

Orientation selectivity properties for the affine Gaussian derivative and the affine Gabor models for visual receptive fields

Tony Lindeberg

Abstract This paper presents an in-depth theoretical analysis of the orientation selectivity properties of simple cells and complex cells, that can be well modelled by the generalized Gaussian derivative model for visual receptive fields, with the purely spatial component of the receptive fields determined by oriented affine Gaussian derivatives for different orders of spatial differentiation.

A detailed mathematical analysis is presented for the three different cases of either: (i) purely spatial receptive fields, (ii) space-time separable spatio-temporal receptive fields and (iii) velocity-adapted spatio-temporal receptive fields. Closed-form theoretical expressions for the orientation selectivity curves for idealized models of simple and complex cells are derived for all these main cases, and it is shown that the orientation selectivity of the receptive fields becomes more narrow, as a scale parameter ratio κ , defined as the ratio between the scale parameters in the directions perpendicular to vs. parallel with the preferred orientation of the receptive field, increases. It is also shown that the orientation selectivity becomes more narrow with increasing order of spatial differentiation in the underlying affine Gaussian derivative operators over the spatial domain.

Additionally, we also derive closed-form expressions for the resultant and the bandwidth descriptors of the orientation selectivity curves, which have previously been used as compact descriptors of the orientation selectivity properties for biological neurons. These results together show that the properties of the affine Gaussian derivative model for visual receptive fields can be analyzed in closed form, which can be highly useful when to relate the results from biological experiments to computational models of the functional prop-

erties of simple cells and complex cells in the primary visual cortex.

For comparison, we also present a corresponding theoretical orientation selectivity analysis for purely spatial receptive fields according to an affine Gabor model. The results from that analysis are consistent with the results obtained from the affine Gaussian derivative model, in the respect that the orientation selectivity becomes more narrow when making the receptive fields wider in the direction perpendicular to the preferred orientation of the receptive field.

The affine Gabor model does, however, comprise one more degree of freedom in its parameter space, compared to the affine Gaussian derivative model, where a variability within that additional dimension of the parameter space does also strongly influence the orientation selectivity of the receptive fields. In this respect, the relationship between the orientation selectivity properties and the degree of elongation of the receptive fields is more direct for the affine Gaussian derivative model than for the affine Gabor model.

1 Introduction

The receptive fields in the primary visual cortex (V1) capture properties of the visual patterns, which are then passed on to higher layers in the visual hierarchy. Being able to understand the computational function of these receptive fields is, hence, essential for understanding the computational function of the visual system.

The task of understanding the visual system has been addressed both neurophysiologically, by measuring the response properties of neurons to visual stimuli, and by formulating mathematical models, that aim at both explaining the computational function of visual neurons, as well

as enabling computational simulation of neural functions in terms of biologically plausible computer vision algorithms, or aiming at making theoretical predictions, which can then be investigated experimentally.

If we want to build computational models of the vision system, then the receptive fields of the visual neurons can be seen as the primary objects with regard to the theoretical modelling step. In terms of neurophysiological measurements, it does, however, usually imply quite a complex procedure reconstruct the receptive fields of individual neurons. First of all, the problem of deriving a receptive field model for a visual neuron constitutes an inverse problem, which may require both an explicit model for the computational function of the neuron, as well as the need for performing a substantial number of measurements for different visual stimuli, to span a sufficiently large subspace of the variability in the possible types of image input that the neuron may be exposed to (DeAngelis *et al.* 1995, 2004, Ringach 2004, Sharpee 2013, Walker *et al.* 2019).

Mapping the orientation selectivity properties of a visual neuron, can, on the other hand, often be performed by a comparably much more straightforward procedure, by just using a probing stimulus, often a sine wave pattern, and then measuring the variations in the output of the neuron when the orientation of the stimulus is varied in the image domain (Ringach *et al.* 2002, Nauhaus *et al.* 2008, Scholl *et al.* 2013, Mazurek *et al.* 2014). For this reason, there is a substantially larger amount of available neurophysiological measurements in terms of orientation selectivity, than in terms of actually reconstructed receptive fields of visual neurons.

