(Dated: April 10, 2023)

The state-of-the-art defect engineering techniques have paved the way to realize novel quantum phases out of pristine materials. Here, through density-functional calculations and model studies, we show that the chain-doped monolayer transition metal dichalcogenides (TMDs), where M atoms on a single the zigzag chains are replaced by a higher-valence transition-metal element M' (MX₂/M'), exhibit one-dimensional (1D) bands. These 1D bands, occurring in the fundamental gap of the pristing material, are dispersive along the doped chain but are strongly confined along the lateral direction. This confinement occurs as the bare potential of the dopant chain formed by the positively charged M' ions resembles the potential well of a uniformly charged wire. These bands could show novel 1D physics, including a new type of Tomonaga-Luttinger liquid behavior, multi-orbital Mott insulator physics, and an unusual optical absorption, due to the simultaneous presence of the spinorbit coupling, strong correlation, multiple orbitals, Rashba spin splitting, and broken symmetry. For the half-filled 1D bands, we find, quite surprisingly, a broadening of the 1D bands due to correlation, as opposed to the expected band narrowing. This is interpreted to be due to multiple orbitals forming the single Hubbard band at different points of the Brillouin zone. Furthermore, due to the presence of an intrinsic electric field along the lateral direction, the 1D bands are Rashba spin-split and provide a new mechanism for tuning the valley dependent optical transitions.

PACS numbers:

I. INTRODUCTION

Successful synthesis of atomistically controlled Van der Waals layered materials in the form of transition metal chalcogenides (TMDs) has given rise to a wide range of mesoscopic non-trivial quantum phases. These include proximity of p-wave superconductivity and charge density wave as in NbSe₂^{1–3}, topological Weyl semimetallic nature and large magnetoresistance as in WTe₂^{4–6}, and the exotic orbital and quantum spin Hall effects^{7–9}.

One of the emerging areas of research on two-dimensional (2D) TMDs is to further reduce the dimensionality and explore sub-nanoscale quantum physics. For example, the Moirè bilayers of TMDs and their heterostructures allow twist angle controlled resonant effects to engineer exciton band structure 10,11. The lateral superlattices and nanoribbons are synthesized out of TMDs to produce edge and interfacial states^{12–17}. A recent study has proposed a typical Moirè lattice out of WTe₂ where an overarching periodicity creates a 1D lattice for electrons residing in collective eigenstates which give rise to rarely observed exotic quantum states of Tomonaga Luttinger liquid (TLL) behavior¹². The ribbon edge states in 1-T'-WTe2 exhibiting TLL behavior is a new experimental result in this direction 15. The TLL state is also experimentally observed in MoS₂ by creating mirror twin boundaries¹⁶. Electron correlation is an important missing factor in TMDs, and therefore, correlation driven exotic quantum phases in the area of magnetism and superconductivity are less evident in this class of compounds.

To achieve the correlated electron phases, narrow bands in the vicinity of Fermi energy need to be created, and one of the ways to make it possible is to confine the electron motion by reducing the dimensionality.

Unlike the semimetallic 1T' phase 18, the 2H phase of TMDs has wide band gaps and hence novel quantum phases and transport can be envisaged in them by inducing mid-gap states of lower dimensions. With growing interest in doped 2D TMDs, there are experimental proposals on tunable doping mechanisms in these systems¹⁹. Recently, Lin et. al.²⁰ reported excellent controllability for substitutional doping of the foreign atoms in 2D TMDs through low energy ion implantation techniques such as site-selective laser-assisted chemical vapor doping²¹. Furthermore, a very recent experimental work demonstrates a controlled doping strategy for TMDs based on a dislocation climb mechanism²². In this study, the authors were successful in forming highly doped nanostripes of Ti, V, Cr, and Fe atoms in WSe₂ and WS₂ monolayers.

In this paper, we have engineered 1D quantum states out of the semiconducting 2H phase of MoX_2 and WX_2 monolayers with X being a chalcogen. This is achieved by replacing a single chain of Mo or W along the zigzag direction with an element M' with one extra valence electron as shown in Fig. 1. We find these chain-doped systems, henceforth represented as MX_2/M' to be dynamically stable. The 1D bands, depending on several other factors, build a perfect platform to induce nontrivial low-dimensional quantum phases, which may include Peierls distortion²³, topological magnons²⁴, charge

