Properties of 2D anyon gas

Douglas $Lundholm¹$

¹Department of Mathematics, Uppsala University, Box 480, SE-751 06, Uppsala, Sweden

An overview is given of the 2D many-anyon gas, including its definition (both for ideal and certain less-than-ideal particles, as well as for abelian and nonabelian braid group representations), its corresponding known properties starting out from the intricate relationship between exchange and exclusion, as well as its emergence from bosons and/or fermions in 3D. For the Encyclopedia of Condensed Matter Physics, 2e. Date: June, 2023

PACS numbers: 05.30.Pr, 03.75.Lm, 71.15.Mb, 73.43.-f Keywords: quantum statistics, anyons, intermediate and fractional statistics, braid group representations, statistics transmutation, exclusion principle, density functional theory, Thomas-Fermi approximation

Key points/objectives

• How can the 2D anyon gas be defined physically and modelled mathematically?

• What are the essential properties of the anyon gas? Does it admit some notion of exclusion statistics intermediate to bosons and fermions?

• How can an anyon gas emerge in a realistic physical system consisting of only bosons and/or fermions?

I. INTRODUCTION

Quantum statistics refers to the symmetry and organizing principle assumed by the components of a quantum system. Primarily we think of particles, described by a joint state or wave function, which can fall into certain symmetry classes due to the fundamental constraints on the information that can be extracted from the system, such as those imposed by the uncertainty principle. Bosons and fermions are ensembles of identical such particle subsystems characterized by symmetry, respectively antisymmetry, with respect to particle exchange. In their ideal limits they manifest the statistical state distributions defined by Bose and Einstein, respectively Fermi and Dirac, with the latter subject to Pauli's exclusion principle. In a sense, whereas bosons unify, fermions individualize. Anyons are defined as identical quantum particles with an intermediate exchange symmetry characterized by representations of the braid group, which is the relevant group of continuous exchanges of particle configurations in 2D (two spatial dimensions). An anyon gas is a quantum system consisting of a large number of such particles subject to a fixed class of exchange symmetries, which is dependent on the specific underlying kinematics and dynamics of the quantum systems from which it emerged. The study of the behavior of the proper anyon gas presents a significant challenge to mathematics and physics. Our aim with this overview is to make these statements precise and to give an updated status report on some of the many facets of the topic.

FIG. 1. Three different perspectives on anyons.

A. Brief historic overview

For completeness and to set our reference point for this overview, we give a very brief account on the origins of the anyon gas, referring to [\[Biedenharn et al.](#page-25-0) [1990,](#page-25-0) Fröhlich [1990,](#page-27-0) [Goldin](#page-27-1) [2022,](#page-27-1) [Leinaas and Myrheim](#page-28-0) [2022\]](#page-28-0) for further background.

1. Three perspectives on anyons

The discovery of anyons and intermediate quantum statistics in two spatial dimensions may be attributed to three independent research groups, working from three distinctly different perspectives^{[1](#page-0-0)}. Chronologically, these are (cf. Fig. [1\)](#page-0-1):

1. Geometric: In 1977, Leinaas and Myrheim used geometric methods from gauge theory, fiber bundles, and extensions of the kinetic energy operator via boundary con- $\frac{d}{dx}$ (also known as "Schrödinger quantization") to arrive at the possibility for what they termed "intermediate statistics" in 2D (as well as in 1D), and worked out some of its detailed consequences for two particles [\[Leinaas and Myrheim](#page-28-1) [1977\]](#page-28-1). They further pointed to the role of the fundamental group of the configuration space for arbitrary numbers of identical particles and the possibility for higher-dimensional fibers (necessary

 $¹$ These three groups were initially unaware of each other's earlier</sup> contributions and their initial works therefore lack the respective citations. There have subsequently been attempts to remedy this in the literature [\[Biedenharn et al.](#page-25-0) [1990\]](#page-25-0).

for nonabelian representations, but they did not explicitly mention the braid group or its representation theory in their work).

2. Algebraic: In 1980-'81, starting out from the representation theory of the Lie algebra of local currents on \mathbb{R}^d and the group of diffeomorphisms (akin to "Heisenberg quantization" and Dirac's canonical quantization scheme [\[Dirac](#page-26-0) [1967\]](#page-26-0)), Goldin, Menikoff and Sharp found a kinematical derivation of the possibilities for quantum statistics with an unexpected dependence on the dimension d [\[Goldin et al.](#page-27-2) [1981,](#page-27-2) [1980\]](#page-27-3). In [\[Goldin et al.](#page-27-2) [1981\]](#page-27-2) they also explored connections to the Aharonov–Bohm effect (in 3D), while subsequently in 1983 they highlighted the role of the one-dimensional unitary representations of the braid group [\[Goldin et al.](#page-27-4) [1983\]](#page-27-4), and in 1985 pointed out that higher-dimensional braid group representations induce inequivalent representations of the current algebra [\[Goldin et al.](#page-27-5) [1985\]](#page-27-5). Such identical particles were later termed "plektons" (see, e.g., [\[Dell'Antonio](#page-26-1) [et al.](#page-26-1) [1997,](#page-26-1) [Korff et al.](#page-27-6) [1999,](#page-27-6) [Mund and Schrader](#page-28-2) [1995\]](#page-28-2)) or simply "nonabelian anyons" (nowadays the more common term; cf. [\[Nayak et al.](#page-29-0) [2008\]](#page-29-0)). It was also pointed out in [\[Goldin et al.](#page-27-5) [1985\]](#page-27-5) that nontrivial exchange phases in 2D do not require indistinguishability; the colored braid group serves as the fundamental group for configurations of distinguishable particles. The general algebraic (and potentially nonabelian) approach to quantum statistics was further developed in the field theory direction by Tsuchiya and Kanie [\[Tsuchiya and Kanie](#page-29-1) [1987,](#page-29-1) [1988\]](#page-29-2), Kohno [\[Kohno](#page-27-7) [1987\]](#page-27-7), as well as Fröhlich, Gabbiani, Ker-ler and Marchetti [Fröhlich and Gabbiani [1990,](#page-26-2) Fröhlich [and Marchetti](#page-26-3) [1988,](#page-26-5) [1989,](#page-26-4) Fröhlich 1988, [1990,](#page-27-0) Fröhlich [and Kerler](#page-27-8) [1993\]](#page-27-8), and Fredenhagen, Rehren and Schroer [\[Fredenhagen et al.](#page-26-6) [1989\]](#page-26-6).

3. Magnetic: In 1982, motivated by topological gauge theory examples in higher dimensions ("θ-vacua" and "dyons"), Wilczek considered a composite of a 2D magnetic flux and a charged particle, coined for it the name "anyon", as well as predicted its fractional spin and worked out the basic quantum mechanics for two such composite particles [\[Wilczek](#page-30-0) [1982a,](#page-30-0)[b\]](#page-30-1). The same line of investigation was continued by Wu in 1984, who connected it to path integrals, extended it to arbitrary numbers of particles, and independently and explicitly invoked the braid group and its one-dimensional representations [\[Wu](#page-30-2) [1984a,](#page-30-2)[b\]](#page-30-3). Further, Arovas, Schrieffer, Wilczek and Zee considered in 1985 the statistical mechanics of a gas of such abelian anyons by means of its lowest-order virial expansion [\[Arovas et al.](#page-25-1) [1985\]](#page-25-1) (see also [\[Dowker](#page-26-7) [1985\]](#page-26-7)).

The first concrete physical application of intermediate/fractional statistics and anyons came from the magnetic perspective and concerned the fractional quantum Hall effect (FQHE) [\[Laughlin](#page-28-3) [1999,](#page-28-3) [Stormer](#page-29-3) [1999,](#page-29-3) [Tsui](#page-29-4) [1999\]](#page-29-4), in which the emergent fractionally charged quasiparticles/holes introduced by Laughlin were proposed by Halperin to have such properties [\[Halperin](#page-27-9)

[1984\]](#page-27-9). Arovas, Schrieffer and Wilczek subsequently verified this [\[Arovas et al.](#page-25-2) [1984\]](#page-25-2) (though under tacit assumptions of adiabaticity [\[Forte](#page-26-8) [1991\]](#page-26-8)) by computing the corresponding Berry phase for quasiholes, thereby converging the geometric and magnetic (and eventually algebraic) perspectives. Further, the latent power of the algebraic perspective was brought to light in the new millennium as Kitaev proposed the usefulness of nonabelian anyons in topological quantum computation [\[Freedman](#page-26-9) [et al.](#page-26-9) [2003,](#page-26-9) [Kitaev](#page-27-10) [2003,](#page-27-10) [2006\]](#page-27-11). Most of the development of the field throughout this time span has been covered in the books and reviews [\[Canright and Johnson](#page-26-10) [1994,](#page-26-10) [Date](#page-26-11) [et al.](#page-26-11) [2003,](#page-26-11) [Forte](#page-26-12) [1992,](#page-26-12) Fröhlich [1990,](#page-27-0) [Iengo and Lech](#page-27-12)[ner](#page-27-12) [1992,](#page-27-12) [Jackiw](#page-27-13) [1990,](#page-27-13) [Khare](#page-27-14) [2005,](#page-27-14) [Lerda](#page-28-4) [1992,](#page-28-4) [Myrheim](#page-29-5) [1999,](#page-29-5) [Nayak et al.](#page-29-0) [2008,](#page-29-0) [Ouvry](#page-29-6) [2007,](#page-29-6) [Stern](#page-29-7) [2008,](#page-29-7) [Wilczek](#page-30-4) [1990\]](#page-30-4).

2. Precursor ideas

As is evident from the above, anyons and intermediate ("fractional") quantum statistics are the convergence of many central ideas and concepts in mathematical physics. The former notion (anyon) is more closely tied into the concepts of exchange phases and symmetry classes of wave functions, while the latter (fractional statistics) to that of the exclusion principle and permissible probability distributions for particles. It has been—and still is—a nontrivial task to rigorously connect these two notions in the strictly intermediate case (see, e.g., the review [\[Canright and Johnson](#page-26-10) [1994\]](#page-26-10)). Exploration of intermediate statistics from the latter approach of exclusion with a finite occupation number of one-body states was considered by Gentile already in 1940-'42 [\[Gentile](#page-27-15) [1940,](#page-27-15) [1942\]](#page-27-16), and—inspired by anyons another, dimension-independent, approach allowing for fractional exclusion statistics was suggested by Haldane in 1991 [\[Haldane](#page-27-17) [1991\]](#page-27-17).

Ideas of charged particles encircling regions of magnetic flux were developed by Ehrenberg and Siday [\[Ehrenberg and Siday](#page-26-13) [1949\]](#page-26-13), Aharonov and Bohm [\[Aharonov and Bohm](#page-25-3) [1959\]](#page-25-3), and the more general con-cept of geometric phases by Pancharatnam [\[Pancharat](#page-29-8)[nam](#page-29-8) [1956\]](#page-29-8), Berry [\[Berry](#page-25-4) [1984\]](#page-25-4) and Simon [\[Simon](#page-29-9) [1983\]](#page-29-9). Methods of geometric quantization were developed by Souriau around 1967-'70, and he pointed out that if the configuration space is not simply connected then more than two different group characters could arise and this "would lead to prequantizations of a new type" [\[Souriau](#page-29-10) [1970\]](#page-29-10). Around the same time, homotopy classes of Feynman paths brought another topological perspective on quantum statistics [\[Dowker](#page-26-14) [1972,](#page-26-14) [Laidlaw and DeWitt](#page-27-18) [1971,](#page-27-18) [Schulman](#page-29-11) [1968\]](#page-29-11) (cf., e.g., [\[Mouchet](#page-28-5) [2021\]](#page-28-5)). For example, Laidlaw and DeWitt remarked that possibilities in two space dimensions are not limited to bosons and fermions, but they did not elaborate further [\[Laidlaw and](#page-27-18) [DeWitt](#page-27-18) [1971\]](#page-27-18).

Foundations for nonabelian anyons were laid much ear-

lier in the theory of parastatistics (nonabelian representations of the permutation group) [\[Green](#page-27-19) [1953,](#page-27-19) [Messiah](#page-28-6) [and Greenberg](#page-28-6) [1964\]](#page-28-6). Further, the central idea employed by Leinaas and Myrheim that equivalent configurations of indistinguishable particles need to be identified goes back all the way to Gibbs (cf. [Fröhlich [1990,](#page-27-0) [Leinaas](#page-28-1) [and Myrheim](#page-28-1) [1977\]](#page-28-1)).

The above shows that the essential ideas that were necessary for the discoveries of anyons were floating around at the time, and it is also of interest to remark that, while it took about half a century from the discovery of bosons and fermions to that of anyons, it took another half a century to see their experimental confirmation.

3. Some remarks concerning one-dimensional anyons

Although this article concerns anyons in the 2D setting, it is unavoidable to note the influence of ideas from generalized notions of quantum statistics in 1D (i.e. 1+1 spacetime dimensions). One of the first works in which generalized commutation relations for field operators can be found is Klaiber in 1968 [\[Klaiber](#page-27-20) [1968\]](#page-27-20), followed by Streater and Wilde [\[Streater and Wilde](#page-29-12) [1970\]](#page-29-12), and Fröhlich [Fröhlich [1976\]](#page-26-15). Transmutation of 1D hard-core bosons (studied classically by Tonks [\[Tonks](#page-29-13) [1936\]](#page-29-13)) into fermions and vice versa was considered by Girardeau [\[Girardeau](#page-27-21) [1960\]](#page-27-21), who also noted topological and dimensional consequences for the configuration space [\[Girardeau](#page-27-22) [1965\]](#page-27-22). The Lieb–Liniger model [\[Lieb](#page-28-7) [and Liniger](#page-28-7) [1963\]](#page-28-7) for point-interacting bosons in 1D constitutes the intermediate statistics found by Leinaas and Myrheim in 1D, however exchange phases (thus "anyonic Lieb–Liniger") may also be added to that model [\[Kundu](#page-27-23) [1999\]](#page-27-23). Leinaas and Myrheim later considered a different approach to statistics in 1D (and in higher dimensions) akin to "Heisenberg quantization" [\[Leinaas and Myrheim](#page-28-8) [1993\]](#page-28-8), and found a relationship to the Calogero–Sutherland model [\[Calogero](#page-25-5) [1969a](#page-25-5)[,b,](#page-25-6) [Poly](#page-29-14)[chronakos](#page-29-14) [1989,](#page-29-14) [Sutherland](#page-29-15) [1971\]](#page-29-15). 2D anyons that are forced into the lowest Landau level of a strong magnetic field may be understood using such 1D concepts [\[Ouvry](#page-29-6) [2007\]](#page-29-6).

B. Key points/objectives

We will in this overview focus on providing answers to the following key questions:

- 1. How can the 2D anyon gas be defined physically and modelled mathematically?
- 2. What are the essential properties of the anyon gas? Does it admit some notion of exclusion statistics intermediate to bosons and fermions?
- 3. How can an anyon gas emerge in a realistic physical system consisting of only bosons and/or fermions?

FIG. 2. The circle of abelian anyons, parametrized by the statistics parameter α . Note that any choice of proper anyons (i.e. neither bosons nor fermions) marks an additional point in this circle and thus breaks its orientation symmetry (mirror symmetry / complex conjugation).

The first question is addressed in the first part of Section [II](#page-2-0) for the case of the ideal abelian anyon gas, and in the first part of Section [III](#page-13-0) for the nonideal abelian gas. Section [IV](#page-18-0) introduces the nonabelian gas in brief. The second question is the subject of the later parts of Sections [II,](#page-2-0) [III](#page-13-0) and [IV.](#page-18-0) The third and final question is addressed in Section [V.](#page-20-0) Conclusions and an outlook are given in Section [VI.](#page-24-0)

II. THE IDEAL ANYON GAS

A. Quantum statistics

The possibility for anyons in 2D boils down to the peculiar geometry and topology of the plane as compared to spaces of higher dimensions. Consider for simplicity two particles at positions x_1 and x_2 in the Euclidean plane \mathbb{R}^2 , with a wave function Ψ encoding the probability density $|\Psi(\mathbf{x}_1, \mathbf{x}_2)|^2$ of observing the particles at these locations. An exchange of the two positions admits then a change in phase:

$$
\Psi(\mathbf{x}_2, \mathbf{x}_1) = e^{\pm i\theta} \Psi(\mathbf{x}_1, \mathbf{x}_2),
$$

where $\theta \in \mathbb{R}$. The sign is included above to specify the way in which the exchange is made, and if there is **orien**tation symmetry then we cannot distinguish between clockwise and counterclockwise exchanges, so that

$$
e^{i\theta} = e^{-i\theta} \quad \Leftrightarrow \quad e^{2i\theta} = 1,
$$

so $\theta/\pi \in \mathbb{Z}$ is either an even integer (bosons) or an odd integer (fermions). However, if we relax the assumption on orientation symmetry and consider a multivalued function for which we keep track of the number and orientation of elementary exchanges (the winding number), then we can allow *any* phase θ (anyons) to appear here. Conventionally, we write $\theta = \alpha \pi$ where α is known as the statistics parameter and can be either $\alpha \in \mathbb{R}$ (defined modulo periodicity 2) or in a suitable interval $\alpha \in (-1, 1]$ or $\alpha \in [0, 2)$; cf. Fig. [2.](#page-2-1)

More generally, we may consider a wave function Ψ for N distinct particles in d -dimensional Euclidean space \mathbb{R}^d and its probability density:

$$
|\Psi(\mathbf{x})|^2, \qquad \mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \in \mathbb{R}^{dN} \setminus \Delta_N,
$$

where, in order to indeed make them distinct we have removed the (fat) diagonal set where any two or more particles overlap:

$$
\mathbb{A}_N := \{ \mathbf{x} \in \mathbb{R}^{dN} : \mathbf{x}_j = \mathbf{x}_k \text{ for some } j \neq k \}.
$$

Our reason for considering distinct particles is that we, for simplicity at this stage, fix the particle number to N and assume that number to be certain and conserved (we shall return to possibilities of collisions on $\mathbb{\Delta}_N$ later).

In the case that the particles are identical and thus indistinguishable, then we should reduce the configuration space further and ignore the (now artificial) labels:

$$
X = {\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N} \in \mathcal{C}^N := (\mathbb{R}^{dN} \setminus \triangle_N) / S_N,
$$

where the permutation group S_N acts on the labels j of $x = (x_j)_{j=1}^N$ while leaving the equivalence class (set) X subject to this action fixed. Indeed, our N -particle configuration space is identical to the manifold

$$
\mathcal{C}^N = \{X = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^d : |X| = N\}
$$

of all N-point subsets of \mathbb{R}^d . If we now consider exchanges of particles then we can no longer act by permutations since it has lost meaning on configurations X of identical particles, however what we can consider instead is the *continuous* exchange of positions in \mathcal{C}^N . Namely, among the continuous paths from a point $X \in \mathcal{C}^N$ to another point $Y \in \mathcal{C}^N$ there are the *loops*, starting and ending at the same point $X = Y$, which we hereby take to represent continuous physical exchanges of identical particles [\[Leinaas and Myrheim](#page-28-1) [1977\]](#page-28-1). Given such exchange loops σ (continuous functions $[0, 1] \rightarrow \mathcal{C}^N$ of a parameter, s.t. $\sigma(0) = \sigma(1)$, we may then consider lifting any wave function Ψ which has been assigned a value on a configuration $X \in \mathcal{C}^N$ to a multivalued function^{[2](#page-3-0)} upon which the loops can act. Let us denote the action of a loop σ on Ψ at the point X by $\Psi(\sigma, X)$. Then we demand the exchange conditions

$$
\Psi(\sigma.X) = \rho(\sigma)\Psi(X),\tag{1}
$$

where $|\rho(\sigma)| = 1$, so that

$$
|\Psi(\sigma.X)|^2 = |\Psi(X)|^2 \tag{2}
$$

unambiguously defines a probability density at $X \in \mathcal{C}^N$. Further, $\rho(1) = 1$ for the trivial (constant) loop $\sigma = 1$, and if we compose two loops σ_1 and σ_2 into a new loop $\sigma_1\sigma_2$ then we demand the compatibility of the action,

$$
\rho(\sigma_1\sigma_2) = \rho(\sigma_1)\rho(\sigma_2).
$$

In other words, ρ is a group homomorphism and thus a representation of the group of exchange loops at X with composition.

