledge the assistance of SUSTech Core Research Facilities. Neutron diffraction measurements used resources at the Spallation Neutron Source, a DOE Office of Science User Facility operated by the Oak Ridge National Laboratory.