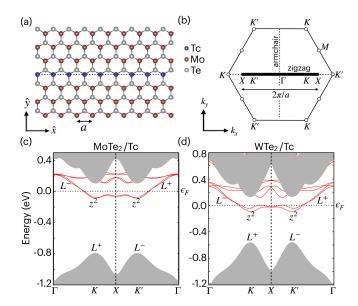

FIG. 1: (a) Top view of the chain-doped MX₂/M' compound, where a single zigzag chain of the pristine MX₂ structure is replaced with an $M'X_2$ chain. (b) The reduced 1D Brillouin zone (line extending between $-\pi/a < k_x < \pi/a$) for the chaindoped structure and its relation to the original 2D Brillouin zone (hexagon). All three valley points K of the hexagonal BZ fall onto the same point, marked by K, on the 1D BZ, and the same happens for the K' points. The hexagonal zone collapses vertically onto the k_x axis, and the points lying outside the 1D BZ in the process, are brought inside it via the reciprocal lattice translation of $2\pi/a$. The "zigzag/armchair" labels in the figure indicate the orientation of the BZ with respect to the crystalline directions in real space. (c) and (d) The DFT+SOC band structure of the pristine MoTe₂ and WTe₂ (shaded grey), projected into the 1D BZ. The red lines indicate the defect bands introduced by the Tc doped chain in the forbidden region. These bands represent 1D propagating states along the chain, while they are confined in the lateral direction. The defect bands are dominated by the orbital characters of Tc. The small splitting of the otherwise degenerate defect bands is because of the Rashba SOC due to a non-zero lateral electric field (see text).

density waves²⁵, TLL²⁶, and 1D magnetism.

In the case of MTe₂/Tc and MTe₂/Re, we find that the weakly SOC driven degenerate half-filled 1D bands running along the chain make them ideal candidates for exhibiting TLL phenomena. In the magnetic phase, the effect of strong correlation can produce Mott insulating states by breaking the half-filled 1D bands to lower and upper Hubbard subbands with a gap in between. However, a new phenomenon emerges where the onsite Coulomb repulsion instead of localizing, delocalizes the lower Hubbard subbands. Upon practical realization, it can give rise to an unusual 1D quantum transport. The dopant chain breaks the reflection symmetry to introduce an intrinsic electric field along the lateral direction. This in turn, makes the 1D bands Rashba spin-split and introduces valley dependent optical transition in the system.

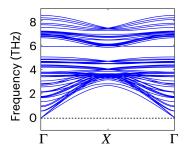

FIG. 2: The phonon frequencies of the chain-doped $MoTe_2/T_c$ ($Mo_6Tc_1Te_{14}$). The force constants obtained from the DFPT method are taken into account through the phonopy $code^{27}$ as implemented in VASP. The absence of imaginary modes implies the dynamical stability of the chain-doped structure.

II. STRUCTURAL AND COMPUTATIONAL DETAILS

The prototype representation of the chain-doped monolayer structures $(MX_2/M' = M_{n-1}M'_1X_{2n})$ is shown in Fig. 1 (a). In this study, the supercell approach is adopted with n=13, which is found to be sufficient to induce the 1D defect bands. The phonon band structures of such systems do not show imaginary frequencies (see Fig. 2), suggesting dynamical stability. With chain doping along the zigzag direction, the 2D Brillouin zone (BZ) reduces to a 1D BZ as shown by a thick black strip in Fig. 1 (b). The high symmetry points of the 2D BZ are projected onto the reduced BZ, which helps us later in discussing the resonance and bound states.

The density functional theory (DFT) calculations are carried out on optimized $M_{n-1}M'_1X_{2n}$ structures us-

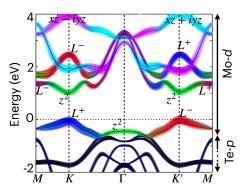

FIG. 3: The orbital resolved band structure of the monolayer MoTe₂ obtained using Wannier90²⁸. The valence band maximum occurring at the valley points, K and K', are dominated by the angular momentum orbitals $L^{\pm} = (x^2 - y^2 \pm ixy)$, while the conduction band minima are formed by the z^2 orbital, all belonging to the Mo atom. The spectrum below the top valence band is formed by the Te-p states.

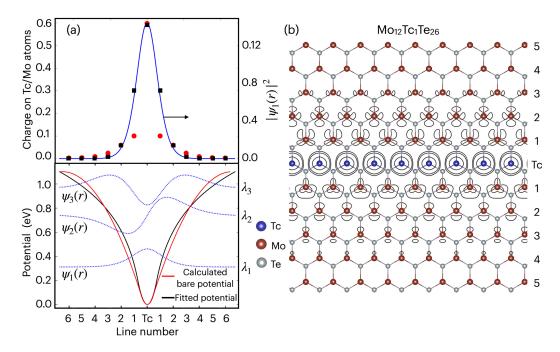

FIG. 4: The confinement of the chain-doped bands along the lateral direction. (a) Lower panel: The cell-averaged bare potential (red solid line) and the model potential (black solid line) as per Eq. 1. The ground and the first two excited states wave functions $(\psi_1, \psi_2, \text{ and } \psi_3)$ are sketched in blue dotted lines. These are obtained by numerically solving the Schrödinger equation for the model potential. Upper panel: The spread of the extra valence electron in this potential. The DFT obtained values are shown in red circles. The cell average of the ground state charge density $(|\psi_1(r)|^2)$ is shown in black squares. ing the pseudopotential based projector-augmented wave (PAW) method 29,30 within the framework of PBE-GGA exchange-correlation functional as implemented in Vienna ab initio simulation package (VASP) 31 . The plane wave energy cut-off of 400 eV and a $1\times8\times2$ Γ -centered k-mesh is used for BZ integration. The Hubbard U formalism is adopted to study the correlation effect arising due to localized defect states. The U values are obtained using the linear response theory 32 . The cell averaged bare potential is calculated using the QUANTUM ESPRESSO simulation package 33 .