In comparison, if we consider a single particle, $\mathcal{C}^{N=1}$ = \mathbb{R}^d , charged and subject to magnetism, then the action of a path should be understood as the (parallel) transport of the charge along the path, and different loops σ may then give rise to different holonomies or phases given by the flux enclosed by the loop:

$$
\rho(\sigma) = e^{i\Phi_{\sigma}}, \qquad \Phi_{\sigma} = \oint_{\sigma} \mathbf{A} \cdot d\mathbf{r} = \int_{\text{interior of } \sigma} B(\mathbf{x}) d\mathbf{x},
$$

where curl $\mathbf{A} = B$ is the magnetic field (viewed as a (pseudo)scalar field in $d = 2$ and appropriately projected in $d \geq 3$. However, for $N \geq 1$ and in the case that there is no external field so that $\rho(\sigma)$ should depend only on the topology of the loop σ , i.e. if we require that $\rho(\sigma) = \rho(\sigma')$ for any two topologically equivalent loops $\sigma \sim \sigma'$ (connected by some continuous deformation), then we consider loops only up to homotopy and the relevant group of (equivalence classes of) loops is the fundamental group of the configuration space [\[Goldin](#page-27-4) [et al.](#page-27-4) [1983,](#page-27-4) [1985,](#page-27-5) [Wu](#page-30-2) [1984a\]](#page-30-2):

$$
\sigma \in \pi_1(\mathcal{C}^N) = \begin{cases} \{1\}, & d = 1, \\ B_N, & d = 2, \\ S_N, & d \ge 3, \end{cases}
$$

where B_N denotes the **braid group**, defined below. The group is trivial[3](#page-3-1) in one dimension because particles then cannot exchange continuously without colliding, i.e. hitting the diagonal set $\mathbb{\Delta}_{N}$.

Now, if Ψ takes values in $\mathbb C$, then $\rho(\sigma)$ is a phase — the exchange phase corresponding to the exchange loop σ — and we may identify different **exchange** quantum statistics as symmetry classes of Ψ defined by ρ in [\(1\)](#page-3-2):

Bosons: $\rho(\sigma) = +1$, the trivial representation. Wave functions Ψ extend symmetrically from \mathcal{C}^N to $\mathbb{R}^{dN}, \frac{4}{3}$ $\mathbb{R}^{dN}, \frac{4}{3}$ $\mathbb{R}^{dN}, \frac{4}{3}$

$$
L^2_{\mathrm{sym}}(\mathbb{R}^{dN}) := \{ \Psi \in L^2 : \Psi(\sigma \mathbf{x}) = \Psi(\mathbf{x}), \ \sigma \in S_N \}
$$

(the usual action of permutations, and with any missing data on $\mathbb{\Delta}_N$ to be filled in, depending on our choice of Hamiltonian). For example, particles may be independent and identically distributed: $\Psi_0 = \otimes^N \psi_0 \in L^2_{sym}$,

$$
\Psi_0(\mathbf{x}) = (\otimes^N \psi_0)(\mathbf{x}) = \prod_{j=1}^N \psi_0(\mathbf{x}_j),
$$

corresponding to Bose–Einstein condensation in the single one-body state $\psi_0 \in L^2(\mathbb{R}^d)$.

² More concretely, a section of a bundle with base space \mathcal{C}^N , or a ρ -equivariant function on the covering space of C^N ; see e.g. [\[Dell'Antonio et al.](#page-26-1) [1997,](#page-26-1) [Dowker](#page-26-7) [1985,](#page-26-7) Fröhlich [1990,](#page-27-0) [Lundholm](#page-28-9) [2019,](#page-28-9) [Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) [Mund and Schrader](#page-28-2) [1995,](#page-28-2) [Myrheim](#page-29-5) [1999\]](#page-29-5). The range/fiber is initially C.

³ Interesting statistics can still emerge as a choice of boundary condition on Δ_N [\[Leinaas and Myrheim](#page-28-1) [1977\]](#page-28-1).

 4 \mathbb{L}^2 denotes the Hilbert space of square-integrable functions with inner product $\langle \Psi, \Phi \rangle = \int \overline{\Psi(x)} \Phi(x) dx$.

Fermions: $\rho(\sigma) = \text{sign}(\sigma) \in \{-1, +1\}$, the signed representation on S_N (signature of permutation). In this case wave functions Ψ extend antisymmetrically from \mathcal{C}^N to $\mathbb{R}^{dN},$

$$
L^2_{\text{asym}}(\mathbb{R}^{dN}) := \{ \Psi \in L^2 \colon \Psi(\sigma \cdot x) = \text{sign}(\sigma) \Psi(\mathbf{x}), \sigma \in S_N \}
$$

(in this case it is natural to require that Ψ vanishes on $\mathbb{\Delta}_N$). We apparently obtain determinantal correlations and the **Pauli principle**, since functions in L^2_{asym} are spanned by **Slater determinants**, such as $\Psi_0 = \psi_0 \wedge$ $\psi_1 \wedge \ldots \wedge \psi_{N-1}$, where

$$
\bigwedge_{k=0}^{N-1} \psi_k(\mathbf{x}_1,\ldots,\mathbf{x}_N) := \det \begin{bmatrix} \psi_0(\mathbf{x}_1) & \cdots & \psi_0(\mathbf{x}_N) \\ \vdots & & \vdots \\ \psi_{N-1}(\mathbf{x}_1) & \cdots & \psi_{N-1}(\mathbf{x}_N) \end{bmatrix}.
$$

Anyons: in $d = 2$ the most general ρ is a unitary representation of B_N . Proper anyons then correspond to those ρ which do not factor through S_N , i.e. for which orientation symmetry is broken. Let us denote by L^2_ρ the Hilbert space of square-integrable multivalued wave functions Ψ based on the configuration space \mathcal{C}^N and subject to the exchange conditions [\(1\)](#page-3-2). A central question is, whether we can anticipate intermediate or fractional exclusion statistics in L^2_{ρ} ? Actually, it turns out that the information at hand is not sufficient to decide this, and even the above conclusions for bosons and fermions can be misleading, as we will see below.

B. The braid group

For $d = 2$, the group of continuous loops in \mathcal{C}^N modulo homotopy is conveniently visualized as a group of Nparticle world lines that evolve in 2+1-dimensional spacetime, subject to composition via some arbitrary but fixed reference configuration $X_0 \in \mathcal{C}^N$. The resulting group, denoted B_N , is the **braid group on** N strands [\[Artin](#page-25-7) [1947,](#page-25-7) [1925,](#page-25-8) [Birman](#page-25-9) [1974\]](#page-25-9):

$$
B_N = \left\langle \sigma_1, \dots, \sigma_{N-1} \right. : \sigma_j \sigma_{j+1} \sigma_j = \sigma_{j+1} \sigma_j \sigma_{j+1},
$$

$$
\sigma_j \sigma_k = \sigma_k \sigma_j \right\rangle_{k \neq j \pm 1}^{j, k = 1 \dots N-1}
$$

That is, the group generated by $N-1$ elementary braids

$$
\sigma_j: \left|\left|\left|\left|\left|\right|\right\rangle\right|\right| \right| \left|\left|\left|\sigma_j^{-1}: \left|\left|\left|\left|\left|\left|\right|\right|\right|\right|\right|\right|\right|
$$

which are composed by stacking one on top of another. These elementary braids are subject to two sets of topological relations; one of which are known as the Yang-Baxter relations, and the other implement the commutativity of independent braids. In B_4 we have, e.g.,

FIG. 3. Exchange loops for a single resp. a pair of particles with p other particles enclosed, and corresponding braid diagrams and phases. From [\[Lundholm and Solovej](#page-28-11) [2013a\]](#page-28-11).

If we add a third set of relations $\sigma_j^2 = 1 \ \forall j$, or equivalently, $\sigma_j = \sigma_j^{-1}$, i.e. clockwise and counterclockwise exchanges cannot be distinguished, then we obtain the **permutation group** S_N . This will be the case for $d \geq 3$ since an elementary exchange may be rotated out of the plane (continuously and homotopically). From now on we shall stick to the anyonic case $d = 2$.

If one looks for irreducible abelian unitary representations, i.e. exchange phases

$$
\rho \colon B_N \to \mathrm{U}(1) = \{ z \in \mathbb{C} : |z| = 1 \},\
$$

then the Yang-Baxter relations single out a unique phase:

$$
\rho(\sigma_j) = e^{i\alpha \pi}
$$
, for all $j = 1, 2, ..., N - 1$; (3)

cf. Figs. [2](#page-2-1)[-3.](#page-4-0) The only representations that factor through S_N require either $\alpha = 0$ ($\alpha \in 2\mathbb{Z}$) or $\alpha = 1$ $(\alpha \in 2\mathbb{Z} + 1)$, thus corresponding to bosons or fermions. We will return to the nonabelian case, and representations with higher rank than 1, in Section [IV.](#page-18-0)

C. Kinetic energy

Above we considered wave functions $\Psi \in L^2_\rho$ that implement an exchange symmetry [\(1\)](#page-3-2) by choice of a representation ρ of B_N . However, it turns out that this is only one part of the data that specifies an anyon model. The other, equally essential, part is the choice of a Hamiltonian or kinetic energy operator. Namely, in order to be able to consider continuous exchanges of particles we also need to resolve space and time at the appropriate energy scale.

Our starting point is the nonrelativistic^{[5](#page-4-1)} free kinetic energy for N particles with mass m :

$$
T = \frac{1}{2m} \sum_{j=1}^{N} \mathbf{p}_j^2,
$$
 (4)

⁵ We remain nonrelativistic throughout this overview and likewise we will ignore spin; see however [Fröhlich [2009,](#page-27-24) [Jackiw](#page-27-13) [1990,](#page-27-13) [Mund](#page-28-12) [2009\]](#page-28-12).

where $\mathbf{p}_j \in \mathbb{R}^2$ is the momentum of the particle with position $\mathbf{x}_j \in \mathbb{R}^2$. If the particles are all distinguishable then the canonical quantization of this expression is obtained with momentum operators $\hat{\mathbf{p}}_j = -i\hbar \nabla_{\mathbf{x}_j}$ canonically conjugate to the position operators $\hat{\mathbf{x}}_i$, i.e.

$$
\hat{T}_{\text{dist}} := \frac{\hbar^2}{2m} \sum_{j=1}^{N} (-i\nabla_{\mathbf{x}_j})^2,\tag{5}
$$

acting on (suitably regular) $\Psi \in L^2(\mathbb{R}^{2N})$.

In our case of identical anyons we may consider the particles to be locally distinguishable. Namely, at any fixed point $X \in \mathcal{C}^N$ we may attach arbitrary labels to them:

$$
\mathcal{C}^N \ni X = \{ \mathbf{x}_1, \dots, \mathbf{x}_N \} \leftrightarrow (\mathbf{x}_1, \dots, \mathbf{x}_N) \in \mathbb{R}^{2N} \setminus \Delta_N,
$$

and we can keep track of these labels along any paths from X in \mathcal{C}^N as long as they cannot exchange nontrivially, i.e. as long as any two possible paths do not compose to a topologically nontrivial loop. So in order to define free anyons, the idea is then that we should keep the kinetic energy operator as above whenever we consider wave functions Ψ supported on topologically trivial subsets of \mathcal{C}^N (i.e. not encircling any of the holes in the manifold), which then can anyway be treated as subsets of the configuration space $\mathbb{R}^{2N} \setminus \Delta_N$ of distinguishable and distinct particles. Additional information must then be added to $\hat{T}_{\rm dist}$ whenever we pass between different such subsets of \mathcal{C}^N so as to complete topologically nontrivial loops $\sigma \in \pi_1(\mathcal{C}^N) = B_N$, $\sigma \neq 1$. One way to implement this concretely is to treat the exchange condition [\(1\)](#page-3-2) as a topological boundary condition^{[6](#page-5-0)} that Ψ must satisfy in order to be in the domain of the operator, which we denote by

$$
\hat{T}_{\rho} := \frac{\hbar^2}{2m} \sum_{j=1}^{N} (-i\nabla_{\mathbf{x}_j}^{(\rho)})^2, \tag{6}
$$

or simply by \hat{T}_{α} if $\rho(\sigma_j) = e^{i\alpha \pi}$. For convenience we also denote the Hilbert space L^2_ρ by L^2_α in this case. Again, we stress that \hat{T}_{α} acts *locally* as the standard Laplacian $\hat{T}_{\rm dist} = \frac{\hbar^2}{2m}$ $\frac{\hbar^2}{2m} \sum_{j=1}^{N} (-\Delta_{\mathbf{x}_j})$ on (suitably regular) $\Psi \in L^2_\alpha$, thus *independently* of α , but *globally* we have also the exchange conditions to account for, such as pair exchange

$$
\Psi(\mathbf{x}_1,\ldots,\mathbf{x}_k,\ldots,\mathbf{x}_j,\ldots,\mathbf{x}_N) = e^{i(2p+1)\alpha \pi} \Psi(\mathbf{x}_1,\ldots,\mathbf{x}_j,\ldots,\mathbf{x}_k,\ldots,\mathbf{x}_N), \quad (7)
$$

where p is the number of other particles enclosed in the exchange loop as x_i and x_k are exchanged once in a counterclockwise manner (as well as other conditions; cf. Fig. [3\)](#page-4-0).

As an example, consider the two-particle case $N = 2$ in center-of-mass and relative coordinates $\mathbf{X} = \frac{1}{2}(\mathbf{x}_1 + \mathbf{x}_2),$ $\mathbf{r} = \mathbf{x}_1 - \mathbf{x}_2$. Then the kinetic energy separates,

$$
\hat{T}_{\alpha} = \frac{\hbar^2}{4m}(-\Delta_{\mathbf{X}}) + \frac{\hbar^2}{m}(-\Delta_{\mathbf{r}}),\tag{8}
$$

and further, expressed in polar coordinates $(r = |\mathbf{r}|, \varphi)$:

$$
-\Delta_{\mathbf{r}} = -\partial_r^2 - \frac{1}{r}\partial_r - \frac{1}{r^2}\partial_\varphi^2.
$$
 (9)

These operators act on functions $\Psi(\mathbf{X}, r, \varphi)$ (here with its proper multivaluedness on \mathcal{C}^2 incorporated in the winding of $\varphi \in \mathbb{R}$ over multiples of π) such that

$$
\Psi(\mathbf{X}, r, \varphi + \pi) = e^{i\alpha \pi} \Psi(\mathbf{X}, r, \varphi), \quad r > 0,
$$
 (10)

corresponding to the exchange condition [\(7\)](#page-5-1) (all braids in B_2 are generated by this simple exchange σ_1). The manifold \mathcal{C}^2 may be parametrized by the set in \mathbb{R}^4 given by the half-space

$$
\Omega = \{ \mathbf{X} \in \mathbb{R}^2, r > 0, 0 \le \varphi < \pi \},
$$

and its boundary

$$
\partial\Omega = \{ \mathbf{X} \in \mathbb{R}^2, r = 0 \text{ or } \varphi = 0 \text{ or } \varphi = \pi \}
$$

relates the two points $(r > 0, \varphi = 0)$ and $(r > 0, \varphi = \pi)$ topologically to the same point in \mathcal{C}^2 . An equivalent de-scription is therefore [\(8\)](#page-5-2)-[\(9\)](#page-5-3) defined on $L^2(\Omega)$ and subject to the boundary condition

$$
\Psi(\mathbf{X}, r, \varphi = \pi) = e^{i\alpha \pi} \Psi(\mathbf{X}, r, \varphi = 0), \quad r > 0.
$$

The operator \hat{T}_{ρ} as defined above is formally hermitian but not self-adjoint (and not even necessarily essentially self-adjoint) since we have still not supplied any information at the diagonal set $\mathbb{\Delta}_N$, which cuts out holes of codimension 2 in the manifold \mathcal{C}^N (for $N=2$ this set is $\mathbb{A}_2 = {\{\mathbf{X} \in \mathbb{R}^2, r = 0\}}$. There is however a canonical choice of a self-adjoint realization (known in the mathematical literature as the Friedrichs extension), obtained by considering the expectation value of the kinetic energy in its formal quadratic form expression^{[7](#page-5-4)}

$$
\langle \Psi, \hat{T}_{\rho} \Psi \rangle = \frac{\hbar^2}{2m} \int_{\mathbb{R}^{2N}} \sum_{j=1}^{N} |\nabla_{\mathbf{x}_j}^{(\rho)} \Psi|^2 d\mathbf{x} \ge 0 \tag{11}
$$

initially on (multivalued) wave functions Ψ that are smooth and compactly supported away from \mathbb{A}_N and

 6 Technically, Ψ is defined as a complex-valued function on the covering space of \mathcal{C}^N subject to the *ρ*-equivariance condition [\(1\)](#page-3-2), which is equivalent to regarding Ψ as a section of a complex line bundle over \mathcal{C}^N with its geometry specified by $\rho: B_N \to$ $U(1)$ (locally flat, but globally curved by the holonomies specified by $\rho(\sigma)$ for $\sigma \in B_N$); see, e.g., [\[Dowker](#page-26-7) [1985,](#page-26-7) [Lundholm and](#page-28-10) [Qvarfordt](#page-28-10) [2020,](#page-28-10) [Mund and Schrader](#page-28-2) [1995\]](#page-28-2).

⁷ This is more appropriately defined on \mathcal{C}^N and observed to extend unambiguously to the covering space [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10).

subject to the exchange conditions (7) resp. $(1).⁸$ $(1).⁸$ $(1).⁸$ $(1).⁸$ For $N = 2$ the energy form (11) is

$$
\langle \Psi, \hat{T}_{\alpha} \Psi \rangle = \frac{\hbar^2}{m} \int_{\mathbf{X} \in \mathbb{R}^2} \int_{r=0}^{\infty} \int_{\varphi=0}^{2\pi} \left(\frac{1}{4} |\nabla_{\mathbf{X}} \Psi|^2 + |\partial_r \Psi|^2 + \frac{1}{r^2} |\partial_\varphi \Psi|^2 \right) d\varphi \, r dr \, d\mathbf{X}, \quad (12)
$$

again subject to the exchange condition [\(10\)](#page-5-6). In general then, this specific choice of a self-adjoint operator \hat{T}_{ρ} resp. \hat{T}_{α} is what we take to mean precisely by **free** (noninteracting, as compared to point-interacting; see below) ideal anyons, by analogy with bosons and fermions.

D. Statistics transmutation in 2D

So far we have worked exclusively in the geometric perspective of anyons, but will now be able to make the connection to the magnetic perspective.