The purpose of this article is to present an in-depth theoretical analysis, that aims at bridging the gap between these two conceptually different ways of characterizing the properties of visual neurons, by deriving closed-form expressions for links between inherent properties of the receptive fields for simple and complex cells in the primary visual cortex and their orientation selectivity properties. In particular, we are interested in characterizing how the degree of elongation, or the eccentricity, for the receptive fields of simple cells is related to the orientation selectivity properties, for the commonly used models of simple cells in terms of either (i) an extension of the regular Gaussian derivative model (Koenderink and van Doorn 1987, 1992; Young 1987) into the affine Gaussian derivative model for visual receptive fields (Lindeberg 2013, 2021), or (ii) the affine Gabor model for visual receptive fields (Marcelja 1980; Jones and Palmer 1987a, 1987b; Ringach 2002).

The motivation for studying these two models for visual receptive fields are that: (i) the generalized Gaussian derivative model can be regarded as the theoretically most principled model, by being derived by necessity in an axiomatic way from principled symmetry requirements, while

(ii) the Gabor model can be regarded as the most commonly used model in the field. In addition to such idealized linear models for simple cells, we will also, assuming that complex cells can be computationally modelled as combining the output from multiple simple cells in a non-linear manner, derive corresponding relationships between properties of the receptive fields for the underlying simple cells and the orientation selectivity properties for idealized models of complex cells.

Specifically, we will focus on quantifying how the degree of orientation selectivity of a receptive field depends on how anisotropic or elongated that the underlying affine Gaussian derivatives are. We will derive explicit expressions for how the degree of orientation selectivity increases with the ratio between the scale parameters in the orientations perpendicular to *vs.* parallel with the preferred orientation of the receptive fields. In this way, we also demonstrate how closed-form theoretical analysis is possible for the generalized Gaussian derivative model for visual receptive fields, which arises from the normative theory of visual receptive fields in (Lindeberg 2021). Affine Gaussian smoothing has also been earlier used for computing more accurate cues to local surface orientation, than is possible if basing the spatial smoothing operations on rotationally symmetric Gaussian kernels only (Lindeberg and Gårding 1997).

We propose that these theoretical connections, between the orientation selectivity and the degree of elongation of the receptive fields, can be useful, when to relate the results from neurophysiological recordings of the orientation selectivity properties of visual neurons to other modelling-based functional characteristics of biological receptive fields. Specifically, in a companion paper (Lindeberg 2024a), theoretical results derived in this paper are, in combination with properties of biological measurements of the orientation selectivity of receptive fields in the primary visual cortex by Nauhaus *et al.* (2008) and Goris *et al.* (2015), used to provide potential indirect support for a previously formulated hypothesis, that the receptive field shapes may span a variability over the eccentricity, or the degree of elongation, of the receptive fields, to support affine covariance over the population of biological receptive fields, to in turn enable the computation of more accurate cues to 3-D scene geometry, when observing the same local surface patch from different slant angles.

More generally, we propose that the theoretical results to be presented, regarding observable properties of the affine Gaussian derivative model for visual receptive fields, as well as for the affine Gabor model also studied for comparison, are important for understanding the properties of these models for visual receptive fields in the primary visual cortex, as well as for relating biological measurements of orientation selectivity, which have been extensively performed in the area of biological vision, to mathematical models of functional properties of the visual neurons.

Compared to the results of purely numerical simulations of properties of networks of visual neurons, the closed-form nature of the results derived in this paper for the affine Gaussian derivative model specifically makes it possible to use these results as first-class results, which can be used as primitives for inferring further properties of receptive fields based on closed-form mathematical analysis, see (Lindeberg 2024a) for other closed-form mathematical characterizations of properties of idealized models for visual receptive fields, based on results derived in this paper.

By performing such idealized theoretical analysis of functional properties and characteristics of visual neurons, we argue that it should be possible to reveal both inherent possibilities and limitations with regard to the computational functions of these functional primitives in the visual pathway, see also Geisler (2011) and Burge (2020) for overviews of the structurally related notion of idealized observers for visual perception. The main difference in relation to our approach, pursued according to our normative conceptual framework for visual receptive fields, is that we instead base the foundations of our analysis on symmetry properties of the environment, in a structurally similar way as symmetry properties can constitute the foundations for formulating fundamental theories in theoretical physics.