III. FORMATION OF 1D BANDS

While a range of chain-doped configurations are investigated, here, we will discuss the electronic structure of MoTe_2/T_c and WTe_2/T_c as prototypes. However, it is useful to first provide a brief overview of the electronic structure of the pristine TMDs so that the formation of the dopant states can be better understood. For this purpose, in Fig. 3, we present the band structure of monolayer 2H-MoTe $_2^{34}$. The electronic properties of the TMDs have been widely studied $_2^{34-36}$. The formation of bands can be described with two step chemical bonding. In the first step, the nearest neighbor Mo-d – Te-p interactions give rise to lower-lying Te-p dominated bands

and upper-lying Mo-d dominated bands. Driven by the trigonal prismatic crystal field, the latter is further split into three groups: $A'_1(z^2)$, $E'(xy, x^2 - y^2)$ and $E''(xz, y^2)$ yz). The second step involves second neighbor interactions where in the monolayer limit the reflection symmetry along \hat{z} direction permits hybridization among the A'₁ and E' orbitals to create a band gap. The valley points K and K' host both the valence band maximum (VBM) and the conduction band minimum (CBM). The VBM at Kand K' are found to be formed by $x^2 - y^2 + ixy$ (L⁺) and $x^2 - y^2 - ixy$ (L⁻) orbitals respectively, giving rise to opposite orbital moments⁸ while the CBM is formed by the z^2 character and hence with zero orbital moments^{8,34}. The role of the spin-orbit coupling (SOC) in this compound is restricted to splitting the bands dominated by L^+ and L^- by a few meV without perturbing the broad band structure. To produce unique quantum transport phenomena, the mid-gap states with varying characters can be generated in these systems through hole or electron doping.

The band structures of the chain-doped systems $MoTe_2/Tc$ and WTe_2/Tc are respectively shown in Figs. 1 (c) and (d). The gray shaded region represents the bands of pristine $MoTe_2/(WTe_2)$ projected along the $k_y = 0$ (see Fig. 1 (c)/(d)). The red bands belong to the chain-doped compounds. Most of them overlap with the bands of the parent compound, but the rest form defect

bands, creating either bound states by lying in the forbidden region or resonating states by overlapping with the bulk bands. The defect bands lying in the vicinity of the Fermi level (ϵ_F) are of significant importance as they can introduce new transport behavior in the system. Our orbital projection analysis indeed shows that these bands are formed by the xy, x^2-y^2 , and z^2 orbitals of the Tc chain. Furthermore, the defect bands are dispersive along the chain direction while remaining bound perpendicular to it and thereby a platform for 1D quantum physics is created.

The basic electronic configuration enables us to explain the formation of the 1D quantum state. In MoTe₂ and WTe₂, Mo⁴⁺ and W⁴⁺ has d^2 configuration while Tc offers one additional electron with d^3 electronic configuration. Therefore, when a chain of Tc is placed in the Mo/W matrix the former adopts a $d^2 + d^1$ electronic configuration. The d^2 primarily contributes to the bulk while the Tc- d^1 is responsible for forming the defect bands.

By giving away the additional electron (d^1) , the Tc chain behaves like a positively charged wire of radius R_0 . From Gauss's law, the potential inside and outside the wire can be expressed as:

$$V = \begin{cases} \frac{\rho}{4\epsilon_r \epsilon_0} r^2, & r < R_0\\ \frac{\rho R_0^2}{4\epsilon_0 \epsilon_r} \left(1 + 2\log(\frac{r}{R_0}) \right), & r > R_0 \end{cases}$$
 (1)

where, $\rho = e/\pi R_0^2 a$ is the charge density of the wire with a being the lattice constant. Based on the earlier theoretical studies the dielectric constant (ϵ_r) is taken to be 20^{37} . We mapped the modeled potential with the cell averaged bare potential obtained from the DFT calculations on a MoTe₂/Tc superlattice. There is an excellent agreement capturing both r^2 and logarithmic behavior inside and outside the wire respectively for $R_0 = 2.6$ Å which is higher than the atomic radii of Tc and lower than the lattice parameter.