Since we have fixed our attention on the plane \mathbb{R}^2 , it is occasionally convenient to switch to complex notation:

$$
\mathbb{R}^{2N} \ni \mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_N) \leftrightarrow \mathbf{z} = (z_1, z_2, \dots, z_N) \in \mathbb{C}^N,
$$

where the real (imaginary) part in $\mathbb C$ is canonically identified with the first (second) coordinate in \mathbb{R}^2 .

Now, consider either a bosonic or a fermionic wave function $\Psi \in L^2_{sym/asym}(\mathbb{C}^N)$ restricted to the subset of distinct coordinates $z \in \mathbb{C}^N \setminus \mathbb{A}_N$ and make there the gauge transformation $\Psi = U\tilde{\Psi}$, where

$$
U(z) := \prod_{j < k} \frac{z_j - z_k}{|z_j - z_k|} = \exp\left(i \sum_{j < k} \arg(z_j - z_k)\right), \tag{13}
$$

the product of all relative phases of pairs of particles. One may verify that this expression is well defined and

single valued on $\mathbb{C}^N \setminus \mathbb{\Delta}_N$, unitary $|U(z)| = 1$, and antisymmetric w.r.t. permutations of labels in $z = (z_j)_{j=1}^N$, so that if Ψ is symmetric then $\tilde{\Psi} = U^{-1} \Psi$ is antisymmetric, and vice versa. Thus, modulo the smaller set of diagonals \mathbb{A}_N where it is not defined, the unitary transformation by U achieves a statistics transmutation $L^2_{sym} \leftrightarrow L^2_{asym}$ between bosons and fermions in 2D. This perhaps seems confusing, however, recall that the kinetic energy is equally important in defining the exchange statistics. Indeed, if we consider the momentum then this transmutation comes at the cost of a gauge potential:

$$
-i\nabla_{\mathbf{x}_j}\Psi = U(-i\nabla_{\mathbf{x}_j} + \mathbf{A}_j)\tilde{\Psi},\tag{14}
$$

where we have defined the vector potentials

$$
\mathbf{A}_{j}(\mathbf{x}) := -iU^{-1}\nabla_{\mathbf{x}_{j}}U = \sum_{k \neq j} \frac{(\mathbf{x}_{j} - \mathbf{x}_{k})^{\perp}}{|\mathbf{x}_{j} - \mathbf{x}_{k}|^{2}},\qquad(15)
$$

for $j = 1, ..., N$, and we denoted a $\pi/2$ rotation in \mathbb{R}^2

$$
\mathbf{x} = (x, y) \quad \mapsto \quad \mathbf{x}^{\perp} = (-y, x)
$$

(or $z \mapsto iz$). In other words, if we had initially

$$
\hat{T}_{\text{asym}} = \frac{\hbar^2}{2m} \sum_{j=1}^{N} (-i\nabla_{\mathbf{x}_j})^2 \quad \text{acting on } L^2_{\text{asym}},
$$

then we now obtain

$$
\hat{T}_{\text{sym}\to\text{asym}} := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j} + \mathbf{A}_j \right)^2 \quad \text{acting on } L^2_{\text{sym}},
$$

so that indeed fermions may be represented as bosons, although with an additional magnetic interaction. The magnetic field seen by particle j ,

$$
\operatorname{curl}_{\mathbf{x}_j} \mathbf{A}_j = 2\pi \sum_{k \neq j} \delta(\mathbf{x}_j - \mathbf{x}_k), \tag{16}
$$

corresponds to the attachment of Aharonov–Bohm **point fluxes** of magnitude 2π to each of the other particles. The set where this field is singular is precisely $\mathbb{\Delta}_{N}$.

Similarly, if we fix a statistics parameter $\alpha \in \mathbb{R}$ and consider $\Psi = U^{\alpha} \tilde{\Psi}$ (now typically a singular gauge transformation involving multivalued functions over $\mathbb{C}^N \setminus \mathbb{\Delta}_N$ then

$$
-i\nabla_{\mathbf{x}_j}\Psi = U^{\alpha}(-i\nabla_{\mathbf{x}_j} + \alpha \mathbf{A}_j)\tilde{\Psi},\tag{17}
$$

and thus if we originally had the anyonic kinetic energy

$$
\hat{T}_{\alpha} = \frac{\hbar^2}{2m} \sum_{j=1}^{N} (-i\nabla_{\mathbf{x}_j})^2 \quad \text{acting on } \Psi \in L^2_{\alpha},
$$

then we obtain an equivalent description in terms of bosons:

$$
\hat{T}_{\text{sym}\to\alpha} := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j} + \alpha \mathbf{A}_j \right)^2, \text{ acting on } \tilde{\Psi} \in L^2_{\text{sym}}.
$$

⁸ There is a natural extension (closure) of the energy form [\(11\)](#page-5-5) to the largest subspace of the Hilbert space L^2_{ρ} upon which the energy is defined and finite, which is also the largest domain of the momentum operator $-i\nabla^{(\rho)}$. Denoting its adjoint $(-i\nabla^{(\rho)})^*$, one then defines $\hat{T}_{\rho} := \frac{\hbar^2}{2m} (-i\nabla^{(\rho)})^* (-i\nabla^{(\rho)})$, canonically selfadjoint on a corresponding smaller subspace of L^2_{ρ} . One might object that this approach seems to assume a hard-core condition on the anyons since functions are initially taken to vanish close to Δ_N , however for bosons and fermions this eventually yields exactly the standard free kinetic energy $\hat{T}_{\text{asym/sym}}$ (with the same expression as \hat{T}_{dist}) on the (Sobolev) spaces of anti/symmetric square-integrable functions with both one and two partial derivatives, that are also square-integrable. It is in fact a peculiarity of dimensions $d \geq 2$ that any extra conditions at the diagonals disappear in this procedure, so that our assumption on distinct particles is justified a posteriori; cf [\[Bourdeau](#page-25-10) [and Sorkin](#page-25-10) [1992,](#page-25-10) [Lundholm and Solovej](#page-28-13) [2014\]](#page-28-13). This can also be understood by means of a more precise version of the Hardy inequality [\(34\)](#page-10-0) discussed below [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10).

$$
\hat{T}_{\text{asym}\to\alpha} := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j} + (\alpha - 1) \mathbf{A}_j \right)^2,
$$

acting on L^2_{asym} . The magnetic field of $\alpha \mathbf{A}_j$ corresponds to the attachment of Aharonov–Bohm fluxes of magnitude $2\pi\alpha$ to each of the other particles. In this way we have the freedom to treat anyons as either bosons or fermions with topological magnetic interactions. This tool can certainly be beneficial as we can trade a simple operator (the free kinetic energy) but on a complicated geometry (multivalued functions with appropriate exchange conditions), for a complicated operator (magnetic interactions) but on a simple geometry (symmetric or antisymmetric functions on \mathbb{R}^{2N} . The former choice is usually referred to as the anyon gauge while the latter is the magnetic gauge, and this connection also brings us from an idealized world of quantum statistics of point particles and closer to the various possibilities for emergent statistics transmutation phenomena.

The procedure we referred to above to ensure the selfadjointness of the kinetic energy operator by extending the energy form (Friedrichs extension) also applies in this magnetic gauge formulation of the problem, so that indeed the operators $\hat{T}_{sym/asym\to\alpha}$ are self-adjoint on appropriate domains in $L^2_{sym/asym}$ where the energy is finite [\[Lundholm and Solovej](#page-28-13) [2014\]](#page-28-13). Further, we remark that multiples of the unitary multiplication operator

$$
U^2: L^2_{\text{sym/asym}/\alpha} \to L^2_{\text{sym/asym}/(\alpha+2)}
$$

may be used, together with complex conjugation symmetry, to obtain that the free ideal anyonic kinetic energies are unitarily equivalent w.r.t. the transformations

$$
\alpha \mapsto \alpha + 2n, \ n \in \mathbb{Z} \quad \text{and} \quad \alpha \mapsto -\alpha. \tag{18}
$$

E. Exchange vs. exclusion

Now that we have managed to define more or less concrete but still hypothetical models for ideal abelian anyons, we come to the next question: How do such anyons actually behave? If we are ever to observe them in nature then we need to know their behavior. So, are they more like bosons or more like fermions, or something in between, like the terms "intermediate statistics" or "fractional statistics" suggest? In other words, can we in any way relate the intermediate (braid) exchange statistics encoded into anyons to some intermediate exclusion statistics concerning the occupation numbers of various states as seen from a one-body perspective. Of course, since the magnetic gauge picture clarifies that anyons are (possibly) at least as complicated as strongly interacting systems of bosons or fermions, it is a priori

FIG. 4. Energy spectra for $N = 2$ (upper) and $N = 3$ (lower) anyons in a harmonic trap (minus the center of mass energy 1, and in suitable units). From [\[Yakaboylu et al.](#page-30-5) [2020\]](#page-30-5); cf. also [\[Leinaas and Myrheim](#page-28-1) [1977,](#page-28-1) [Murthy et al.](#page-29-16) [1991,](#page-29-16) [Sporre](#page-29-17) μ al. [1991\]](#page-29-17).

not at all obvious whether this is possible. The issue of exchange vs. exclusion was referred to as " α to β " by Canright and Johnson in their review [\[Canright and](#page-26-10) [Johnson](#page-26-10) [1994\]](#page-26-10) on the matter.

Hermitian vector bundle) over the configuration space of *N* Only in cases of very few particles, $N = 2, 3, 4$, are energy spectra for ideal anyons well understood, because they have then been computed analytically (for $N = 2$) [\[Arovas et al.](#page-25-1) [1985,](#page-25-1) [Leinaas and Myrheim](#page-28-1) [1977,](#page-28-1) [Wilczek](#page-30-1) [1982b\]](#page-30-1), also extending to a collective [\[Date and Murthy](#page-26-16) [1993,](#page-26-16) [Date et al.](#page-26-11) [2003\]](#page-26-11) part of the spectrum for all N [\[Chou](#page-26-17) [1991,](#page-26-17) [Wu](#page-30-3) [1984b\]](#page-30-3)) or numerically (the remaining change phase which comes in units of the condition of $\frac{1001 \text{ N}}{2}$ and $\frac{1001 \text{ N}}{2}$ and $\frac{1001 \text{ N}}{2}$ part of the spectrum [\[Murthy et al.](#page-29-16) [1991,](#page-29-16) [Sporre et al.](#page-29-17) $1001, 1001$]) in a formation spectrum in the spectrum spectrum in the spectrum spectrum in the spect [1991,](#page-29-17) [1992\]](#page-29-18)), in a few situations.

In order to lift the degeneracy of the spectrum and facilitate comparison, it is convenient to confine the particles in a harmonic trapping potential $V(\mathbf{x}) = \frac{1}{2}m\omega^2 |\mathbf{x}|^2$. For N anyons in the magnetic gauge description w.r.t. bosons we thus consider the Hamiltonian operator

$$
\hat{H}_N = \hat{T}_{\text{sym}\to\alpha} + \hat{V} = \sum_{j=1}^N \left[\frac{\hbar^2}{2m} \left(-i \nabla_{\mathbf{x}_j} + \alpha \mathbf{A}_j \right)^2 + V(\mathbf{x}_j) \right],
$$

FIG. 5. Schematic energy spectrum for $N \gg 1$ (left) and estimates for the g.s.e. near bosons and fermions (right) for anyons with statistics $\alpha = \theta/\pi$ in a harmonic trap. From [\[Chitra and Sen](#page-26-18) [1992\]](#page-26-18).

and its corresponding ground-state energy (g.s.e.)

$$
E_N := \inf \operatorname{spec} \hat{H}_N = \inf_{0 \neq \Psi \in L^2_{\text{sym}}} \langle \hat{H}_N \rangle_{\Psi}, \qquad (19)
$$

where $\langle \hat{A} \rangle_{\Psi} := \langle \Psi, \hat{A} \Psi \rangle / \langle \Psi, \Psi \rangle$ denotes the expectation of any operator \hat{A} in a state $\Psi \neq 0$. The spectrum of the 2D harmonic oscillator $\hat{H}_{N=1}$ is well known:

spec
$$
\hat{H}_1 = {\hbar \omega n}_{n=1,2,3,...}
$$
 (each with multiplicity *n*),

and for bosons one thus obtains N times the lowest eigenvalue, $E_N(\alpha = 0) = \hbar \omega N$, while for (spinless) fermions, due to the Pauli principle, we must sum over the N first eigenvalues according to their multiplicity: $E_N(\alpha=1) \sim \frac{\sqrt{8}}{3} \hbar \omega N^{3/2}$ as $N \to \infty$. Further, because of rotation symmetry, the Hamiltonian commutes with the total angular momentum operator

$$
\hat{L}/\hbar = -i \sum_{j=1}^{N} \left[x_j \partial_{y_j} - y_j \partial_{x_j} \right] = \sum_{j=1}^{N} \left[z_j \frac{\partial}{\partial z_j} - \bar{z}_j \frac{\partial}{\partial \bar{z}_j} \right],
$$

and its eigenvalues $L \in \mathbb{Z}$ can therefore be used to separate the energy spectrum further.

The spectrum of H_N for $N = 2$ and $N = 3$ is shown in Fig. [4,](#page-7-0) and while in the former case it manifests a strictly linear interpolation between bosons and fermions, [\[Leinaas and Myrheim](#page-28-1) [1977\]](#page-28-1)

$$
E_2(\alpha) = \hbar \omega \left(2 + \min_{q \in \mathbb{Z}} |2q + \alpha| \right), \tag{20}
$$

in the latter case there are also nonlinearly interpolating states at various L, and such a state with $L \neq 0$ comes down from an excited level at $\alpha = 0$ to reach the Fermi energy at $\alpha = 1$. Similar features are also seen in the numerical spectrum for $N = 4$ [\[Sporre et al.](#page-29-18) [1992\]](#page-29-18) and expected to occur for all $N \geq 3$ [\[Chitra and Sen](#page-26-18) [1992\]](#page-26-18).

9

Rough upper bounds for E_N at any α and N are obtained simply by considering trial states which localize the particles on separate domains in \mathbb{R}^2 , so that their exchange statistics is not seen (in the magnetic gauge picture one may then gauge away all magnetic interactions, while in the anyon gauge picture one then stays within a domain of distinguishability). By balancing the localization energy and the spread into the potential one then finds that $E_N(\alpha) \leq \hbar \omega N^{3/2}$, i.e. the energy is at most at the order of fermions. Note however that the fermionic energy does not provide a strict upper bound, as seen for $N = 3$ where $E_3(\alpha \approx 0.7) > E_3(\alpha = 1)$.

On the other hand, it is also useful to note that the bosonic energy, for which the g.s. Ψ_0 is a Gaussian at the origin $x = 0$, always gives a rigorous lower bound:

$$
E_N(\alpha) \ge E_N(0) = \hbar \omega N, \qquad (21)
$$

since the kinetic energy satisfies a diamagnetic inequality [\[Lundholm and Solovej](#page-28-13) [2014\]](#page-28-13)

$$
\langle \hat{T}_{\alpha} \rangle_{\Psi} \ge \langle \hat{T}_{\text{sym}} \rangle_{|\Psi|}. \tag{22}
$$

This is observed by factoring Ψ into its modulus and phase, and dropping the phase contribution to the momentum $-i\nabla\Psi$.

Chitra and Sen [\[Chitra and Sen](#page-26-18) [1992\]](#page-26-18) provided a more interesting lower bound to the spectrum for any N , ex-tending [\(20\)](#page-8-0): for an arbitrary state Ψ with angular momentum L , it holds

$$
\langle \hat{H}_N \rangle_{\Psi} \geq \hbar \omega \left(N + \left| L + \alpha \frac{N(N-1)}{2} \right| \right). \tag{23}
$$

Combined with our a priori upper bound, this implies that in the ground state the angular momentum needs to be close to

$$
L \approx -\alpha \binom{N}{2}
$$
, since $\left| L + \alpha \binom{N}{2} \right| \lesssim O(N^{3/2})$, (24)

so that on the average there needs to be an angular momentum $-\alpha$ for every pair of particles in order to cancel the shifted inherent/anyonic angular momentum (the number of attached units of magnetic flux per particle). This also means that as N grows large there will be a large number $O(N^{1/2})$ of level crossings in the g.s. between different integer angular momenta, because any fixed angular momentum L can only be good on a scale $\Delta \alpha = \tilde{O}(N^{-1/2})$. The situation is sketched in Fig. [5,](#page-8-1) where at fixed $N \gg 1$ one expects to find curves corresponding to families of states at fixed L, that are smoothly varying with α , to eventually come down to an energy $O(N^{3/2})$ on a $O(N^{1/2})$ -neighborhood around a suitable minimum $\alpha \approx \alpha_0(L)$, and then to again shoot upwards in energy with a slope $\geq O(N^2)$.

Chitra and Sen went on to estimate (again, see Fig. [5\)](#page-8-1) the enveloping g.s.e. curve close to bosons (suggesting $E_N/(\hbar\omega N^{3/2}) \approx \frac{7\sqrt{3}}{9}$ $\sqrt{\alpha}$) and to fermions (suggesting

 $E_N/(\hbar \omega N^{3/2}) \approx \frac{\sqrt{8}}{3}$, but left it as an open problem whether there are nonanalyticities in the limiting function

$$
h(\alpha) := \liminf_{N \to \infty} E_N(\alpha) / (\hbar \omega N^{3/2}), \tag{25}
$$

concluding that "This is an interesting but difficult question to answer."

F. Towards density functionals for anyons

The few-particle spectra led to some initial results on the thermodynamics of the anyon gas, by considering the high-temperature, low-density virial expansions [\[Arovas](#page-25-1) [et al.](#page-25-1) [1985,](#page-25-1) [Dowker](#page-26-7) [1985\]](#page-26-7) (see [\[Khare](#page-27-14) [2005,](#page-27-14) [Mancarella](#page-28-14) [et al.](#page-28-14) [2013a,](#page-28-14) [Myrheim](#page-29-5) [1999\]](#page-29-5) for review). In the lowtemperature regime, in order to make the many-anyon ground state problem more manageable, we could wish for a limiting effective description with a relatively limited number of degrees of freedom that are sufficient to describe the collective state of the system at $N \to \infty$. Such a state might converge towards the minimizer of a suitable functional, i.e. (taking some suitable scale $a > 0$ for normalization):

$$
E_N/N^a \xrightarrow{N \to \infty}
$$
 minimum of $\mathcal{E}[\psi]$ or $\mathcal{E}[\varrho]$, and

some marginal of g.s. Ψ_0 of $\hat{H}_N \xrightarrow{N \to \infty}$ minimizer of \mathcal{E} ,

where $\mathcal E$ is typically an energy functional of either onebody states $\psi \in L^2(\mathbb{R}^2)$ or of corresponding probability densities $\rho = |\psi|^2 \in L^1(\mathbb{R}^2)$ (with mass 1 or N).