The wave functions of the ground and first two excited states $(\psi_n(r))$ and their corresponding eigenvalues (λ_n) are shown in Fig. 4 (a) lower panel, which were obtained from the numerical solution to the one-particle Schrödinger equation with the potential given in Eq. 1. The eigenstates resemble those of the Airy functions which are the solutions of the Schrödinger equation for at linearly varying potential well³⁸. The $|\psi_1(r)|^2$ plotted in a blue solid line in the upper half of Fig. 4 (a) reflects the charge spread away from the Tc chain. For validation, we computed the cell average of $|\psi_1(r)|^2$ (black filled squares) along the direction perpendicular to the chain and compared them with the atom wise contribution of partially occupied lower lying defect band, and values are depicted through the red filled circles and found a very good match among them. The rapid exponential decay of the charge spread is also demonstrated through the logarithmic charge density $(\rho_{DFT}(r))$ contours calculated for the 1D band. The $\rho_{DFT}(r)$ is calculated by integrating the lower lying defect band upto ϵ_F . From Fig. 4 (b), we observe that the spread vanishes after three layers on

TABLE I: Rashba strength (in eV · Å) and the hopping integrals (in eV) for the 1D defect bands in MX_2/M' .

Compound name	λ_R	t	t'	t''

either side of the Tc chain while accumulating most of the charge on the chain itself. This implies that the defect state is bound laterally and dispersive along the Tc chain.

IV. PLATFORM FOR 1D PHYSICS

A. Rashba SOC and valley-dependent optical transitions

The partially filled non-degenerate defect bands can be fitted with a tight-binding model on the doped chain along with a Rashba-like term, viz.,

$$E = (\varepsilon_0 + 2t\cos k_x + 2t'\cos 2k_x + 2t''\cos 3k_x)I + \lambda_R(\hat{E} \times \vec{k}) \cdot \vec{\sigma},$$

where the chain runs along \hat{x} , ε_0 is the on-site energy taken to be zero, t, t', and t'' are, respectively, the hopping to the first, second, and the third nearest neighbor. Here, I is 2×2 identity matrix and $\vec{\sigma}$ are Pauli spin matrices. λ_R is the Rashba strength. From the symmetry of the structure (Fig. 4 (b)), an electric field exists in the y direction on the plane, which translates to a magnetic field $\vec{B} = \vec{v} \times \vec{E}/c^2$ in the electron's rest frame that couples to the spin moment. This leads to the spin-split band structure with a linear dispersion described by the last term in Eq. (2).

The TB parameters, obtained by fitting to the DFT results, are listed in Table I for a number of chain-doped compounds. We note that there is a substantial 2^{nd} neighbor hopping t', but the 3^{rd} neighbor hopping is substantial only for the Re chains and negligible for the Tc chains. The TB bands fitted with DFT for WTe₂/Tc is shown in Fig. S10 of supplementary materials (SM). Similar models can also be developed for the Rashba spin-split defect bands that lie in the forbidden regions other than the fundamental gap.

The schematic band structure along with the Rashba spin splitting is illustrated in Fig. (5), which suggests interesting valley dependent optical properties. In the parent MX_2 material, circularly polarized light with op-

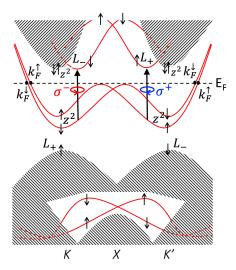

FIG. 5: Schematic 1D defect bands indicating the Rashba spin splitting and valley dependent optical absorption. The shaded bands indicate the band structure of the 2D host material, while the red lines indicate the localized 1D defect bands introduced in the band gap of the host. The red dashed lines in the valence band indicate resonance states. Some dipole-allowed optical transitions for circularly polarized light are indicated by σ^- and σ^+ . The orbital projected bands of prototype WTe₂/Tc are shown in Fig. S11 of SM.

posite polarization is absorbed at the two different vallevs K and K'. Due to the Rashba-like spin splitting, we predict the chain-doped compounds to exhibit additional features in the valley-dependent optical absorption between the bulk to the defect states. The lowest-energy optical transitions at the valley points are forbidden because the lower defect band has spin opposite to that of the bulk valence band edge. Note that the projected bands onto the 1D BZ of the chain-doped compound not only shows the fundamental gap extending through the full BZ, but also gaps that exist at certain regions of the BZ as indicated for the valence bands in Fig. 5. As also indicated in the figure, localized 1D bands can exist within these gaps, and valley-dependent optical transitions would occur between these states including the localized 1D bands lying in the fundamental gap. To illustrate, the dipole allowed lowest-energy optical transitions (σ^+ and σ^-) between partially filled and localized 1D conduction bands in the vicinity of valley points are indicated in the figure.

B. Electronic Correlation

Electron correlation effects are expected to be important for the 1D defect bands, since the bandwidth is quite narrow. A key parameter for characterizing the strength of the correlation effects is the on-site Coulomb repulsion U, which we now proceed to compute using the DFT and the linear response approach.

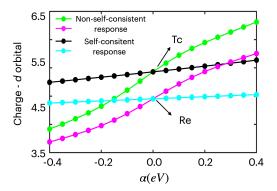

FIG. 6: Calculation of the Coulomb repulsion U_0 for the metal atom on the doped chain, Tc or Re, using Eq. 3. Plotted are the occupation numbers, n_i^{KS} and n_i , as a function of the perturbing potential α at the doped metal site, obtained using 1×4 supercell of MoSe₂/Tc and MoSe₂/Re, i.e. $(M_{n-1}M_1'X_{2n}, n=7)\times 4$, where the perturbing potential was applied to a single Tc or Re atom.