For example, for 2D fermions in a trapping potential V , one has the **Thomas–Fermi approximation** [\[Fermi](#page-26-19) [1927,](#page-26-19) [Thomas](#page-29-19) [1927\]](#page-29-19):

$$
E_N = \inf_{0 \neq \Psi \in L^2_{\text{asym}}} \langle \hat{T}_{\text{asym}} + \hat{V} \rangle_{\Psi} \approx \inf_{\varrho \ge 0: \int_{\mathbb{R}^2} \varrho = N} \mathcal{E}^{\text{TF}}[\varrho],\tag{26}
$$

where the density $\rho = \rho^{\text{TF}} \approx \rho_{\Psi_0}$ (one-body marginal of g.s.) minimizes the Thomas–Fermi (TF) functional

$$
\mathcal{E}^{\mathrm{TF}}[\varrho] := \int_{\mathbb{R}^2} \left[2\pi \varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x}.
$$
 (27)

(Note: To simplify our discussion, we shall now and in the remainder of this article assume that the physical constant $\hbar^2/(2m) = 1$, i.e. $T = \mathbf{p}^2$, by an appropriate choice of units $\hbar = 2m = c = e = 1$.) The kinetic energy density is here given by the energy per unit area of the homogeneous 2D Fermi gas at density $\rho(\mathbf{x})$, obtained e.g. by confining N fermions in a box of area $L \times L$, summing the one-body eigenvalues, and taking the thermodynamic limit:

$$
E_N/L^2 \xrightarrow{N,L \to \infty} 2\pi \bar{\varrho}^2
$$
, at fixed $\bar{\varrho} = N/L^2$.

On the other hand, for bosons with sufficiently weak scalar interactions one has the Gross–Pitaevskii (GP)

functional [\[Gross](#page-27-25) [1961,](#page-27-25) [Pitaevskii](#page-29-20) [1961\]](#page-29-20):

$$
\mathcal{E}^{\rm GP}[\psi] := \int_{\mathbb{R}^2} \left[\left| (-i\nabla + \mathbf{A}_{\rm ext})\psi \right|^2 + V|\psi|^2 + g|\psi|^4 \right], (28)
$$

describing approximate condensation into the state $\psi \in$ $L^2(\mathbb{R}^2)$ as $E_N/N \to$ minimum of \mathcal{E}^{GP} . In regimes where the interaction strength $g \in \mathbb{R}$ (related to the scattering length of the interaction potential) dominates over the kinetic term one may neglect that term and keep only the last two terms, again leaving a functional of $\rho = |\psi|^2$ of the Thomas–Fermi type with $q \leftrightarrow 2\pi N$ (this is only a formal analogy at the level of functionals, since the two mechanisms of the approximations are very different).

In view of the above, could one then suggest the following interpolating functional for $0 < \alpha \leq 1$, describing an "average-field" approximation for anyons

$$
\mathcal{E}^{\text{af}}[\varrho] \approx \int_{\mathbb{R}^2} \left[2\pi \alpha \varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x} \quad ? \tag{29}
$$

Indeed, in a mean-field^{[9](#page-9-0)} (**Hartree**) ansatz for the ground state in the bosonic representation, consider:

$$
\Psi(\mathbf{x}) = \psi(\mathbf{x}_1)\psi(\mathbf{x}_2)\dots\psi(\mathbf{x}_N),\tag{30}
$$

and we may think of a single particle $\psi \in L^2(\mathbb{R}^2)$ in the magnetic field of the others (identically distributed):

$$
B(\mathbf{x}) \approx 2\pi\alpha (N-1)|\psi(\mathbf{x})|^2 \approx 2\pi\alpha \varrho_{\Psi}(\mathbf{x}). \tag{31}
$$

If the density $\varrho_{\Psi} = N |\psi|^2$ is approximately constant on an area $L \times L$ where N bosons condense into the lowest Landau level of the field B (cf. [\(64\)](#page-16-0) below), then one indeed obtains an energy per unit area

$$
E_N/L^2 \approx BN/L^2 \approx 2\pi\alpha \bar{\varrho}^2, \qquad \bar{\varrho} = N/L^2, \qquad (32)
$$

thus suggesting [\(29\)](#page-9-1). For the ideal anyon gas this argument is not rigorous, because one cannot apply such an ansatz in the singular magnetic field (it is not in the appropriate domain of \hat{T}_{α}). This difficulty can be overcome using regularization however, and we return to it in Section [III B](#page-14-0) in conjunction with the extended anyon gas. Thus, after accepting some refinements to the "averagefield" approach in that context, it has been successfully applied in the limits $\alpha \to 0$ and $\alpha \to 1$ as $N \to \infty$.

To be precise, if we wish to refer to the approximation as above with an almost constant field (on the scale of a trap) then it is perhaps more appropriate to call it a "constant-field" approximation. We also note that if [\(29\)](#page-9-1) would be a valid description for proper anyons then it suggests that for the harmonic oscillator problem

$$
E_N \stackrel{?}{\approx} \inf_{\substack{\varrho \ge 0 \\ \int \varrho = N}} \int_{\mathbb{R}^2} \left[\frac{\hbar^2 \pi \alpha}{m} \varrho(\mathbf{x})^2 + \frac{m\omega^2}{2} |\mathbf{x}|^2 \varrho(\mathbf{x}) \right] d\mathbf{x}
$$

$$
= \frac{\sqrt{8}}{3} \sqrt{\alpha} \, \hbar \omega N^{3/2}, \qquad 0 < \alpha \le 1. \tag{33}
$$

⁹ We differentiate between "average-field" and "mean-field", partly to distinguish the anyonic context, but also because of more technical reasons that will be clarified below.

Early applications of variants of density functional theory (DFT) to the anyon context were made by Chitra and Sen, who proposed the refinement as in Fig. [5](#page-8-1) due to the bosons' hard core [\[Chitra and Sen](#page-26-18) [1992\]](#page-26-18), and by Li, Bhaduri and Murthy who considered an extension of TF theory to excited states in the spectrum [\[Li et al.](#page-28-15) [1992\]](#page-28-15). Again, only some aspects have been rigorously justified, in the limits close to bosons and fermions.

G. Local exclusion principle and degeneracy pressure for the ideal anyon gas

An approach that has been successful for an increased qualitative understanding of the genuine ideal anyon gas at arbitrary α is to take a strictly *local* route to exclusion via the wider concept of statistical repulsion. Namely, one may note that statistical repulsion manifests itself in the anyon gas in (at least) three ways:

1. Effective scalar pairwise repulsion. The exchange conditions [\(7\)](#page-5-1) for each pair of particles transpire to yield a pair repulsion between particles. Its simplest form can be stated as a lower bound (known in mathematics as a many-particle Hardy inequality [\[Hoffmann-Ostenhof et al.](#page-27-26) [2008,](#page-27-26) [Lundholm and Solovej](#page-28-11) $2013a$) for the kinetic energy: for any N,

$$
\hat{T}_{\alpha} \ge \frac{4\alpha_N^2}{N} \sum_{j < k} \frac{1}{|\mathbf{x}_j - \mathbf{x}_k|^2},\tag{34}
$$

interpreted in the sense of forms or expectation values, and where the so-called N-fractionality of α , defined

$$
\alpha_N := \min_{p=0,1,\dots,N-2} \min_{q \in \mathbb{Z}} |(2p+1)\alpha - 2q|,
$$

is the arcwise distance (in units of π) on the unit circle from the set $\{e^{i(2p+1)\alpha\pi}\}_{p=0,1,\ldots,N-2}$ of all possible pairexchange phases to the point $+1$ of bosons. Taking the limit as $N \to \infty$ one finds (see Fig. [6\)](#page-10-1)

$$
\alpha_{N \to \infty} = \begin{cases} \frac{1}{\nu}, \text{ if } \alpha = \frac{\mu}{\nu} \text{ odd-numberator reduced rational,} \\ 0, \text{ otherwise,} \end{cases}
$$

an odd variant of Thomae's "popcorn function".

The origin of the scalar lower bound [\(34\)](#page-10-0) lies in the effective angular momentum barrier of each pair of particles at distance $r > 0$:

$$
V_{\text{stat}}(r) = |(2p+1)\alpha - 2q|^2 \frac{1}{r^2} \ge \frac{\alpha_N^2}{r^2}.
$$
 (36)

(35)

Namely, in an exchange of two particles, as in [\(7\)](#page-5-1) where p other particles happen to be ensnared, an anyonic phase shift $e^{i(2p+1)\alpha\pi} \neq 1$ leaves a residual angular momentum according to [\(36\)](#page-10-2). Heuristically, we can anticipate this effect in the two-particle energy form [\(12\)](#page-6-1), where the quantization condition [\(10\)](#page-5-6) in the angular variable φ is

FIG. 6. ∞ -fractionality of α given by the odd popcorn function [\(35\)](#page-10-3) [\[Lundholm](#page-28-16) [2017,](#page-28-16) [Lundholm and Solovej](#page-28-11) [2013a\]](#page-28-11).

appropriately modified to account for the presence of any extra particles, assuming all other position variables are fixed and the relative angular variable undergoes a full loop $\varphi \to \varphi + \pi$ in configuration space. The anyonic phase then shifts the relative angular momentum of the pair, which however is quantized over the even integers due to the half-circle symmetry for identical particles.^{[10](#page-10-4)}

We expect the repulsive barrier [\(36\)](#page-10-2) to be stronger than the r.h.s. on average as the number p fluctuates. Indeed, the coupling constant of the pair-interaction potential on the r.h.s. of [\(34\)](#page-10-0) can be strengthened to a nearest-neighbor version, which only depends on the 2 fractionality α_2 (periodized α), if it is at the same time weakened by yet another factor of N [\[Lundholm and](#page-28-10) [Qvarfordt](#page-28-10) [2020,](#page-28-10) [Rougerie and Yang](#page-29-21) [2023\]](#page-29-21). Anyway, the repulsion offered by the potential is strong enough to imply that $\Psi \to 0$ at Δ_N if $\alpha_2 \neq 0$, and can therefore be viewed as a generalized Pauli principle for anyons [\[Lundholm](#page-28-16) [2017,](#page-28-16) [Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) [Lund](#page-28-17)[holm and Solovej](#page-28-17) [2013b\]](#page-28-17) (other variants were considered in [Fröhlich and Marchetti [1988,](#page-26-3) [1989,](#page-26-4) [Goldin and Majid](#page-27-27) [2004,](#page-27-27) [Goldin and Sharp](#page-27-28) [1996\]](#page-27-28)).

2. Local exclusion principle. The bound [\(34\)](#page-10-0) (with its various refinements [\[Larson and Lundholm](#page-28-18) [2018,](#page-28-18) [Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) [Lundholm and Solovej](#page-28-11) [2013a\]](#page-28-11)) can also be applied locally on subsets of the plane and is strong enough to yield a linear bound $E_N \gtrsim N - 1$ for the local (Neumann) energy [\[Lundholm and Seiringer](#page-28-19) [2018,](#page-28-19) [Lundholm and Solovej](#page-28-17) [2013b\]](#page-28-17). Again, this holds modulo a (positive) constant that either depends on α_N ,

¹⁰ The operator $\hat{\ell} = -i\partial_{\varphi}$ on $[0, \pi]$ with twisted boundary conditions $\psi(\pi) = e^{i\alpha\pi}\psi(0)$ has eigenvalues $\{\alpha - 2q\}_{q \in \mathbb{Z}}$. Therefore the minimum of $\hat{\ell}^2$ is $\min_{q \in \mathbb{Z}} |\alpha - 2q|^2 = \alpha_2^2$. Compare also [\(20\)](#page-8-0).

FIG. 7. Lower bounds to the homogeneous ideal anyon gas energy [\[Larson and Lundholm](#page-28-18) [2018,](#page-28-18) [Lundholm and Seiringer](#page-28-19) [2018\]](#page-28-19). The blue points are numerical lower bounds for $E_2(\alpha) = 4\pi\alpha + O(\alpha^{4/3})$ at $\alpha = \alpha_{N\to\infty}$, while the orange curve describes $F_2(\alpha_2) = \frac{1}{4} \min\{E_2(\alpha_2), 0.147\}$, correspondingly.

or a typically weaker one (still positive) that only depends on α_2 (cf. Fig. [7\)](#page-11-0).

For comparison, take e.g. the unit square $Q = [0, 1]^2$ and consider fermions which there satisfy the bound

$$
E_N(\alpha = 1, Q) \ge \pi^2 (N - 1)
$$
 for $N \ge 1$, (37)

since each added particle is orthogonal to the ground state (the constant function) and thus adds at least the energy $E_2 = \pi^2$ of a first-excited state $\psi(x, y) \propto \cos(\pi x)$ or $\cos(\pi y)$.

For anyons, we denote the N-particle Neumann energy on Q by

$$
E_N(\alpha, Q) := \inf_{0 \neq \Psi \in L^2_{\text{sym}}(Q^N)} \langle \hat{T}_{\text{sym}\to\alpha} \rangle_{\Psi}. \tag{38}
$$

It is known that [\[Larson and Lundholm](#page-28-18) [2018,](#page-28-18) [Lundholm](#page-28-19) [and Seiringer](#page-28-19) [2018\]](#page-28-19)

$$
E_2(\alpha, Q) = 4\pi\alpha_2 + O(\alpha_2^{4/3}) \qquad \text{for any } \alpha, \qquad (39)
$$

and furthermore, all higher-particle energies can be bounded uniformly in terms of this energy, or a suitable approximation^{[11](#page-11-1)} \tilde{E}_2 to it: for $N \geq 2$,

$$
E_N \ge (N-1)\tilde{E}_2(\alpha_N),\tag{40}
$$

as well as

$$
E_N/N \ge \frac{1}{4} \min\{E_2, E_3, E_4\} \ge \frac{1}{4} \min\{E_2(\alpha_2), 0.147\}.
$$
\n(41)

This r.h.s. we denote by $F_2(\alpha_2)$; cf. Fig. [7.](#page-11-0) An interpretation of the above is that the nearest-neighbor energy E_2 is a relatively good approximation at every scale (at least as a lower bound) due to a balancing of uncertainty and exclusion in the gas.

3. Degeneracy pressure. Lastly, a combination of the above local exclusion principle and the uncertainty principle (also in a local formulation) yields a convenient measure of the degeneracy pressure in the anyon gas.

Compare the TF functional [\(27\)](#page-9-2) which shows that the effect of the exclusion principle for fermions is a selfenergy for the density that penalizes localization and thus forces a spread of the profile into the more expensive regions of the trapping potential. Indeed, the ideal Fermi gas satisfies the following kinetic energy inequality (known in mathematics as a Lieb–Thirring inequality [\[Lieb and Thirring](#page-28-20) [1975\]](#page-28-20)) which captures this type of degeneracy pressure: for any number N of particles and any N-fermion state $\Psi \in L^2_{\text{asym}}(\mathbb{R}^{2N}),$

$$
\langle \hat{T}_{\rm asym} \rangle_{\Psi} \gtrsim \int_{\mathbb{R}^2} \varrho_{\Psi}(\mathbf{x})^2 \, d\mathbf{x} \tag{42}
$$

(modulo a universal constant^{[12](#page-11-2)}), where ϱ_{Ψ} is the onebody density associated to Ψ , obtained by marginalizing $N-1$ particles. Inequalities of this type have been useful to prove qualitative properties of large fermionic systems such as their thermodynamic stability w.r.t. Coulomb interaction with a mixture of charges [\[Dyson and Lenard](#page-26-20) [1967,](#page-26-20) [Lieb and Seiringer](#page-28-21) [2010,](#page-28-21) [Lieb and Thirring](#page-28-20) [1975\]](#page-28-20). In the case that ν species of fermions or spin states are considered, the constant in [\(42\)](#page-11-3) is weakened by a factor $1/\nu$.

The degeneracy pressure for anyons is measured by a similar inequality [\[Lundholm and Solovej](#page-28-11) [2013a,](#page-28-11)[b\]](#page-28-17) (see [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10) for review): for any number N of particles and any N-anyon state $\Psi \in L^2_\alpha$,

$$
\langle \hat{T}_{\alpha} \rangle_{\Psi} \gtrsim \alpha_2 \int_{\mathbb{R}^2} \varrho_{\Psi}(\mathbf{x})^2 d\mathbf{x} \tag{43}
$$

(again modulo a universal constant). Its strength thus depends to leading order on the 2-fractionality, i.e. the nearest-neighbor exchange statistics α . It then follows, like for fermions, that charged anyonic systems (except bosons) with Coulomb interaction are also stable [\[Lund](#page-28-19)[holm and Seiringer](#page-28-19) [2018,](#page-28-19) [Lundholm and Solovej](#page-28-13) 2014.

Applied to the harmonic trap [\(19\)](#page-8-2), the degeneracy pressure [\(43\)](#page-11-4) yields the bound

$$
E_N(\alpha, \text{harm.osc.}) \gtrsim \sqrt{\alpha_2} \,\hbar \omega N^{3/2},\tag{44}
$$

¹¹ $\tilde{E}_2(\alpha) \approx 2\pi (j'_{\alpha_2})^2 \geq 4\pi \alpha_2$, where j'_{α} denotes the first zero of the derivative of the Bessel function J_{α} [\[Larson and Lundholm](#page-28-18) [2018\]](#page-28-18).

 12 Deciding on the best constant in this inequality is a long-standing open problem, but it is conjectured [\[Lieb and Thirring](#page-28-22) [1976\]](#page-28-22) to be given by that of its restriction to $N = 1$ (a Sobolev constant) and is strictly smaller than the TF constant 2π . See [\[Seiringer](#page-29-22)] [and Solovej](#page-29-22) [2023\]](#page-29-22) for recent progress.

[et al.](#page-27-29) [2018\]](#page-27-29): lowest energy branch of a 100×100 square Josephson junction array (left/blue) resp. the Hofstadter butterfly (right/orange), which also is proportional to the critical tem-FIG. 8. Universal energy phenomena in 2D, from [\[Lankhorst](#page-27-29) perature of a superconducting square network. (For comparison, $\alpha \sim 2f$.)

which indeed matches the constant-field approximation state energy. [\(33\)](#page-9-3), and Fig. [5,](#page-8-1) up to the value of the universal constant. [Lundholm 20

 \overrightarrow{O} a disk geometry D with unit area, the analysis of \overrightarrow{O} mize the kinet Chitra and Sen again suggests a large number of level statistics para crossings as $N \to \infty$, and thus possibly nonanalyticities an even-nume in the limiting g.s.e. per particle and unit density of the $K = 1, 2, \ldots$ homogeneous ideal anyon gas 13

$$
e(\alpha) := \liminf_{N \to \infty} E_N(\alpha, D) / N^2. \tag{45} \qquad \Psi_{\alpha} := \prod_{j < k} \prod_{j < k} E_j
$$

Most details about this function are still open, but from α funtion analysis of the homogeneous field anyon gas a further analysis of the homogeneous ideal anyon gas one can at least derive the rigorous uniform bounds (cf. Fig. [7\)](#page-11-0) [\[Lundholm and Seiringer](#page-28-19) [2018\]](#page-28-19)

$$
\frac{1}{4}\max\{\tilde{E}_2(\alpha_N), F_2(\alpha_2)\} \le e(\alpha) \le 2\pi^2, \qquad (46)
$$
\nHere $z_{ik} := z_k$

and

$$
\alpha_2 \lesssim e(\alpha) \lesssim \alpha_2,\tag{47}
$$

modulo lower and upper universal constants (certainly not optimal). Subject to the assumption that $e(\alpha)$ indeed has a fractal structure which captures universal aspects of planar geometry, a conjecture on its possible form can be given as in Fig. [8;](#page-12-1) cf. [\[Lankhorst et al.](#page-27-29) [2018\]](#page-27-29).

FIG. 9. From [\[Lundholm](#page-28-16) [2017\]](#page-28-16). A coloring of $N = 12$ particles with $\nu = 3$ colors into $K = 4$ 3-clusters \mathcal{V}_q^* . Each colored edge $(j, k) \in \mathcal{E}_q$ corresponds to one unit $-\mu$ of pairwise angular momentum. Also shown is the contribution to the magnetic potential $\alpha \mathbf{A}_i$ and the current \mathbf{J}_i of particle j due solely to the 3-cluster \mathcal{V}_1^* .

H. Some states of particular interest

balance between exclusion and uncertainty in the ground We saw above that there is a nontrivial and delicate state energy. Certain types of states have been proposed [\[Lundholm](#page-28-16) [2017,](#page-28-16) [Lundholm and Solovej](#page-28-17) [2013b\]](#page-28-17) to minimize the kinetic energy $\hat{T}_{\text{sym}\to\alpha}$ at particular values of the statistics parameter: in the case of $\alpha = \mu/\nu \in [0, 1]$ being an even-numerator reduced fraction, and for $N = \nu K$, $K = 1, 2, \ldots$, a suitable sequence of particle numbers, let

$$
\Psi_{\alpha} := \prod_{j < k} |z_{jk}|^{-\alpha} \mathcal{S} \left[\prod_{q=1}^{\nu} \prod_{(j,k) \in \mathcal{E}_q} (\bar{z}_{jk})^{\mu} \right] \prod_{l=1}^{N} \psi_0(\mathbf{x}_l),\tag{48}
$$

while for *odd* numerators μ , let

one can at least derive the rigorous uniform bounds (cf.
\nFig. 7) [Lundholm and Seiringer 2018]
\n
$$
\Psi_{\alpha} := \prod_{j < k} |z_{jk}|^{-\alpha} \mathcal{S} \left[\prod_{q=1}^{\nu} \prod_{(j,k) \in \mathcal{E}_q} (\bar{z}_{jk})^{\mu} \bigwedge_{k=0}^{K-1} \psi_k (\mathbf{x}_{l \in \mathcal{V}_q}) \right].
$$
\n
$$
\frac{1}{\pi} \max \{ \tilde{E}_2(\alpha_N), F_2(\alpha_2) \} < e(\alpha) < 2\pi^2, \qquad (46)
$$
\n(49)

Here $z_{jk} := z_j - z_k$ are the pairwise relative complex coordinates and we have grouped, or 'colored', the particles into ν different colors where $G_q = (\mathcal{V}_q, \mathcal{E}_q)$ denotes the complete graph over each such group of $|\mathcal{V}_q| = K$ ver-tices=particles (see Fig. [9\)](#page-12-2). The symmetrization S over all the particles then amounts to symmetrization over all such colorings, and can be viewed as passing from a set of distinguishable particles (by color) to indistinguish-able (cf. [\[Regnault et al.](#page-29-23) [2008\]](#page-29-23)). The $\psi_k, k = 0, 1, 2, ...,$ are the eigenstates (ordered by increasing energy) of the corresponding one-body Hamiltonian \hat{H}_1 . The states Ψ_α are moderately singular and so we should actually consider $\Psi = \Phi \Psi_{\alpha} \in L^2_{sym}(\mathbb{R}^{2N})$ with Φ a suitably chosen regularization factor to allow inclusion into the domain of $\hat{T}_{sym\to\alpha}$.

Some of the reasons why these states appear to be of interest in the many-anyon problem include:

¹³ Although it has not been rigorously shown, we may expect the thermodynamic limit to be independent of the shape of the domain (and otherwise take the infimum over reasonable shapes).

• They have the right average angular momentum [\(24\)](#page-8-3) and are (for harmonic trap and certain K) homogeneous with a degree suitable to optimize the bound [\(23\)](#page-8-4).

• They enjoy certain clustering properties that are beneficial to minimize the pair repulsion $V_{\text{stat}}(r)$ on large scales r. States of the form [\(48\)](#page-12-3) for $\mu = 2$, $\nu =$ 3, 5, . . . are known in the FQHE context as Read–Rezayi states and are known to form clusters of ν particles bound to μ vortices [\[Cappelli et al.](#page-26-21) [2001,](#page-26-21) [Read and](#page-29-24) [Rezayi](#page-29-24) [1999\]](#page-29-24), while [\(49\)](#page-12-4) for $\mu = 1$, $\nu = 2$ correspond to Dyson–Moore–Read/BCS/Pfaffian states subject to pairing [\[Dyson](#page-26-22) [1967,](#page-26-22) [Moore and Read](#page-28-23) [1991\]](#page-28-23). Further, excitations on top of these states appear to have nonabelian character [\[Bonderson et al.](#page-25-11) [2011,](#page-25-11) [Nayak et al.](#page-29-0) [2008,](#page-29-0) [Stern](#page-29-7) [2008\]](#page-29-7).

• They manifest certain structural stabilities with the smallness of $1 \leq \mu \leq \nu$, similar to the Laughlin states of the FQHE and indicative of a scale of robustness.

• Some of the states [\(48\)](#page-12-3) are exact but moderately singular/generalized low-energy eigenfunctions of the Hamiltonian with singular boundary conditions (cf. point interactions below, Sec. [III E\)](#page-17-0) [\[Chou](#page-26-17) [1991,](#page-26-17) [Murthy et al.](#page-29-25) [1992\]](#page-29-25).

III. THE NONIDEAL ANYON GAS

The "average(/constant)-field" approach, suggesting [\(29\)](#page-9-1), leads to difficulties when applied to strictly ideal and pointlike particles, and it is both realistic and helpful to instead consider extended particles as well as other nonideal models of anyon gases which can more easily incorporate the average effects of exchange phases or flux. Heuristic approaches to ensure averaged influence of the statistics include a "self-consistency argument" wherein a typical cyclotron orbit of the generated field ought to contain a large number of particles, suggesting a better approximation if [\[Chen et al.](#page-26-23) [1989,](#page-26-23) [Trugenberger](#page-29-26) [1992b\]](#page-29-26)

$$
\alpha_2 \ll 1 \qquad \text{or} \qquad (1 - \alpha_2)^2 \ll 1 \tag{50}
$$

(i.e. slightly better around fermions due to Pauli repulsion), as well as a similar orbital argument but based instead on the scattering angles of combined Aharonov–Bohm and hard-disk interaction [\[Caenepeel](#page-25-12) [and MacKenzie](#page-25-12) [1994\]](#page-25-12), again suggesting the conditions $(50).$ $(50).$

A. The extended anyon gas

In the extended anyon gas, we work in the magnetic perspective and replace the point magnetic fluxes of ideal anyons by extended fluxes. For simplicity (and not completely ad hoc from the perspective of emergent models) we may consider the flux to be constantly spread over

a disk-shaped magnetic field attached to each particle, with radius $R > 0$. We then replace the anyon magnetic potentials [\(15\)](#page-6-2) by

$$
\mathbf{A}_{j}^{R}(\mathbf{x}) := \sum_{k \neq j} \frac{(\mathbf{x}_{j} - \mathbf{x}_{k})^{\perp}}{|\mathbf{x}_{j} - \mathbf{x}_{k}|_{R}^{2}}, \qquad |\mathbf{x}|_{R} := \max\{|\mathbf{x}|, R\},\tag{51}
$$

so that, if $\mathbb{1}_{D(\mathbf{y},R)}$ denotes the indicator function on a disk of radius R centered at y , the field is

$$
\operatorname{curl}_{\mathbf{x}_j} \alpha \mathbf{A}_j^R = 2\pi \alpha \sum_{k \neq j} \frac{\mathbb{1}_{D(\mathbf{x}_k, R)}(\mathbf{x}_j)}{\pi R^2} \xrightarrow{R \to 0} 2\pi \alpha \sum_{k \neq j} \delta_{\mathbf{x}_k}(\mathbf{x}_j).
$$

The kinetic energy of the extended anyon gas with bosons as reference is then

$$
\hat{T}_{\text{sym}\rightarrow\alpha}^{R} := \frac{\hbar^2}{2m} \sum_{j=1}^{N} \left(-i \nabla_{\mathbf{x}_j} + \alpha \mathbf{A}_j^{R} \right)^2,
$$

acting on L^2_{sym} , while if we use fermions as reference then

$$
\hat{T}_{\text{asym}\to\alpha}^R := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j} + (\alpha - 1) \mathbf{A}_j^R \right)^2,
$$

acting on L^2_{asym} .

There is now an additional natural dimensionless parameter in the problem that can be defined as the ratio of the size of the magnetic flux disk to the average interparticle distance,

$$
\bar{\gamma} := R\bar{\varrho}^{1/2}.\tag{52}
$$

This density parameter has been called the magnetic filling ratio in [\[Larson and Lundholm](#page-28-18) [2018,](#page-28-18) [Trugen](#page-29-27)[berger](#page-29-27) [1992a](#page-29-27)[,b\]](#page-29-26). The limit $\bar{\gamma} = 0$ corresponds to ideal anyons, while $\bar{\gamma} \sim 1$ is the "smearing" limit when particles typically begin to overlap, and $\bar{\gamma} \rightarrow \infty$ would describe the constant-field limit.

At any fixed choice of the two parameters $\alpha \in \mathbb{R}, \overline{\gamma} \geq 0$, the energy per particle and unit of density of the homogeneous extended anyon gas may thusly be defined via the thermodynamic limit

$$
e_{\text{sym}/\alpha, \bar{\gamma}} := \liminf_{\substack{N, L \to \infty \\ N/L^2 = \bar{\varrho}}} \frac{E_N(\alpha, R, LQ)}{\bar{\varrho}N},\tag{53}
$$

where $E_N(\alpha, R, LQ)$ denotes the g.s. energy of the respective operator $\hat{T}_{sym/asym\rightarrow\alpha}^{R}$ on $L_{sym/asym}^{2}(LQ^{N})$. A corresponding TF-type functional for a **local-density approximation** within a trapping potential V is then

$$
\mathcal{E}_{\substack{\text{sym}\\ \text{asym}}}^{\alpha,R}[\varrho] := \int_{\mathbb{R}^2} \left[e_{\substack{\text{sym}\\ \text{asym}}} (\alpha, R\varrho(\mathbf{x})^{1/2}) \varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x},\tag{54}
$$

with $\int_{\mathbb{R}^2} \varrho = N$.

The qualitative analysis of local exclusion effects of the ideal gas discussed in Section [II G](#page-10-5) has been extended to the extended gas, both in the bosonic and the fermionic references. Up to constants, one finds the qualitative bounds [\[Larson and Lundholm](#page-28-18) [2018\]](#page-28-18)

$$
e_{\mathrm{sym}}(\alpha, \bar{\gamma}) \gtrsim \begin{cases} |\mathrm{ln}\, \bar{\gamma}|^{-1} + \alpha_{\infty}, & \bar{\gamma} \ll 1 \,\, (\alpha \,\, \mathrm{fixed}), \\ |\alpha|, & \bar{\gamma} \gtrsim 1, \end{cases}
$$

where the first regime is a combination of a dilute 2D Bose gas [\[Lieb and Yngvason](#page-28-24) [2001,](#page-28-24) [Schick](#page-29-28) [1971\]](#page-29-28) and the strongest of the two lower bounds [\(46\)](#page-12-5) for the ideal gas at odd numerators, $\tilde{E}_2(\alpha_{\infty}) \gtrsim \alpha_{\infty}$, while the second regime indeed captures the constant-field energy [\(29\)](#page-9-1) for arbitrarily large α. The full regime $\bar{\gamma} \lesssim 1$ is more difficult to describe, since it covers both soft-core and hard-core behavior (see Sec. [III F](#page-18-1) below), and we should expect to replace α_{∞} with α_2 in a suitable limit. Trugenberger [\[Trugenberger](#page-29-26) [1992b\]](#page-29-26) suggested that this gas with fixed extension parameter $R > 0$ will at low temperatures prefer to adjust its density to $\bar{\gamma} \gtrsim 1$, where the average-field approximation is good and the gas becomes a superfluid, while for high temperatures the density drops, $\bar{\gamma} \ll 1$, the average-field loses validity and superfluidity is lost.

In the fermionic reference [\[Girardot and Rougerie](#page-27-30) [2022\]](#page-27-30)

$$
e_{\text{asym}}(\alpha, \bar{\gamma}) \gtrsim \begin{cases} \alpha_2, \quad & \bar{\gamma} \lesssim 1, \\ 1, \quad & \bar{\gamma} \gtrsim 1. \end{cases}
$$

In this case the inherent Pauli principle improves the dependence to nearest neighbor due to its scale independence. Note that both energies $e_{sym/asym}$ must be periodic in α at $\overline{\gamma} = 0$, but not at any finite $\overline{\gamma} > 0$, which therefore requires an interesting interpolation between the regimes.

B. Almost-bosonic anyons

The average-field approach [\(29\)](#page-9-1) can be made fully rigorous in the limit $N \to \infty$ close to bosons:

$$
\alpha = \beta/N \to 0, \quad \text{at fixed } \beta \in \mathbb{R},
$$

in which the interaction may indeed be treated in a meanfield sense if anyons are also extended/smeared out to a finite size $R > 0$, as above. It is even possible to simultaneously take $R \sim N^{-\eta} \to 0$ at some sufficiently slow rate η (an "almost-ideal" limit). The idea is then as a final step to take $\beta = \alpha N$ (total flux) large (then "less bosonic") and study the appropriate ground-state energy functionals in this limit. Because of this particular order of limits, it is not completely clear whether this indeed describes the ideal anyon gas as defined above, or perhaps some nonideal model (see Sec. [III F\)](#page-18-1). We shall simply refer to it as "almost-bosonic" anyons.

In any case, the first steps above yield the seemingly correct average-field functional w.r.t. bosons for any fixed $\beta \in \mathbb{R}$ [\[Lundholm and Rougerie](#page-28-25) [2015\]](#page-28-25):

$$
\mathcal{E}_{\beta}^{\text{af}}[\psi] = \int_{\mathbb{R}^2} \left[\left| (-i\nabla + \beta \mathbf{A}[\psi|^2]) \psi \right|^2 + V|\psi|^2 \right]. \tag{55}
$$

The magnetic potential $\mathbf{A}[\varrho] = |\psi|^2$ is chosen such that it generates exactly the field $2\pi\varrho$:

$$
\operatorname{curl}\beta\mathbf{A}[\varrho](\mathbf{x}) = 2\pi\beta\varrho(\mathbf{x}), \qquad \int_{\mathbb{R}^2} \varrho = 1. \qquad (56)
$$

Thus, the scalar self-interaction of the GP model [\(28\)](#page-9-4) is here replaced with a *magnetic* self-interaction. This produces a peculiar new balancing problem, namely in order to lower its energy in the self-generated magnetic field, as the coupling β (total number of flux units) grows there needs to be an increasing phase and angular momentum in $\psi = |\psi|e^{i\phi}$ to cancel this magnetic field:^{[14](#page-14-1)}

$$
|(-i\nabla + \beta \mathbf{A})\psi|^2 = |\nabla |\psi||^2 + |\nabla \phi + \beta \mathbf{A}|^2 |\psi|^2. \quad (57)
$$

Further, in order to preserve regularity, any nontrivial such phase circulation must appear in the form of quantized vortices. On a typical disk $D(\mathbf{x}, R)$, the phase circulation

$$
\Phi(\mathbf{x}, R) := \oint_{\partial D(\mathbf{x}, R)} \beta \mathbf{A} \cdot d\mathbf{r} \approx - \int_{D(\mathbf{x}, R)} \operatorname{curl} \nabla \phi \, d\mathbf{y} \tag{58}
$$

then needs to minimize the residual angular momentum,

$$
\int_0^{2\pi} \left| \partial_{\varphi} \phi + \beta A_{\varphi} \right|^2 d\varphi \ge \min_{q \in \mathbb{Z}} \left| q - \Phi(\mathbf{x}, R) \right|^2. \tag{59}
$$

However, the amount of flux to be cancelled by each vortex also depends on the typical value of the density ρ there, which therefore sets a varying length scale for vortex formation [\[Correggi et al.](#page-26-24) [2017\]](#page-26-24). It is thus expected (see also [\[Chen et al.](#page-26-23) [1989\]](#page-26-23) for an early conjecture) and indeed confirmed in numerical studies [\[Correggi et al.](#page-26-25) [2019,](#page-26-25) [Girardot](#page-27-31) [2021\]](#page-27-31) that there is the formation of an Abrikosov-like vortex lattice. However, unlike in the Abrikosov setting with homogeneous rotation/field, the density of vortices here follows the average density profile in the trap V, which for $\beta \gg 1$ turns out to be given again by the minimizer of an effective Thomas–Fermi-type functional [\[Correggi et al.](#page-26-24) [2017\]](#page-26-24):

$$
\mathcal{E}_{\beta}^{\text{aTF}}[\varrho] := \int_{\mathbb{R}^2} \left[C_{\text{aTF}} |\beta| \varrho(\mathbf{x})^2 + V(\mathbf{x}) \varrho(\mathbf{x}) \right] d\mathbf{x}.
$$
 (60)

Indeed, numerical simulations [\[Correggi et al.](#page-26-25) [2019,](#page-26-25) [Gi](#page-27-31)[rardot](#page-27-31) [2021\]](#page-27-31) (see Fig. [10\)](#page-15-0) confirm the theoretical predic-tion of [\[Correggi et al.](#page-26-24) [2017,](#page-26-24) [2018\]](#page-26-26) that the g.s. ψ_{β}^{af} of [\(55\)](#page-14-2) exhibits an approximately triangular vortex lattice distribution with scales set by the TF profile (minimizer) $\varrho^{\textrm{aTF}}_{\beta}$ of [\(60\)](#page-14-3), and it is further estimated numerically that [\[Correggi et al.](#page-26-25) [2019\]](#page-26-25)

$$
C_{\text{aTF}} \approx 4\pi^{3/2}/3 \approx 1.18 \times 2\pi. \tag{61}
$$

¹⁴ Due to the reasons described below, the cancellation is not com-plete, but both terms in [\(57\)](#page-14-4) contribute an energy of order β .

FIG. 10. Numerical simulation of the ground-state density $|\psi_{\beta}^{\text{af}}|^2$ in the average-field functional [\(55\)](#page-14-2) for $\beta = 90$ in a harmonic trap, averaged over rotations and then compared with the exact minimizer $\varrho_{\beta}^{\text{aTF}}$ of [\(60\)](#page-14-3). From [\[Correggi et al.](#page-26-25) [2019\]](#page-26-25).

The fact that this constant is strictly bigger than the fermionic TF constant and constant-field prediction^{[15](#page-15-1)} 2π can be understood from the microscopic lattice inhomogeneity of $|\psi_{\beta}^{\text{af}}|^{2}$ as compared to its average density $\varrho_{\beta}^{\text{aTF}}$, which effectively raises the energy by a factor which is at least as big as the Abrikosov constant (≈ 1.1596 ; cf. [\[Af](#page-25-13)[talion et al.](#page-25-13) $2006a, b$ $2006a, b$.

C. Almost-fermionic anyons

A similar regularization approach can be taken close to fermions:

$$
\alpha = 1 - \beta/\sqrt{N} \to 1, \qquad \beta, \hbar \text{ fixed},
$$

for which the leading terms of the kinetic energy can be compared with the Fermi gas $E_N(\alpha = 1) \sim 2\pi N^2$,

 $N \to \infty$. By rescaling the parameters, it is equivalent to study a semiclassical mean-field limit

$$
\alpha = 1 - \beta/N \to 1, \qquad \hbar \sim N^{-1/2} \to 0.
$$

Also here we can allow "almost-ideal" or "virtually" extended anyons, $0 < R \sim N^{-\eta} \to 0$, if the rate η is small $enough^{16}$ $enough^{16}$ $enough^{16}$.