In this method³², U is computed by calculating the difference between interacting and non-interacting density response functions:

$$U = \chi_0^{-1} - \chi^{-1} = \left(\frac{\partial n_i^{KS}}{\partial \alpha_i}\right)^{-1} - \left(\frac{\partial n_i}{\partial \alpha_i}\right)^{-1}, \quad (3)$$

where α_i is a perturbative shift in the single particle potential at site i, for which U is being computed. Since the bandwidth of the d bands of the host compound MX₂ are rather large, and the bands are either occupied or unoccupied, the correlation effects are relatively weak. In contrast, the defect bands are one-dimensional, relatively narrow, and half-filled, so that the correlation effects are expected to be important there. Therefore, we compute U only for the 1D defect bands. To obtain the response functions, the variation in occupation numbers is obtained by performing the DFT calculations in two ways: (i) by allowing the Kohn-Sham potential to adjust selfconsistently which optimally screens the perturbation α_i to give χ_0 and (ii) by calculating the Kohn-Sham potential without screening to get χ . The latter is achieved by a single loop, without enforcing self-consistency. The variation of $n_i^{\vec{K}\vec{S}}$ and n_i as a function of α_i at the doped metal site (Tc or Re) is shown in Fig. 6 for MoSe₂/Tc and $MoSe_2/Re$. The onsite Coulomb repulsion U_0 calculated with this procedure is listed for various chain-doped compounds in Table II, together with the Fermi velocity v_F and the bandwidth W. The spin resolved Fermi velocities v_F^{\uparrow} and v_F^{\downarrow} are computed at the Fermi momentum k_F^{\uparrow} and k_F^{\downarrow} , which is roughly halfway along the $\Gamma - X$ line (see Figs. 1 and 7), by taking the derivative of the energy $\hbar v_F^{\uparrow\downarrow} = (\partial E^{\uparrow\downarrow}(k)/\partial k)_{k=k_F^{\uparrow\downarrow}}$. The k_F^{\uparrow} and k_F^{\downarrow} differ as the SOC makes the spin-resolved bands non-degenerate. As seen from Table II, U/W >> 1 for all compounds studied, which would put these materials in the strong correlation limit.

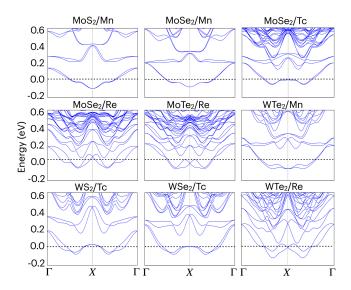

FIG. 7: The non-magnetic band structures of several chain-doped compounds. The SOC is included.

TABLE II: Characteristics of the 1D defect band for various compounds. U, W, and v_F are the onsite Coulomb repulsion, bandwidth, and Fermi velocity, respectively.

C. Tomonaga Luttinger-Liquid Physics

The low-energy behavior of the correlated electrons in 1D is described by the TLL theory, with features generic to many interacting 1D electron systems, such as the spin-charge separation and the anomalous scaling of the correlation functions. ^{39,41–4344}. A few years ago, the TLL theory was extended to include SOC. When SOC is introduced, the complete spin-charge separation is destroyed, resulting in mixed bosonic excitations involving these two degrees of freedom. However, the anomalous scaling of the correlation functions remains with modified exponents^{45,46}. The TLL with SOC has been studied experimentally in the context of quasi-1D systems such as the carbon nanotubes, quantum wires, and 2D electron gases confined to a narrow channel by gate electrodes, but much remains to be done both from theoretical and experimental points of view.

We propose the chain-doped TMDs to be an important class of materials to study the TLL physics. As illustrated for a number of cases in Figs. 1 and 7, the defect bands in the chain-doped TMDs are spin split at the Fermi energy to a varying degree due to the SOC. For example, the splitting is near zero for MoTe₂/Tc, while it is quite large for WS₂/Tc. The 1D defect bands in the chain-doped TMDs are nominally half-filled, for which the TLL behavior would be absent⁴⁷. However, departure from the half-filling scenario can occur naturally due to the presence of impurities and/or applied gate voltage, which may furthermore be used to alter the spin-splitting at the Fermi energy. Thus the chain-doped TMDs may serve as a rich laboratory for the study of TLL behavior.