This almost-fermionic approach takes us back to the actual TF functional for fermions [\(27\)](#page-9-2), which remains correct for any finite β in this limit [\[Girardot](#page-27-31) [2021,](#page-27-31) [Gi](#page-27-32)[rardot and Rougerie](#page-27-32) [2021\]](#page-27-32). More precisely, one obtains a semiclassical Vlasov functional:

$$
\mathcal{E}_{\beta}^{\text{Vla}}[\mu] := \frac{1}{(2\pi)^2} \int_{\mathbb{R}^4} \left| \mathbf{p} + \beta \mathbf{A}[\varrho] \right|^2 \mu(\mathbf{x}, \mathbf{p}) \, d\mathbf{x} d\mathbf{p} + \int_{\mathbb{R}^2} V \varrho \, d\mathbf{x}
$$

for $0 \leq \mu(\mathbf{x}, \mathbf{p}) \leq 1$ a measure on phase space \mathbb{R}^4 which is subject to the Pauli principle and normalized $\int_{\mathbb{R}^4} \mu =$ $(2\pi)^2$. The minimizing measure μ of this functional is the corresponding filled Fermi sea:

$$
\mu(\mathbf{x}, \mathbf{p}) = \mathbb{1} \left\{ |\mathbf{p} + \beta \mathbf{A}[\varrho](\mathbf{x})|^2 \le 4\pi \varrho(\mathbf{x}) \right\},\qquad(62)
$$

with spatial density $\rho = \rho^{\text{TF}}$ independent of β :

$$
\varrho(\mathbf{x}) = \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \mu(\mathbf{x}, \mathbf{p}) d\mathbf{p} = (4\pi)^{-1} (\lambda^{\mathrm{TF}} - V(\mathbf{x}))_+.
$$

The **momentum density** $t = t_{\beta}^{\text{TF}},$

$$
t(\mathbf{p}) = \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \mu(\mathbf{x}, \mathbf{p}) d\mathbf{x},
$$

does depend on β however, in a nonlocal way. The energy $\mathcal{E}_{\beta}^{\text{Vla}}[\mu] = \mathcal{E}^{\text{TF}}[\varrho^{\text{TF}}]$ is locally a constant at $\alpha \approx 1$ in this approximation, thus confirming this aspect of Fig. [5.](#page-8-1)

The almost-fermionic regime was also studied numerically by Girardot et al. in [\[Girardot](#page-27-31) [2021\]](#page-27-31) using a Hartree–Fock approach, i.e. on Slater determinants, and with a self-generated field $B = 2\pi \beta \varrho / N$ (total flux $2\pi\beta$), showing good agreements to the above. In fact, it can be interpreted as a multicomponent version of the bosonic functional [\(55\)](#page-14-2) on orthogonal states ψ_k , $k = 1, 2, \ldots, N$. These are then able to complement each other's densities so as to fill in any holes left by vortices, and thus eventually smoothen out the overall density profile:

$$
\varrho(\mathbf{x}) = \sum_{k=1}^{N} |\psi_k(\mathbf{x})|^2 \approx \varrho^{\mathrm{TF}}(\mathbf{x}),\tag{63}
$$

thereby validating the "constant-field" (local density) approximation in this regime when β is not too large.

¹⁵ Also in comparison to Fig. [5,](#page-8-1) Chitra and Sen, who estimated a substantially larger factor [\[Chitra and Sen](#page-26-18) [1992\]](#page-26-18), assumed rotational symmetry for the density to simplify their functional, plus added a hard-core delta regularization that itself amounts to the constant-field energy $2\pi|\beta|\varrho^2$.

 16 The rate is better than for bosons because of the Pauli principle; cf. [\(50\)](#page-13-1).

D. Magnetic TF theory

For higher ratios of the magnetic field to the density one may expect [\[Girardot](#page-27-31) [2021\]](#page-27-31) a magnetic Thomas-Fermi theory [\[Lieb et al.](#page-28-26) [1995,](#page-28-26) [McEuen et al.](#page-28-27) [1992\]](#page-28-27) to become valid. Namely, for a field $B(x)$ which is approximately constant on the scale of the trapping potential V , we can think of distributing the density

$$
\varrho(\mathbf{x}) = \sum_{n=0}^{\infty} \varrho_n(\mathbf{x})
$$

locally into the **Landau levels** (LLs) \mathcal{H}_n of the corre-sponding one-body Landau Hamiltonian^{[17](#page-16-1)}

$$
\hat{H}_1^{\text{Lan}} = (-i\nabla_{\mathbf{x}} + B\mathbf{x}^{\perp}/2)^2 = \sum_{n=0}^{\infty} |B|(2n+1)\mathbb{1}_{\mathcal{H}_n}.
$$
 (64)

The degeneracy (per unit area) of each level is the number of flux units (per unit area), $d_B := |B|/(2\pi)$. Thus, defining the corresponding expected local magnetic energy at a given density ρ ,

$$
j_B(\varrho) := \sum_{n=0}^{\infty} |B|(2n+1)\varrho_n, \qquad 0 \le \varrho_n \le d_B,
$$

the **magnetic TF** functional for N fermions in a fixed external field $B > 0$ is then

$$
\mathcal{E}^{\text{mTF}}[\varrho] := \int_{\mathbb{R}^2} \left[j_B(\varrho(\mathbf{x})) + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x}, \quad \int_{\mathbb{R}^2} \varrho = N. \tag{65}
$$

At fixed B and ϱ , in order to minimize $j_B(\varrho)$ we fill all $N_B := \lfloor \varrho/d_B \rfloor$ lower Landau levels maximally:

$$
\varrho_n = \begin{cases} d_B, & 0 \le n \le N_B - 1, \\ \varrho - N_B d_B, & n = N_B, \\ 0, & n \ge N_B + 1, \end{cases}
$$

so that in the limit $B \to 0$, implying $d_B \to 0$,

$$
j_B(\varrho) \approx \sum_{n=0}^{N_B - 1} |B|(2n+1)d_B = |B|N_B^2 d_B
$$

$$
\approx |B|\varrho^2/d_B = 2\pi\varrho^2,
$$

returning us to the usual TF for the free Fermi gas. On the other hand, if B is large enough that $d_B \geq \rho$, then all particles will fit into the lowest Landau level (LLL):

$$
j_B(\varrho) = |B|\varrho. \tag{66}
$$

Now, considering a sufficiently extended anyon gas and formally taking the anyonic (average) magnetic field

 $B(\mathbf{x}) = 2\pi\beta\varrho(\mathbf{x})$, where $\beta = 1 - \alpha \in [0, 1]$ is the number of flux units per particle attached to fermions, we then obtain a magnetic TF self-interaction functional for anyons:

$$
\mathcal{E}_{\beta}^{\text{amTF}}[\varrho] := \int_{\mathbb{R}^2} \left[j_{B=2\pi\beta\varrho(\mathbf{x})}(\varrho(\mathbf{x})) + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x}.\tag{67}
$$

At any point $\mathbf{x} \in \mathbb{R}^2$ where $\varrho(\mathbf{x}) \neq 0$ let us consider there the fractions of density $f_n := \varrho_n(\mathbf{x})/\varrho(\mathbf{x})$ in the LLs:

$$
\frac{j_B(\varrho)}{2\pi\varrho^2} = \sum_{n=0}^{\infty} \beta(2n+1)f_n, \qquad 0 \le f_n \le \beta \le 1,
$$

which again is minimized by filling the lowest N_B = $\lfloor \beta^{-1} \rfloor$ levels:

$$
f_n = \begin{cases} \beta, & 0 \le n \le \lfloor \beta^{-1} \rfloor - 1, \\ 1 - \beta \lfloor \beta^{-1} \rfloor, & n = \lfloor \beta^{-1} \rfloor, \\ 0, & n \ge \lfloor \beta^{-1} \rfloor + 1. \end{cases}
$$

Hence, our minimum is

$$
\frac{j_B(\varrho)}{2\pi\varrho^2} = \sum_{n=0}^{\lfloor \beta^{-1} \rfloor - 1} (2n+1)\beta^2 + \beta(2\lfloor \beta^{-1} \rfloor + 1)(1 - \beta\lfloor \beta^{-1} \rfloor),
$$

which simplifies to

$$
\frac{j_B(\varrho)}{2\pi\varrho^2} - 1 = \beta^2 (1 - {\beta^{-1}}) {\beta^{-1}} =: M(\beta) \in [0, \beta^2/4),
$$

where $\{\beta^{-1}\} = \beta^{-1} - \lfloor \beta^{-1} \rfloor \in [0, 1)$ is the fractional part of β^{-1} . Therefore our proposed functional for the g.s. (a pointwise lower bound to [\(67\)](#page-16-2)) takes the form

$$
\tilde{\mathcal{E}}_{\beta}^{\text{amTF}}[\varrho] := \int_{\mathbb{R}^2} \left[2\pi \varrho(\mathbf{x})^2 \left(1 + M(\beta) \right) + V(\mathbf{x}) \varrho(\mathbf{x}) \right] d\mathbf{x},\tag{68}
$$

thus refining both the "constant-field" approximation [\(29\)](#page-9-1) around fermions as well as the above almostfermionic approximation.

The corresponding energy landscape (see Fig. [11\)](#page-17-1) is now indicative of **stability** at the Fermi point $\beta = 0$. A possible interpretation for the gas is that the discretization of the Fermi sea into Landau levels imposes a more rigid structure in phase space, i.e., as the attached flux β per particle increases, particles come from plane-wave states which homogenize easily in space and then need to start organizing into the respective cyclotron orbits with decreasing radii as the field increases. Thus the Fermi sea becomes less fluid and more crystalline, with the most synergetic situation when a whole number of levels are approximately filled $({\beta}^{-1}) \approx 0$ or 1) so adjustments to the density can be accommodated at all levels in parallel while keeping the fractions f_n constant, and least synergetic when half a level is filled $({\beta}^{-1}) \approx 1/2$ and a larger fraction $\beta\{\beta^{-1}\}\$ of particles need to organize their motion into that specific LL. However, we cannot expect this picture to be valid all the way to bosons at $\beta = 1$ (compare

¹⁷ In our units the cyclotron frequency is $\omega_c = 2|B|$.

FIG. 11. The factor $M(\beta) = \beta^2 (1 - {\beta^{-1}}) {\beta^{-1}} \leq {\beta^2}/4$ (r.h.s. dashed) in the magnetic TF functional [\(68\)](#page-16-3) as a function of the relative statistics parameter $\beta = 1 - \alpha$ around fermions $\beta = 0$.

also [\(50\)](#page-13-1)) because there will also be correlations across Landau levels, leading to effective attractions, clustering and condensation, and for example, if the LLL is filled and there are only few particles in the first-excited LL then one might consider the statistics transmutation situation discussed below where the excited particles would effectively rather be treated as bosons than fermions.

An analysis at these seemingly beneficial fractions $\alpha = 1 - 1/n$ was conducted by Chen et al. [\[Chen et al.](#page-26-23) [1989\]](#page-26-23) in the homogeneous setting (building on [\[Fetter](#page-26-27) [et al.](#page-26-27) [1989\]](#page-26-27)), where they indeed observed characteristics of superfluidity. For example, the energy there increases linearly when a small external magnetic field is applied in either direction, which is interpreted as a Meissner effect. Recently another approach to a DFT for anyons, via Kohn–Sham theory with neglected exchange correlation (then similar to self-consistent Hartree–Fock), was taken by Hu et al. to study these effects [\[Hu et al.](#page-27-33) [2021\]](#page-27-33). Their numerics agree well with the semiclassical TF approximation close to fermions and show significant deviations only when the magnetic field is strong enough that particles in the bulk occupy only the lowest few LLs. For trapped systems they also observe a boundary effect which can compensate for the otherwise necessary fractional filling of LLs, but which vanishes in the thermodynamic limit. Indeed, due to the many parallels to the FQHE, Chen et al. suggested that "the physics of the anyon gas at general values of θ is likely to be quite rich and to depend quite strongly on 'number-theoretic' properties of θ ."

E. Point-interacting anyons

Introducing **point** or contact interactions corresponds to specifying the behavior of wave functions at the diagonal (contact) set Δ_N , i.e. imposing boundary conditions there so as to render the Hamiltonian selfadjoint, while allowing a different behavior than that of the canonical/free choice (Friedrichs; cf. Sec. [II C\)](#page-4-2). This is equivalent to considering all of the possible boundary conditions, or self-adjoint extensions, of the operator \hat{T}_{α} starting from its initial definition on wave functions vanishing at $\mathbb{\Delta}_N$ and having finite expected energy in the standard sense (11) . For general N this is difficult even for distinguishable particles, but one may reduce this problem significantly by adding assumptions such as translation and scale covariance. Our present understanding of general point-interacting (and pointlike, i.e. non-extended) anyons is currently rather limited (cf. [\[Dell'Antonio et al.](#page-26-1) [1997\]](#page-26-1)), however for $N = 2$ anyons the situation is now well understood [\[Bourdeau and Sorkin](#page-25-10) [1992,](#page-25-10) [Correggi and Oddis](#page-26-28) [2018,](#page-26-28) [Coutinho et al.](#page-26-29) [1992,](#page-26-29) [Grundberg et al.](#page-27-34) [1991,](#page-27-34) [Manuel and Tarrach](#page-28-28) [1991,](#page-28-28) [Murthy](#page-29-25) [et al.](#page-29-25) [1992,](#page-29-25) [Oddis](#page-29-29) [2020\]](#page-29-29), and extends the corresponding analysis of the standard non-magnetic two-body pointinteraction problem in various dimensions (see, e.g., [\[Al](#page-25-15)[beverio et al.](#page-25-15) [2005\]](#page-25-15)).

For $\alpha_2 \neq 1$ (non-fermions) the problem admits a circle of different possibilities for point interaction, all of which are attractive and correspond to allowing wave functions with singularities at the diagonals. One simple way to understand this is via the form [\(12\)](#page-6-1), which in the s-wave (radially symmetric) with $\Psi = r^{\pm \alpha_2} \phi(r)$ turns out to be equivalent to [\[Manuel and Tarrach](#page-28-28) [1991,](#page-28-28) [Oddis](#page-29-29) [2020\]](#page-29-29)

$$
\int_0^\infty |\phi'(r)|^2 r^{d_\alpha - 1} dr,\tag{69}
$$

for a parameter giving an effective "intermediate dimension"

$$
2 \le d_{\alpha} := 2 + 2\alpha_2 \le 4. \tag{70}
$$

Thus, for bosons the problem is indeed two-dimensional and has a circle of extensions, where a unique one \hat{T}_{sym} (Friedrichs, $\Psi \sim 1$ as $r \to 0$) is nonnegative. For fermions it is more akin to four dimensions where the corresponding bosonic problem is essentially self-adjoint, i.e. has a unique extension \hat{T}_{asym} (Friedrichs, $\Psi \sim r$). For proper anyons the situation is intermediate and actually closest akin to three dimensions. In this case there is again a circle of extensions, but the circle now splits into two halves (cf. Fig. [2\)](#page-2-1): in one half one has negative extensions and a scale of increasingly negative bound states, and in the other a scale of decreasingly nonnegative (i.e. increasingly attractive) extensions. The largest (least attractive / "free") such extension is the usual free kinetic energy $\hat{T}_{\alpha} = \hat{T}_{\alpha}^{\text{F}}$ (Friedrichs, $\Psi \sim r^{\alpha_2}$), while the smallest $\hat T^{\rm K}_\alpha$ (most attractive, $\Psi \sim r^{-\alpha_2}$, and known as the Krein extension [\[Alonso and Simon](#page-25-16) [1980\]](#page-25-16)) is also singled out as scale covariant while all the other intermediate extensions have scale.

If these observations extend to $N \geq 3$ particles then it is reasonable to expect such "kreinyons" to be of interest in physics, and in fact may even correspond to some of the moderately singular "noninterpolating" exact eigenstates [\[Murthy et al.](#page-29-25) [1992\]](#page-29-25) found in the harmonic oscillator problem (cf. Section [II H\)](#page-12-6). Other relevant connections of anyons to geometry and quantum mechanics on cone-like manifolds were reviewed in [\[Jackiw](#page-27-13) [1990\]](#page-27-13).

F. Other interactions and fields

One can obviously also include other (scalar) interactions into the magnetic models for anyons, as well as an external magnetic field (coupled by a charge $-q$), e.g.

$$
\hat{H}_N := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j} + q \mathbf{A}_{\text{ext}} + \alpha \mathbf{A}_j^R \right)^2
$$

$$
+ \sum_{j=1}^N V(\mathbf{x}_j) + \sum_{j < k} W(\mathbf{x}_j - \mathbf{x}_k). \tag{71}
$$

Reasonable external fields have been incorporated into some parts of the average-field theory [\[Girardot](#page-27-35) [2020,](#page-27-35) [Gi](#page-27-32)[rardot and Rougerie](#page-27-32) [2021\]](#page-27-32), as well as point interactions [\[Correggi and Fermi](#page-26-30) [2021,](#page-26-30) [Oddis](#page-29-29) [2020\]](#page-29-29), and interacting anyons are certainly relevant in emergent models, as we will see below. Coulomb interactions and the thermodynamic stability of "anyonic matter" was addressed in [\[Lundholm](#page-28-9) [2019,](#page-28-9) [Lundholm and Seiringer](#page-28-19) [2018,](#page-28-19) [Lund](#page-28-13)[holm and Solovej](#page-28-13) 2014. We note that since scalar interactions can show features akin to statistics, such as effective TF-type functionals and degeneracy pressure [\[Larson](#page-28-29) [et al.](#page-28-29) [2021,](#page-28-29) [Lieb et al.](#page-28-30) [2005,](#page-28-30) [Lundholm](#page-28-9) [2019,](#page-28-9) [Lundholm](#page-28-31) [et al.](#page-28-31) [2015,](#page-28-31) [2016\]](#page-28-32), it is important to isolate the features that are due to the actual quantum statistics (cf. [\[Lam](#page-27-36)[bert et al.](#page-27-36) [2023\]](#page-27-36)).

Another way to view the effect of the magnetic flux disks in the average-field approximation is as an effective scalar potential

$$
W(\mathbf{x}_j - \mathbf{x}_k) = \frac{2\pi|\alpha|}{\pi R^2} \mathbb{1}_{D(\mathbf{x}_k, R)}(\mathbf{x}_j)
$$
(72)

added to anyons (in the bosonic reference this is indeed correct as a lower bound [\[Larson and Lundholm](#page-28-18) [2018\]](#page-28-18)). One may then consider the combination of parameters

$$
\frac{|\alpha|}{\bar{\varrho}R^2} = |\alpha|\bar{\gamma}^{-2},\tag{73}
$$

i.e. the height of the potential compared to the average density, as a dimensionless measure of interaction strength, and for fixed α and $\bar{\gamma} \ll 1$ this then corresponds to a hard-core interaction, while if $|\alpha|\bar{\gamma}^{-2} \ll 1$, such as if $\sqrt{|\alpha|} \ll \bar{\gamma}$ where either side may be taken to grow or decline, then W instead corresponds to a weak soft-core interaction. With the convergence rates η currently allowed in the derivations of almost-bosonic and almost-fermionic models $(0 < n < 1/4$ [\[Girardot](#page-27-35) [2020\]](#page-27-35) resp. $0 < \eta < 1/3$ [\[Girardot and Rougerie](#page-27-30) [2022\]](#page-27-30)), we find that on a fixed homogeneous trap, $\bar{\gamma} \sim N^{1/2-\eta} \to \infty$ and $|\alpha|\bar{\gamma}^{-2} \sim N^{2\eta - 2} \to 0$ resp. $|1 - \alpha|\bar{\gamma}^{-2} \sim N^{2\eta - 3/2} \to 0$

as $N \to \infty$, that is a combined high-density and weak soft-core limit, indeed beneficial to the average-field approximation.