The TLL behavior is characterized by several parameters such as the spin/charge velocities for the collective spin and charge excitations and the anomalous dimension α which is a function of onsite Coulomb repulsion and v_F . Explicit expressions for these quantities exist in the weak-coupling limit, but for the strong-coupling limit, numerical results have been obtained for certain models. For the 1D Hubbard model, the TLL parameters have been computed for different values of U/t and band filling n^{48} . For $U/t \to \infty$, which is the case for the chain-doped compounds, one gets $\alpha = 1/8$. When SOC is present, its strength is parameterized by the Fermi velocity difference $(v_{F\uparrow} - v_{F\downarrow})/(v_{F\uparrow} + v_{F\downarrow})$, and the TLL exponent α is modified⁴⁵. The TLL behavior of the 1D Hubbard model with next-nearest-neighbor hopping but without the SOC has been studied using the densitymatrix renormalization group⁴⁹. For the chain-doped TMDs, the second neighbor interaction is substantial and furthermore the strength of the SOC can also be tailored by changing the metal dopant M', so that these materials can serve as a rich laboratory for studying the TLL behavior.

D. Half-Filled Defect Bands: Mott-Hubbard Insulating State and Unusual Band Widening

For the half-filled case, the 1D defect bands would not show the TLL behavior due to the presence of a charge gap for all values of U within the Hubbard model. In the strong-coupling limit $(U/W \to \infty)$, which is the case here, the mean-field treatment adequately describes the gross physics of the system, and this is accomplished by the DFT + U formalism in the density-functional theory.

We find two surprising features for the 1D defect bands: (i) Instead of an AFM ground state expected from the Hubbard model physics at half filling, we find that the ground state is usually ferromagnetic. (ii) With U, the bandwidth of the Hubbard bands increases instead of decreasing which is normally the case for strongly-correlated systems where the motion of the electron is inhibited due to correlated motion, resulting in a larger effective mass. The increase of the bandwidth of the Hubbard bands with U can be explained in terms of a

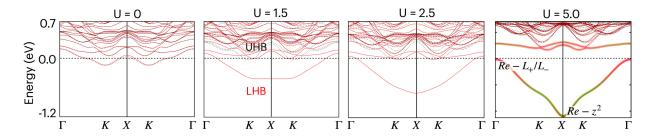

FIG. 8: The DFT+U spin polarized band structures of MoSe₂/Re. The transition to Mott insulating phase occurs through the formation of lower and upper Hubbard bands (LHB and UHB)). The LHB widens with U, which is unusual and is interpreted to be due to its multiple-orbital origin.

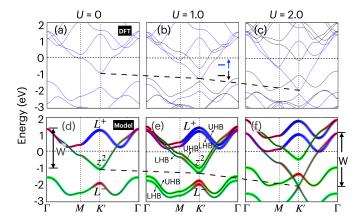

FIG. 9: The spin-polarized band structure of 2H-ReSe₂ monolayer as obtained from DFT+U calculations (upper row) and three-orbital based Hubbard model (lower row) showing excellent agreement. The evolution of the bottom of the LHB with U has been indicated by the dashed line. There is an excellent agreement between the model and DFT results. Like the chain-doped system $MoSe_2/Re$ (see Fig. 8), the LHB bandwidth as indicated in (d) and (f), increases with increasing strength of the onsite Coulomb repulsion.

multi-band model as discussed below in some detail.

A plausible explanation for the ferromagnetism is that we don't have an isolated 1D Hubbard chain, rather that the electrons are coupled via the electrons of the host materials. In fact, our charge density contour plot in Fig. 3 infers that in the case of MoTe₂/Tc there is a covalent bonding between the 1D states with the nearest-neighbor Te-p states of the host material to favor the ferromagnetic ordering.

The band-widening feature can be explained using a multi-band Hubbard model. In essence, different parts of the BZ consists of different type of orbitals (for instance, z^2 at K and L^- at Γ for the defect bands as seen from Fig. 1), which can shift around in energy depending on the magnitude of U.

To demonstrate the case of Mott insulating phase and band widening, we examine the case of $MoSe_2/Re$ as an example. The non-magnetic band structure shown in Fig. 7 indicates that the half-filled 1D bands with

the bandwidth of about 0.24 eV (see Table II). From spin-polarized DFT + U calculations, we find (see Fig. 8) that with increasing U, the degenerate non-magnetic half-filled bands spin separate to form a more-occupied lower Hubbard and a less-occupied upper Hubbard band. With further increase in U, the two Hubbard bands separate completely to form a gap, leading to a Mott insulating state. We see similar effects for other chain-doped compounds, which are not shown here to avoid redundancy.

This is in contrast to the conventional Mott insulator, where increasing U makes the Hubbard bands narrower, as the electron's motion becomes restricted due to electron correlation, resulting in a larger effective mass. In the present case, there is a rapid increase in the bandwidth with an increase in U. For example, by increasing U from 0 to 5 eV, the bandwidth has gone from 0.4 eV to 1.1 eV, as can be seen in Fig. 8.