G. Lowest Landau level (LLL) anyons

If the anyons are ideal but in a strong external constant magnetic field, then all anyons fall into the LLL (cf. [\(66\)](#page-16-4)), and the model actually becomes exactly solvable. The reason is that their wave function becomes (anti)analytic (modulo a Gaussian factor) and corresponds to changing the Jastrow factors in [\(48\)](#page-12-3)-[\(49\)](#page-12-4) from $|z_{jk}|^{-\alpha}$ to $(\bar{z}_{jk})^{\alpha}$, $\alpha \in [0,1]$. It results in a description in terms of fractional exclusion statistics (cf. [\[Hal](#page-27-17)[dane](#page-27-17) [1991\]](#page-27-17)) with one-body occupation numbers (angular momenta) shifted by α , and a relation to Calogero– Sutherland models. We refer to [\[Ouvry](#page-29-6) [2007\]](#page-29-6) for an overview of this approach.

IV. THE NONABELIAN ANYON GAS

Let us now generalize our context further and consider an ideal N-anyon wave function as locally a map^{[18](#page-18-2)}

$$
\Psi \colon \mathcal{C}^N \to \mathcal{F}
$$
, subject to $\Psi(\sigma X) = \rho(\sigma)\Psi(X)$, (74)

where the **fiber** $\mathcal F$ is a Hilbert space of 'internal' (nonspatial) degrees of freedom on which B_N acts unitarily^{[19](#page-18-3)}:

$$
\rho\colon B_N\to\mathrm{U}(\mathcal{F}).
$$

Now $\rho(\sigma)$ is an exchange operator on F corresponding to the braid $\sigma \in B_N$. There may be other observables of the considered system acting in \mathcal{F} , but for simplicity we here assume that it is finite dimensional, i.e. $\mathcal{F} = \mathbb{C}^{\mathcal{D}}$ for some $D \in \mathbb{N}$, and $U(\mathbb{C}^D) = U(D)$ is the group of $D \times D$ unitary matrices. We then identify three possibilities for these representations ('reps'):

1. Irreducible abelian: $\mathcal{F} = \mathbb{C}$, which is the case we treated above, with elementary exchange phase

$$
\rho(\sigma_j) = e^{i\alpha \pi} \qquad \text{for all } j,
$$

for a fixed statistics parameter α of abelian anyons.

2. Reducible abelian: $\mathcal{F} = \mathbb{C}^D$, $D > 1$, where all elementary exchange operators $\rho(\sigma_i)$ commute and thus are

¹⁸ Again, one way to concretize this is to regard the multivalued function Ψ as a ρ -equivariant function on the covering space of $\mathcal{C}^N,$ or as a section of a vector bundle $E\,\rightarrow\,\mathcal{C}^N$ with fiber $\mathcal F$ [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10).

¹⁹ We can even let go of the unitarity condition on reps if one is willing to consider multivalued probability distributions (cf. [\[Abramsky and Brandenburger](#page-25-17) [2011\]](#page-25-17)).

simultaneously diagonalizable:^{[20](#page-19-0)}

$$
\rho(\sigma_j) \cong \text{diag}(e^{i\alpha(1)\pi}, \dots, e^{i\alpha(D)\pi}) \quad \text{for all } j,
$$

for statistics parameters $\alpha(k)$ corresponding to different sectors of particles that do not interact quantum statistically.

3. **Nonabelian:** $\mathcal{F} = \mathbb{C}^D$, $D > 1$, where not all elementary exchange operators commute:

$$
\rho(\sigma_j)\rho(\sigma_k) \neq \rho(\sigma_k)\rho(\sigma_j) \quad \text{for some } j \neq k.
$$

Actually, it turns out that

$$
D \ge N - 2 \qquad \text{if} \quad N \ge 7,\tag{75}
$$

because otherwise the rep is necessarily abelian (this is a theorem in the rep theory of the braid group [\[Formanek](#page-26-31) [1996\]](#page-26-31); cf. [\[Weinberger](#page-30-6) [2015\]](#page-30-6), [\[Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) Theorem 3.13]). Furthermore, if $N \geq 7$ and $D =$ $N-2$ or $D = N-1$ then the rep is either abelian or, up to an abelian factor, the nonabelian (reduced) Burau representation. For any other reps we need $D \geq N$.

Because of this last remark, we cannot simply fix the fiber Hilbert space $\mathcal F$ or the rank of the representation $D = \dim \mathcal{F}$ and then study growing numbers N of anyons, because they will then eventually abelianize. Further, in the nonabelian case it is, as far as this author is aware, not certain whether statistics transmutation is available, i.e. whether one may always pass from the geometric to the magnetic perspective (this is a question in topology; see [\[Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) [Maciazek](#page-28-33) [and Sawicki](#page-28-33) [2019\]](#page-28-33) for further discussion). Some models have magnetic formulations however [\[Kohno](#page-27-7) [1987,](#page-27-7) [Lee and Oh](#page-28-34) [1994,](#page-28-34) [Wen](#page-30-7) [1991\]](#page-30-7), but for simplicity in this overview we will remain in the geometric perspective and furthermore pull in a small sample of results from the algebraic perspective as well, where certain reps can be systematically and consistently constructed from elementary fusion and braiding rules, and exchange operators can be computed explicitly. The topic is quite complex and extends far outside the scope of this overview; instead we refer to [\[Beer et al.](#page-25-18) [2018,](#page-25-18) [Lahtinen and Pachos](#page-27-37) [2017,](#page-27-37) [Lundholm and Qvarfordt](#page-28-10) [2020,](#page-28-10) [Masaki et al.](#page-28-35) [2023,](#page-28-35) [Nayak et al.](#page-29-0) [2008,](#page-29-0) [Stern](#page-29-7) [2008\]](#page-29-7) for more detail on the algebraic and diagrammatic aspects of anyon models (and note that the representation theory of the braid group is a still incomplete and very active field of mathematics). Anyons with nonabelian braid group representations are generally called "nonabelions" or "plektons".

A many-anyon model is a sequence of fiber Hilbert spaces \mathcal{F}_N , $D_N = \dim \mathcal{F}_N$, and braid group representations

$$
\rho_N: B_N \to \mathrm{U}(\mathcal{F}_N), \qquad N = 1, 2, 3, \dots, \qquad (76)
$$

together with a sequence of kinetic energy operators

$$
\hat{T}_{\rho_N} = \frac{\hbar^2}{2m} \sum_{j=1}^N (-i \nabla_{\mathbf{x}_j}^{(\rho_N)})^2
$$
\n(77)

which implement these reps (by means of parallel transport) as the corresponding exchange operators in (74) .^{[21](#page-19-1)}

The free kinetic energy operator \hat{T}_{ρ_N} is again locally the same as the free Laplacian \hat{T}_{dist} , supplemented with holonomies $\rho_N(\sigma) \in U(D_N)$ w.r.t. any nontrivial exchange loops $\sigma \in B_N$. Instead of the abelian pairexchange conditions [\(7\)](#page-5-1), one now has

$$
\Psi(\mathbf{x}_1,\ldots,\mathbf{x}_k,\ldots,\mathbf{x}_j,\ldots,\mathbf{x}_N) = U_{N,p}\Psi(\mathbf{x}_1,\ldots,\mathbf{x}_j,\ldots,\mathbf{x}_k,\ldots,\mathbf{x}_N), \quad (78)
$$

with pair-exchange operators 22 22 22

$$
U_{N,p} \cong \rho_N(\sigma_1 \sigma_2 \dots \sigma_p \sigma_{p+1} \sigma_p \dots \sigma_2 \sigma_1) \tag{79}
$$

for any counterclockwise two-particle exchange loop in which $p \leq N-2$ other particles are enclosed, corresponding to the second figure in Fig. [3.](#page-4-0) We denote their eigenvalues by

spec
$$
U_{N,p} = \{e^{i\pi\gamma_k}\}_{k=1,2,\ldots,D_N},
$$

where we normalize the full range of statistics parameters $\gamma_k = \gamma_k(N, p)$ in the interval $(-1, 1]$.

Nonabelions are still harder to treat as perturbations close to bosons or fermions, since typically the eigenvalues of $U_{N,p}$ are separated from (or coincide with) ± 1 . Also, because of a lack of general magnetic formulations, it is even more unclear what we should mean with an extended gas of nonabelions, except as derived from emergent models and Berry connections (see below). However, concerning the qualitative features and local exclusion properties for the ideal gas, somewhat analogous results as for the abelian gas may be obtained [\[Lundholm and](#page-28-10) [Qvarfordt](#page-28-10) [2020\]](#page-28-10), as follows.

The N-fractionality is now replaced by

$$
\alpha_{N,n} := \min_{p=0,1,...,n-2} \beta_{N,p}, \qquad n \le N, \tag{80}
$$

where the **pair-exchange parameter** with $p \leq N - 2$ particles enclosed,

$$
\beta_{N,p} := \min_{k=1,2,...,D_N} |\gamma_k(N,p)| = \text{dist}(\text{spec}(U_{N,p}), +1),
$$

is again the arcwise distance (in units of π) from the spectrum of $U_{N,p}$ to $+1$. Then, the statistical repulsion as

²⁰ We write $A \cong B$ if two matrices or operators are similar, i.e. unitarily equivalent.

²¹ One might also require a compatibility between reps ρ_N w.r.t. the embedding sequence $B_{N-1} \hookrightarrow B_N$ of braid groups, which may be nontrivial (see [\[Delaney et al.](#page-26-32) [2016,](#page-26-32) [Rowell and Wang](#page-29-30) [2012\]](#page-29-30)).

²² Defined up to similarity; note e.g. that $\rho(\sigma_j) \cong \rho(\sigma_k)$ with similarities depending on j and k [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10).

given both by the Hardy inequality [\(34\)](#page-10-0) (and its variants, depending on $\alpha_{N,n}$, the local exclusion principle [\(40\)](#page-11-5)-[\(41\)](#page-11-6), as well as the degeneracy pressure [\(43\)](#page-11-4), generalize to the ideal nonabelion gas:

$$
\langle \hat{T}_{\rho_N} \rangle_{\Psi} \gtrsim \alpha_{N,2} \int_{\mathbb{R}^2} \varrho_{\Psi}(\mathbf{x})^2 d\mathbf{x}.\tag{81}
$$

Thus, it is again the nearest-neighbor pair exchange (in the rep ρ_N) that sets the main behavior of the gas w.r.t. fractional exclusion statistics.

Three classes of representations of special interest were considered in some detail in [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10): Burau, Ising and Fibonacci. Note that variations of these may arise by composing with abelian models. Some important features have been obtained also for other reps, such as scattering and dilute thermodynamics based on the nearest-neighbor pair exchange [\[Mancarella](#page-28-14) [et al.](#page-28-14) [2013a](#page-28-14)[,b,](#page-28-36) [Verlinde](#page-30-8) [1991,](#page-30-8) [Wilczek and Wu](#page-30-9) [1990\]](#page-30-9).

A. Burau

The Burau rep [\[Burau](#page-25-19) [1935\]](#page-25-19) is a simple deformation of the defining rep of the permutation group, $S_N \to U(N)$, that also must be reduced $(D_N = N - 1 \text{ or } N - 2)$ and unitarized to fit in the above framework. We are only aware of the simplest case $N = 3$, $\mathcal{F} = \mathbb{C}^2$ having been worked out explicitly so far [\[Weinberger](#page-30-6) [2015\]](#page-30-6), and then

$$
spec U_{3,0} = \{1, -w^2\}, \qquad spec U_{3,1} = \{w^3, -w^3\}
$$

for a parameter $w = e^{i\alpha \pi}, |\alpha| < 1/3$, of the representation. Here we find $\alpha_{3,2}(w) = 0$ for all such w and indeed there are states that do not vanish on the diagonal because of a lack of exclusion there [\[Lundholm and](#page-28-10) [Qvarfordt](#page-28-10) [2020\]](#page-28-10).

B. Ising

Here $D_N = \dim \mathcal{F}_N$ grows roughly as $(\sqrt{2})^N$, which is related to reps of Clifford algebras [\[Nayak and Wilczek](#page-29-31) [1996\]](#page-29-31) (and there are distinctions between even/odd numbers of such anyons and of fermions which also appear in the models). The spectra of all pair-exchange operators have been computed [\[Lundholm and Qvarfordt](#page-28-10) [2020\]](#page-28-10):

$$
\begin{array}{ll}\operatorname{spec} U_{N,p} = \\ \begin{cases} \{e^{-i\pi/8}, e^{i\pi 3/8}\}, & \text{if } p = 0, \\ \{e^{-i\pi/8}, e^{i\pi 7/8}\}, & \text{if } p \ge 1 \text{ is odd,} \\ \{e^{-i\pi 5/8}, e^{-i\pi/8}, e^{i\pi 3/8}, e^{i\pi 7/8}\}, & \text{if } p \ge 2 \text{ is even,} \end{cases} \end{array}
$$

(in one rep, and their complex conjugates in another rep, and with multiplicities that grow with N). Thus,

$$
\alpha_{N,n} = \beta_{N,0} = 1/8 \qquad \text{for all } N, n \ge 2,
$$

so the Ising gas has an exclusion at the diagonals and a degeneracy pressure. Since these n-fractionalities are independent of n (and N), we do not see any benefits of clustering to minimize statistical repulsion, at this level of inquiry.

C. Fibonacci

Here $D_N = \dim \mathcal{F}_N$ grows with the Fibonacci sequence, so that $D_{N+1}/D_N \xrightarrow{N \to \infty} \phi$, the golden ratio. Furthermore, the spectra of all pair-exchange operators have been computed [\[Qvarfordt](#page-29-32) [2017\]](#page-29-32):

$$
\operatorname{spec} U_{N,p} = \begin{cases} \{e^{-i\pi 3/5}, e^{i\pi 4/5}\}, & \text{if } p = 0, \\ \{e^{-i\pi/5}, e^{i\pi/5}, e^{i\pi 4/5}\}, & \text{if } p = 1, \\ \{e^{-i\pi 3/5}, e^{-i\pi/5}, e^{i\pi/5}, e^{i\pi 4/5}\}, & \text{if } p \ge 2, \end{cases}
$$

(in one rep, and their complex conjugates in another rep, and with multiplicities that grow with N , also along the Fibonacci sequence). Thus,

$$
\alpha_{N,n} = \begin{cases} \beta_{N,0} = 3/5, & \text{if } n = 2, \\ \beta_{N,1} = 1/5, & \text{if } n \ge 3, \end{cases}
$$

and therefore also the Fibonacci gas is subject to exclusion at the diagonals and a degeneracy pressure. Since $\alpha_{N,n} < \alpha_{N,2}$ for $n \geq 3$, this may be indicative of clustering in this gas in order to minimize statistical repulsion over long ranges.

V. EMERGENCE OF THE ANYON GAS

In the study of emergent quantum statistics, we typically consider two distinct species of particle, one of which is numerous and numbered by e.g. $N \gg 1$, which we shall refer to as the bath, and another species which is much less numerous, $1 \leq n \ll N$, which we refer to as tracers or impurities. These two species could be physically the same type of particle but effectively distinguished by some quantum number, such as their Landau level index for example. The bath forms a background and a collective coherence for the tracers, so that its macroscopically well-defined state provides a limiting reference frame with respect to which tracers may transmute their properties.

A. The quantum Hall setting

In the quantum Hall (QH) setting we assume that all particles are confined to a plane and subject to a large and approximately constant magnetic field $\mathbf{B} = -b\mathbf{e}_z$, $b > 0$, i.e. the relevant one-body operator is again the Landau Hamiltonian [\(64\)](#page-16-0)

$$
\hat{H}_1^{\text{Lan}} = \frac{1}{2m} \left(-i\hbar \nabla_{\mathbf{x}} + qb\mathbf{x}^\perp / 2 \right)^2 = \hbar \omega_c (\hat{a}^\dagger \hat{a} + 1/2),
$$

 $\omega_c = |qb|/m$, and particles then distribute into the Landau levels (LLs) of this field. The lowest Landau level (LLL) is the kernel of \hat{a} (let us now fix $\hbar = 1$ and $q = -1$):

$$
LLL := \mathcal{H}_0
$$

= $\left\{ \psi \in L^2(\mathbb{R}^2) : \psi(\mathbf{x}) = f(z)e^{-\frac{b}{4}|z|^2}, f \text{ analytic} \right\}$ (82)

and spanned by the orthonormal basis of Fock–Darwin states

$$
\psi_l(z) = c_l z^l e^{-\frac{b}{4}|z|^2}, \qquad l = 0, 1, 2, \dots,
$$

for normalization constants $c_l > 0$. We assume electron spin is out of the picture due to the strong band separation, and also that there is a radial trapping potential centered at $z = 0$, penalizing higher angular momenta l.

The first concrete prediction of emergent anyonic statistics was made in the context of the fractional quantum Hall effect (FQHE) for electrons [\[Tsui et al.](#page-29-33) [1982\]](#page-29-33), i.e. fractional filling of the LLL, for which Laughlin proposed the following trial states in the electrons' coordinates $z_j \in \mathbb{C}$, $z = (z_j)_{j=1,\dots,N}$, to explain the effect [\[Laughlin](#page-28-37) [1983,](#page-28-37) [1999\]](#page-28-3):^{[23](#page-21-0)}

$$
\Psi_{\mu}^{\text{Lau}}(\mathbf{z}) \propto \prod_{j < k} z_{jk}^{\mu} e^{-\frac{b}{4}|\mathbf{z}|^2}.
$$

For electrons, μ is an odd integer, so that $\Psi_{\mu}^{\text{Lau}} \in L^2_{\text{asym}}$. In the case that $\mu = 1$, suitable for an *integer* QH effect, the state corresponds to a Fermi sea filling of LLL with the least angular momentum: $\Psi_{\mu=1}^{\text{Lau}}(z)$ is proportional to

$$
\bigwedge_{l=0}^{N-1} \psi_l(z) \propto \det \begin{bmatrix} 1 & 1 & \dots & 1 \\ z_1 & z_2 & \dots & z_N \\ \vdots & \vdots & & \vdots \\ z_1^{N-1} & z_2^{N-1} & \dots & z_N^{N-1} \end{bmatrix} e^{-\frac{b}{4}|z|^2},
$$

by Vandermonde's formula for the determinant. For fractional filling $1/\mu$, and to reduce Coulomb interaction energy among electrons, Laughlin thus proposed taking the determinant above to a power $\mu > 1$. On top of such states, Laughlin also considered states of quasiholes pinned to positions $w_k \in \mathbb{C}$, $w = (w_k)_{k=1,\ldots,n}$:

$$
\Psi_{\mu}^{\text{qh}}(\mathbf{w}; \mathbf{z}) \propto \prod_{k=1}^{n} \prod_{j=1}^{N} (w_k - z_j) \Psi_{\mu}^{\text{Lau}}(\mathbf{z})
$$

(all states with appropriate normalization, and $y_k \leftrightarrow w_k$, $\mathbf{x}_j \leftrightarrow z_j$ respective real and complex coordinates).