To describe this physics, we have adopted a multiorbital Hubbard model with three orbital basis $(z^2, xy,$ and $x^2 - y^2)$, with the Hamiltonian

$$H = \sum_{i\mu} \epsilon_{i\mu} c_{i\mu}^{\dagger} c_{i\mu} + \sum_{ij;\mu\nu} t_{i\mu j\nu} c_{i\mu}^{\dagger} c_{j\nu} + h.c. +$$

$$U \sum_{i\mu} n_{i\mu\uparrow} n_{i\mu\downarrow} + (U' - \frac{J_{\rm H}}{2}) \sum_{i\mu<\nu} n_{i\mu} n_{i\nu}$$

$$- 2J_{\rm H} \sum_{i,\mu<\nu} S_{i\mu}^z \cdot S_{i\nu}^z.$$

$$(4)$$

Here, the first two terms describe the onsite and the kinetic energy of the electrons, while the third and fourth terms are the energy cost of having the electrons in the same or different orbitals at the same lattice site. The last term defines the Hund's rule coupling. The relation U'=U- $2J_{\rm H}$ has been used here with J_H/U ratio estimated to be 0.03 based on the agreement between DFT and model band structures. The $n_{{\rm i}\mu}=n_{{\rm i}\mu\uparrow}+n_{{\rm i}\mu\downarrow}$ are the occupation numbers which are obtained from the DFT+U density matrix.

It is too complex to solve the problem for the supercell of MoSe₂/Re. Since the defect bands originate from the doped ReSe₂ chain, and the bulk ReSe₂ shows a similar band-widening behavior as well (see Fig. 9), we study

the phenomenon for bulk ReSe₂ using the multi-orbital Hubbard model, Eq. (4).

The results, obtained from both the DFT + U calculations as well as the multi-orbital Hubbard model, are shown in Fig. 9. From the top panel in the figure, we observe that for U=0, it has three spin degenerate bands in the vicinity of the ϵ_F , like in all 2H-TMD compounds. Out of the three, one is completely occupied, another is completely unoccupied and the third one is a halfoccupied band. With an increase in U, the half-occupied band becomes spin non-degenerate. Also, like the case of MoSe₂/Re, the lower Hubbard sub-band becomes more dispersive. The model results, shown in the lower panel of Fig. 9, match very well with the DFT+U results, and the widening of the lower Hubbard band is seen from both results (indicated by the long-dashed lines). As mentioned already, the lowest conduction band running through E_F has a combination of the orbital characters L^{\pm} (dominant around K') and z^2 (dominated around Γ). The band-widening happens because the inter-orbital interaction term (the fourth term in the Hamiltonian Eq. 4) lowers the onsite energy for z^2 orbital (dominant around K'), while increasing the same for the L^+ orbitals (dominant around Γ). In fact, when this term was switched off, there is a band narrowing, clearly seen for the LHB (see Fig. S12 in SM).

V. SUMMARY

To summarize, by employing density functional theory calculations and theoretical models, we show that the chain-doped transition metal dichalcogenides $(MX_2/M' = M_{n-1}M'_1X_{2n})$, with a M' dopant chain along the zigzag direction, form a sharply localized one-dimensional (1D) band structure. While the 1D states are strongly confined along the lateral direction, they are highly mobile along the chain direction. The localization in the lateral direction is interpreted in terms of the bound states of the bare potential of the dopant chain. The partially-filled 1D bands provide a platform to explore exotic spin-orbit coupled one-dimensional quantum phases and properties. These include the Tomonaga Luttinger liquid (TLL) behavior, ferromagnetic Mott

insulator, Rashba type spin-orbit coupling and valley-dependent optical transition. The half-filled 1D bands are ideal candidates for stabilizing the anti-ferromagnetic Mott insulating phase. However, the interaction between the 1D states via the host X-p states makes it ferromagnetic and insulating. When the 1D bands deviate from half-filling, the substantial second-neighbor interactions between the M' states make it favorable for practical realization of the TLL behavior. The deviation from half-filling can be achieved via impurities and gate biasing.

The widening of the lower Hubbard subband with increasing onsite Coulomb repulsion strength in these chain-doped systems is a non-trivial outcome of this study. This phenomenon, which is anti-intuitive and goes against the conventional assumption of band narrowing with increasing repulsion strength, has hardly been observed in the literature, which makes this class of materials worth exploring for non-trivial quantum transport and phases. We have explained the cause of band widening by developing a multi-orbital Hubbard model. Another important outcome of the present study is that due to the presence of an intrinsic electric field along the lateral direction, the 1D bands are Rashba spin-split and provide a new mechanism to tune the valley-dependent optical transition in MX_2/M' .

Our study opens new avenues to tailor 1D quantum physics in 2D TMDs. With the advent of state-of-the-art techniques such as low-energy ion implantation, dislocation climb mechanism, etc., the chain-doped TMDs can be synthesized in a controlled manner. In addition to the electron doping and emergent properties as discussed in this work, hole doping is also equally likely to introduce interesting features such as orbital and spin Hall effects in such chain-doped compounds. As a whole, we believe that the present study will excite experimenters and theoreticians alike to envisage exotic quantum phenomena and applications.