1. Berry phases

Halperin [\[Halperin](#page-27-9) [1984\]](#page-27-9) suggested that if the quasiholes are treated as quantum particles then they ought to have fractional anyonic statistics, and Arovas, Schrieffer and Wilczek [\[Arovas et al.](#page-25-2) [1984\]](#page-25-2) subsequently proposed a Berry-phase approach to determine their statistics. Namely, if we view Ψ_{μ}^{qh} as a map

$$
\mathbb{C}^n \to L^2_{\text{asym}}(\mathbb{R}^{2N}), \qquad \mathbf{w} \mapsto \Psi^{\text{qh}}_{\mu}(\mathbf{w}; \cdot)
$$

from the parameters w into the (fiber) Hilbert space of electrons, then Berry associates to such a geometry a canonical connection [\[Berry](#page-25-4) [1984,](#page-25-4) [Simon](#page-29-9) [1983\]](#page-29-9):

$$
\tilde{\mathbf{A}}_{j}(y) := \langle -i \nabla_{\mathbf{y}_{j}} \rangle_{\Psi^{\mathrm{qh}}(y; \cdot)} \n= -i \int_{\mathbb{C}^{N}} \overline{\Psi_{\mu}^{\mathrm{qh}}(y; z)} \nabla_{\mathbf{y}_{j}} \Psi_{\mu}^{\mathrm{qh}}(y; z) dz.
$$
\n(83)

The holonomies of the connection w.r.t. loops on the parameters, $\sigma \colon [0,1] \to \mathbb{C}^n$,

$$
\rho(\sigma) = e^{i\Phi_{\sigma}}, \qquad \Phi_{\sigma} = \oint_{\sigma} \sum_{j=1}^{n} \tilde{\mathbf{A}}_{j} \cdot d\mathbf{y}_{j}, \qquad (84)
$$

are then interpreted to be the exchange phases [\(1\)](#page-3-2) (now including an "external" field of constant curvature) effectively associated to the motion of the quasiholes in the bath of electrons. Thus, under the adiabatic assumption that the electrons move much faster than the holes, one can take statistical averages over $z \in \mathbb{C}^N$ and use an analogy with a classical charged plasma to compute $|\Psi^{\text{qh}}(y; \cdot)|^2$ and Φ_{σ} , and then indeed conclude that there is, on top of geometric holonomies corresponding to a constant field $B/\mu = -b/\mu$ (i.e. effectively coupled to a fractional charge $+1/\mu$ that *reduces* the field), also topological exchange phases corresponding to the localized (but somewhat extended) attachment of fractional flux $-2\pi/\mu$ to the quasiholes. For a relatively recent review of the approach, including possible extensions to nonabelian scenarios (for which the quasihole map Ψ^{qh} is multidimensional), see [\[Bonderson et al.](#page-25-11) [2011\]](#page-25-11).

2. Transmuted Hamiltonian

Forte [\[Forte](#page-26-8) [1991\]](#page-26-8) argued that the above approach is not necessarily sufficient to determine the anyonic statistics because, as we have noted above with the freedom of statistics transmutation, the knowledge of the specific Hamiltonian for the quasiholes is essential, since that is what ultimately sets the scale of validity of any adiabatic treatment. Thus, a different approach was suggested in [\[Lambert et al.](#page-27-36) [2023,](#page-27-36) [Lundholm and Rougerie](#page-28-38) [2016\]](#page-28-38) to remedy this situation and supply the missing dynamical information, by considering quasiholes pinned to already present quantum particles.

In brief, one may consider the following idealized situation (see Fig. [12\)](#page-22-0):

 23 Note that these also coincide with the anyonic trial states [\(48\)](#page-12-3)-[\(49\)](#page-12-4) if extended to $\alpha = \mu$ with trivial Jastrow factors [\[Lundholm](#page-28-16) [2017\]](#page-28-16).

FIG. 12. Statistics transmutation in the QH setting. Bath particles (red) are repelled from tracers (black) by short-range interactions (green), and all particles move in an external homogeneous magnetic field (blue arrows). Subtracting the almost-homogeneous effective field generated by the bath as $b \sim N \gg 1$ then leaves a reduced/zero field plus remnant field (blue disks) at the holes punched in the bath by the tracers.

- 1. large 2D bath of noninteracting fermions, $N \gg 1$,
- 2. n tracers/impurities (initially can be either bosons or fermions), $1 \leq n \ll N$,
- 3. strong external transverse magnetic field, $b \to \infty$,
- 4. strong short-range repulsive bath-tracer interaction, at coupling $q \to \infty$.

Taking the bath particles x_j to have unit mass and unit negative charge, the tracers y_k to have mass m and charge $-q$, and allowing for interaction and trapping of tracers in a joint potential W , the Hamiltonian of the joint system is:

$$
H_{n \oplus N} := \frac{1}{2} \sum_{j=1}^{N} \left(-i \nabla_{\mathbf{x}_j} - b \mathbf{x}_j^{\perp} / 2 \right)^2
$$

+
$$
\frac{1}{2m} \sum_{k=1}^{n} \left(-i \nabla_{\mathbf{y}_k} - q b \mathbf{y}_k^{\perp} / 2 \right)^2
$$

+
$$
g \sum_{j=1}^{N} \sum_{k=1}^{n} \delta(\mathbf{x}_j - \mathbf{y}_k) + W(\mathbf{y}_1, \dots, \mathbf{y}_n),
$$

acting on states

$$
\Psi(\mathbf{y}_1,\ldots,\mathbf{y}_n;\mathbf{x}_1,\ldots,\mathbf{x}_N)\in L^2(\mathbb{R}^{2n})\otimes L^2_{\text{asym}}(\mathbb{R}^{2N}).
$$

If one takes $b \sim N$ and $N \gg n$, and assumes the bath then sits entirely in the LLL, thus forming a disk-shaped QH droplet of size \sim 1, the Hilbert space is reduced to

$$
\mathcal{H}^{n\oplus N}_{\mathrm{sym/asym}}:=L^2_{\mathrm{sym/asym}}(\mathbb{R}^{2n})\otimes \bigwedge\nolimits^N LLL
$$

(allowing for either bosonic or fermionic tracers), with g.s.e.

$$
E_{n\oplus N}:=\inf_{0\neq\Psi\in \mathcal{H}^{n\oplus N}_{\mathrm{sym/asym}}}\langle H_{n\oplus N}\rangle_{\Psi}.
$$

For $g \to \infty$, we then take as our ansatz for the ground state of the system a state in the kernel of the interaction:

$$
\Psi_{\Phi}(y; x) := \Phi(w)c^{qh}(w)\Psi^{qh}(w; z), \tag{85}
$$

with $\Phi \in L^2_{sym/asym}(\mathbb{C}^n)$, $c^{qh} > 0$ and

$$
\int_{\mathbb{C}^n} |\Phi(w)|^2 dw = 1, \ \ c^{\text{qh}}(w)^{-2} := \int_{\mathbb{C}^N} |\Psi^{\text{qh}}(w; z)|^2 dz,
$$

ensuring the correct normalization $\int_{\mathbb{C}^{n+N}} |\Psi_{\Phi}|^2 d\mathbf{w} d\mathbf{z} = 1$.

The bath in LLL forces an *analytic* vanishing as $z_j \rightarrow$ w_k , i.e. $\mathbf{x}_j \to \mathbf{y}_k$. It suggests to take $\Psi^{\text{qh}} = \Psi^{\text{qh}}_\mu$ as above, corresponding to fractional filling $1/\mu$ of the LLL, or

$$
\Psi_{\mu,p}^{\text{qh}}(w; z) := \prod_{k=1}^{n} \prod_{j=1}^{N} (w_k - z_j)^p \, \Psi_{\mu}^{\text{Lau}}(z),
$$

thus also allowing for non-simple quasiholes if $p > 1$.

It was conjectured in [\[Lambert et al.](#page-27-36) [2023,](#page-27-36) [Lundholm](#page-28-38) [and Rougerie](#page-28-38) [2016\]](#page-28-38) that in this ansatz

$$
\langle H_{n\oplus N} \rangle_{\Psi_{\Phi}} = \frac{bN}{2} + \langle H_n^{\text{eff}} \rangle_{\Phi} + \text{error}_{\Phi}(n/N), \qquad (86)
$$

for an effective statistics-transmuted Hamiltonian for the tracers:

$$
H_n^{\text{eff}} := \frac{bn}{2m} \frac{p}{\mu} + \frac{1}{2m} \sum_{j=1}^n \left(-i \nabla_{\mathbf{y}_j} - \left(q - \frac{p}{\mu} \right) \frac{b}{2} \mathbf{y}_j^{\perp} - \frac{p^2}{\mu} \mathbf{A}_j \right)^2 + W(\mathbf{y}),
$$

thus implying an effective renormalized charge $-q + p/\mu$ and shifted statistics parameter by $-p^2/\mu$.

In [\[Lambert et al.](#page-27-36) [2023\]](#page-27-36) it was proved mathematically that [\(86\)](#page-22-1) is indeed a correct conclusion, with an error term of order $o(N)$ at fixed n and reasonable Φ , if $\mu = 1$ and $p = 1$, corresponding to transmutation of bosons into fermions and vice versa (cf. Sec. [II D\)](#page-6-3). Many crucial simplifications occur for these specific parameters, having to do with the Vandermonde structure of the state, and in the proof it is also required that tracers have sufficient extra repulsion to not cluster too strongly at the diagonal set Δ_n , which is ensured either by them being initially bosons and then eventually (free, if $q = 1$) fermions, or that W includes an additional and sufficiently strong intra-species repulsion.

B. Impurities in the plane and polarons

Another route to statistics transmutation is to place tracers/impurities in a bath of bosons, such as the

FIG. 13. Statistics transmutation in the polaron setting. An initial ladder of even-integer fluxes/vortices (composite bosons or fermions) is in the adiabatic limit transmuted into a ladder of fractional fluxes/vortices (anyons).

phonon vibrational modes of a crystal lattice, or photonic optical modes. Such systems are well known to enable transmutation of the impurities into polarons, i.e. bound states of impurity particles and coherent states of phonons/photons [Fröhlich [1954,](#page-26-33) [Landau](#page-27-38) [1933,](#page-27-38) [Pekar](#page-29-34) [1946\]](#page-29-34). In [\[Yakaboylu and Lemeshko](#page-30-10) [2018,](#page-30-10) [Yakaboylu](#page-30-5) [et al.](#page-30-5) [2020\]](#page-30-5) it was observed that, subject to suitable external fields and rotation of such systems, the polarons can also transmute their statistics.

As an illustrative toy model, we consider a single bosonic collective degree of freedom:

$$
[\hat{a},\hat{a}^\dagger]=1,\quad \hat{N}:=\hat{a}^\dagger\hat{a},\;\;\text{with eigenstates}\;|N\rangle,\;N\geq0,
$$

and an initial n -particle Hamiltonian

$$
\hat{H}_0 = \sum_{j=1}^n (-i\nabla_{\mathbf{x}_j})^2 + W(\mathbf{x})
$$

for bosons or fermions on $\mathcal{H}_0 = L^2_{sym/asym}(\mathbb{R}^{2n})$. Let us then define the interaction Hamiltonian

$$
\hat{H}_{\omega,\gamma} := \hat{H}_0 + \omega \hat{a}^\dagger \hat{a} + \gamma \omega (F \hat{a}^\dagger + F^{-1} \hat{a}) + \gamma^2 \omega, \quad (87)
$$

with two parameters $\omega > 0$ and $\gamma \in \mathbb{R}$. The interpretation of the terms added to \hat{H}_0 is that ω is the energy associated to an attachment or detachment of two units of flux or vorticity to each of the particles, which is done by the respective hopping terms with coupling $\gamma\omega$ and such that γ defines the ratio between these two effects. The last term is only a constant added for convenience.

We now denote $Z = \prod_{j < k} z_{jk}$, and consider two possible choices for F (or their complex conjugates, depending on which way the orientation symmetry is to be broken):

1. $F = (Z/|Z|)^2 = U^2$ corresponding to flux attachment,

2. $F = Z^2$ corresponding to **vortex attachment**.

By acting with Fa^{\dagger} on the reference system $\mathcal{H}^0 = \mathcal{H}_0 |0\rangle$ one obtains a ladder of Hilbert spaces of composite bosons/fermions (see Fig. [13\)](#page-23-0):

$$
\mathcal{H}^N := F^N \mathcal{H}_0 |N\rangle, \qquad N = 0, 1, 2, \dots
$$

Upon taking the "adiabatic limit" $\omega \to \infty$ at fixed γ , we claim that in the bottom of the spectrum of $\hat{H}_{\omega,\gamma}$ we then obtain a ladder of transmuted anyons with statistics parameter $\alpha = 2\gamma^2 + 2N$ [\[Yakaboylu et al.](#page-30-5) [2020\]](#page-30-5). These anyons are either *interacting* by means of a scalar potential $\sum_j \mathbf{A}_j^2$ (for the more realistic, unitary choice $F = U^2$, or free (for the more algebraic, non-unitary choice $F = Z^2$, yielding a non-hermitian Hamiltonian with $i\mathbf{A}_j = \nabla_{\mathbf{x}_j} \log Z$. Namely, the transformations

$$
\hat{S} = F^{\hat{N}} = e^{\hat{N}\log F}, \qquad \hat{U} = e^{-\gamma(\hat{a}^\dagger - \hat{a})}, \qquad (88)
$$

which diagonalize $\hat{H}_{\omega,\gamma}$,

$$
\hat{U}^{-1}\hat{S}^{-1}\hat{H}_{\omega,\gamma}\hat{S}\hat{U}
$$
\n
$$
= \omega \hat{a}^{\dagger}\hat{a} + \sum_{j=1}^{N} \left[-i\nabla_{\mathbf{x}_{j}} + 2\mathbf{A}_{j}(\hat{a}^{\dagger} - \gamma)(\hat{a} - \gamma) \right]^{2} + W(\mathbf{x}),
$$

create coherent-state mixtures

$$
\hat{S}\hat{U}|0\rangle = e^{-\gamma^2/2} \sum_{N=0}^{\infty} \frac{(-\gamma)^N}{\sqrt{N!}} F^N|N\rangle \tag{89}
$$

over the initial ladder of integer composites and enable a shift of the expected amount of flux/vorticity by $\alpha_0 = 2\gamma^2 \geq 0$, possibly to non-integer values. This transmutation procedure has indeed been used (with the choice $F = Z^2$ to compute the numerical spectra seen in Fig. [4.](#page-7-0)

A possible plane polaron model with the above form is obtained upon applying a constant magnetic field B and shifting to a counter-rotating frame at half the cyclotron frequency $\Omega = B/(2m)$ (cf. Fig. [14,](#page-24-1) upper):

$$
\begin{aligned} \hat{H}_N &= \frac{1}{2m}\sum_{j=1}^n \hat{\mathbf{p}}_j^2 + W^\Omega(\mathbf{x}) + \sum_\mathbf{k} \omega_\mathbf{k}^\Omega \hat{b}_\mathbf{k}^\dagger \hat{b}_\mathbf{k} \\ &\quad + \sum_\mathbf{k} \lambda_\mathbf{k}(\mathbf{x}) \left(e^{-i\beta_\mathbf{k}(\mathbf{x})} b_\mathbf{k}^\dagger + e^{i\beta_\mathbf{k}(\mathbf{x})} b_\mathbf{k} \right), \end{aligned}
$$

for phonon vibration modes $b_{\mathbf{k}}, \mathbf{k} \in \mathbb{R}^2$ with dispersion $\omega_{\mathbf{k}}^{\Omega}$ (which is their bare dispersion shifted by their angular momentum coupled to Ω), and phonon-impurity

*H*ˆ FR = − ¹ **∇**2 *^r* + 1 *M*² *r*² + ωμ*b*ˆ† *^k*μ*b*ˆ*^k*^μ FIG. 14. We have here focused on its precise definition in typical ideal and nonideal contexts, its most basic physics as regards
the connection between exchange and exclusion statistics. the connection between exchange and exclusion statistics, as well as its inevitable emergence in a few conceptu-¹ ally simple scenarios involving relatively well-understood any simple scenarios involving relatively we \mathbf{e}_{e} = bosonic and fermionic systems with manifes orientation symmetry, such as the rotated polaron and the quantum Hall setup. [AI and Collaborators](#page-27-40) [2022,](#page-27-40) [Nakamura et al.](#page-29-39) [2020\]](#page-29-39), it is r_{max} and r_{max} and r_{min} a t_{e} bosonic and fermionic systems with manifest breaking of

In preparation for future experiments and theoretical research, one could make a few observations and high*nght* some potential obstacts. This, it is hoped that accurate density functional theories for large systems of Instead of a three-dimensional consideration of the set of a three-dimensional constant $\frac{1}{2}$ anyons will provide more robust, detectable signatures, such as spatial and momentum density profiles, as com- \vec{v} pared to the typically extremely fragile phases probed by interferometry (cf. [\[Camino et al.](#page-26-38) [2005,](#page-26-38) [Nakamura et al.](#page-29-39) [2020\]](#page-29-39)). Second, the development of impurity models and $\lim_{n \to \infty}$ the pinning of quasiholes, fluxes and vortices to already well-understood quantum particles promises to eliminate light some potential obstacles. First, it is hoped that some of the ambiguities inherent in conventional Berry phase and adiabatic treatments (cf. [\[Forte](#page-26-8) [1991,](#page-26-8) [Jain](#page-27-41) [2007,](#page-27-41) [Lambert et al.](#page-27-36) [2023,](#page-27-36) [Lundholm and Rougerie](#page-28-38) [2016,](#page-28-38) [Myrheim](#page-29-5) [1999\]](#page-29-5)). Third, with the steadily growing literature on anyons and an increasing interest in their fascinating physics, even from the general public, it is important to be aware of potential confusion on how the term

"anyon" is used. Hopefully, this overview has helped to clarify both the nontrivial relationship between exchange and exclusion statistics, as well as the crucial differences between: a) the choice or construction of a concrete braid group representation $\rho_N : B_N \to U(\mathcal{F}_N)$ (algebra, kinematics, or simply an action of a permutation on a system); b) its practical realization such as by means of motion of classical parameters (magnetics, or computation using a classical or quantum computer; cf. [\[Noh et al.](#page-29-40) [2020\]](#page-29-40)); and c) actual anyons (or bosons or fermions) endowed with quantum kinetic energy \hat{T}_{ρ_N} (geometrodynamics), uncertainty and exclusion.

Acknowledgments. The study of the magnetic TF functional for anyons was done in collaboration with Dinh Thi Nguyen, following helpful discussions with Nicolas Rougerie and Théotime Girardot. Further, I thank

the editor Tapash Chakraborty for the timely invitation to write this overview, as well as Vincent Cavalier, Ask Ellingsen, Gerald Goldin and Wolfgang Staubach for useful comments on the manuscript. I am thankful to numerous other colleagues for insightful discussions on this topic over the last 13 years, in particular Jan Philip Solovej, who raised my interest in it, as well as Eddy Ardonne, Morris Brooks, Michele Correggi, Romain Duboscq, Luca Fresta, Jürg Fröhlich, Thors Hans Hansson, Gaultier Lambert, Simon Larson, Jon Magne Leinaas, Tomasz Maciazek, Per Moosavi, Luca Oddis, Stéphane Ouvry, Viktor Qvarfordt, Robert Seiringer, Andrea Trombettoni, Susanne Viefers, and Enderalp Yakaboylu. The research project was funded by the Swedish Research Council (grant no. 2021-05328, "Mathematics of anyons and intermediate quantum statistics").