Supplementary material

I. DFT fitted TB band structures of 1D localized Tc bands in $\mathrm{WTe_2/Tc}.$

To estimate the hopping strengths for the dopant chain, we have designed a single-band tight-binding (TB) model including hopping interactions upto third-neighbor. Furthermore, to obtain spin texture, the electric field is applied perpendicular to the chain along the y-direction. The Hamiltonian is provided in Eq. 2 of the main text. Taking WTe₂/Tc as an example, we have shown the TB band fitting with the DFT bands (see Fig. S10). The estimated hopping strengths are listed in Table I of the main text.

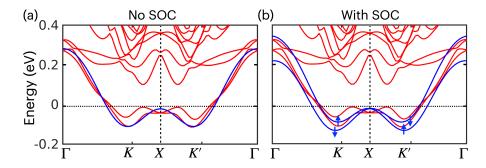

FIG. S10: (a) DFT (red) and TB band structures (blue) of WTe_2/Tc . (b) The spin texture of the TB bands with an electric field of strength 0.2 eV.

II. Orbital resolved band structure of WTe₂/Tc

Figure S11 shows the density functional theory (DFT) obtained orbital resolved band structure of Tc atom in WTe₂/Tc. For the half-filled 1D defect band, while the valleys are dominated by z^2 orbitals, rest band in the Brillouin zone is dominated by L_{\pm} orbitals. As the figure shows, the valleys of unoccupied Tc bands are formed by L_{\pm} orbitals. Therefore, the presence of z^2 (l=0) and L_{\pm} (l= \pm 1) states at the valley points of the partially occupied and unoccupied defect bands opens up the possibilities of valley-dependent optical transitions.

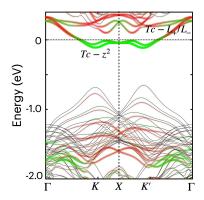

FIG. S11: The orbital and atom resolved band structure of WTe₂/Tc

III. Widening of the Hubbard band

To investigate the underlying interaction causing the band widening, see subsection-IV(D) of the main text, we employ the multi-orbital Hubbard model for pristine ReSe₂. The obtained modeled band structures with varying U strength are shown in Fig. S12. The band structures presented in the first, second, and third columns are obtained by considering the intra-orbital Coulomb repulsion (the third term of H), inter-orbital Coulomb repulsion (the fourth term of H), and third, fourth, and fifth terms in H, respectively. As inferred from the first column, the bandwidth remains almost unchanged with varying intra-orbital interaction, however, with inter-orbital interaction, the bandwidth increases substantially from 2.37 to 3.18 eV. With the inclusion of all terms in H, more or less, the bandwidth remains unchanged as compared to the case when only inter-orbital interaction is considered. This is expected as Hund's coupling strength is weak (J_H/U =0.03), and U hardly affects the bandwidth. This clearly depicts the dominant role of inter-orbital Coulomb repulsion in band widening.

$$H_{\text{int}} = \sum_{i,\mu} \epsilon_{i\mu} c_{i\mu}^{\dagger} c_{i\mu} + \sum_{ij;\mu\nu} t_{i\mu j\nu} c_{i\mu}^{\dagger} c_{j\nu} + h.c. + U \sum_{i,\mu} n_{i,\mu,\uparrow} n_{i,\mu,\downarrow} + (U' - \frac{J_{\text{H}}}{2}) \sum_{i,\mu<\nu} n_{i,\mu} n_{i,\nu} - 2J_{\text{H}} \sum_{i,\mu<\nu} S_{i,\mu}^z \cdot S_{i,\nu}^z.$$

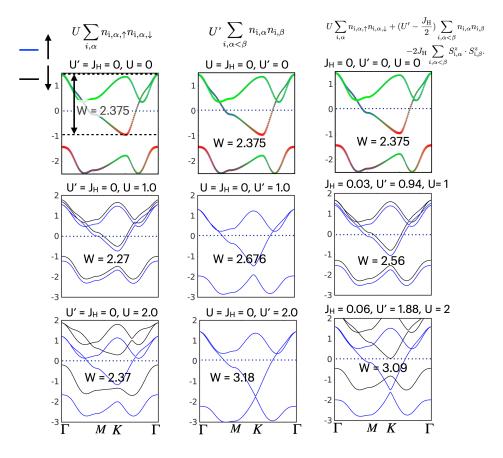

FIG. S12: The modeled band structures of pristine ReSe₂ obtained by considering only the onsite intra-orbital Coulomb repulsion (first column), only inter-orbital Coulomb repulsion (second column), and inter-orbital, intra-orbital, and Hund's coupling (third column), respectively. The relation $U' = U - 2J_H$ between Kanamori parameters has been used here. More or less the bandwidth remains same with varying onsite Coulomb repulsion U, however, it changes significantly when only inter-orbital interaction is switched on. The bandwidths obtained in third column closely resembles with those in second column as the Hund's coupling is weak ($J_H/U=0.03$) and U hardly affects the bandwidth. Hence, inter-orbital Coulomb interaction U' plays the dominant role in band widening (see main text).