Additionally, when using a computational modelling approach to understand the function of the vision system, it is essential to also understand the theoretical properties of the model. The analysis presented in this paper shows that it is possible to fully understand the orientation selectivity properties for the affine Gaussian derivative model for simple cells in terms of the degree of elongation of the receptive fields, combined with the order of spatial differentiation. As will be shown in the paper, there is, however, not such a direct relationship between the orientation selectivity properties and the degree of elongation for the affine Gabor model as for the affine Gaussian derivative model, which is important to consider when modelling the functional properties of visual receptive fields in terms of idealized models.

Furthermore, with regard to theory developments, the results derived in this paper extend the axiomatically determined computational and normative theory for visual receptive fields in terms of the generalized Gaussian derivative model (Lindeberg 2013, 2021) from provable covariance properties under natural image transformations (Lindeberg 2023b, 2024b) to explicit formulations of orientation selectivity properties in closed form, for the idealized receptive fields according to this theoretically principled model for visual receptive fields.

1.1 Structure of this article

This paper is organized as follows: After an overview of related work in Section 2, Section 3 provides the theoretic

cal background to this work, by describing the generalized Gaussian derivative model for visual receptive fields, both in the cases of a purely spatial domain, where the receptive fields are pure affine Gaussian derivatives, and for a joint spatio-temporal domain, where the affine Gaussian derivatives are complemented by temporal derivatives of either a non-causal Gaussian kernel over the temporal domain, or a genuine time-causal kernel, referred to as the time-causal limit kernel, as well as complemented with possible velocity adaptation, to enable Galilean covariance.

Beyond these models of simple cells, we do both review a previously formulated purely spatial model for complex cells, based on a Euclidean combination of scale-normalized affine Gaussian derivatives of orders 1 and 2, as well as propose two new spatio-temporal models for complex cells, based on image measurements in terms of affine Gaussian derivatives over the spatial domain, complemented by explicit temporal processing operations. Two special cases are treated, in terms of either space-time separable spatio-temporal receptive fields, or velocity-adapted spatio-temporal receptive fields, with the latter tuned to particular motion directions and motion velocities in joint space-time.

Section 4 then performs a detailed mathematical analysis of the orientation selectivity of these models, over the three main cases of either (i) a purely spatial domain, (ii) a space-time separable spatio-temporal domain, or (iii) a velocity-adapted spatio-temporal domain. For each one of these main cases, we analyze the properties of simple cells of orders 1 and 2, corresponding to first- or second-order Gaussian derivatives, as well as the orientation selectivity properties for idealized models of complex cells, defined in terms of quasi-quadrature measures, constituting Euclidean combinations of the underlying idealized models of simple cells.

Concerning simple cells, it is shown that both the pure spatial receptive fields and the joint spatio-temporal receptive fields have similar orientation selectivity properties, which only depend on the order of spatial differentiation and the degree of anisotropy of the receptive field. For complex cells, a different dependency is, however, derived for the model based on space-time separable receptive fields, as opposed to the models for either a purely spatial domain or a joint spatio-temporal domain based on velocity-adapted spatio-temporal receptive fields.

To widen the scope of the treatment in the paper, beyond a theoretical analysis of properties of idealized visual receptive field models according to the generalized Gaussian derivative model for visual receptive fields, we will also in Section 5 perform a corresponding orientation selectivity analysis for an affine Gabor model of receptive fields, as well as give a derivation of affine covariant properties of a further generalized affine Gabor model, with the details of that analysis in Appendix A.2.

As a service for the reader, who may want to use the results from the theoretical analysis in this paper for comparing biological measurements of the orientation selectivity of visual neurons to characteristic properties of idealized models of visual receptive fields, we do then in Section 6 compute two explicit compact measures of the degree of orientation selectivity for the idealized models of receptive fields in terms of affine Gaussian derivatives, in terms of the resultant of the circular distribution of the orientation selectivity curves as well as the orientation bandwidth, as functions of the scale parameter ratio κ of the receptive fields.

Finally, Section 7 gives a summary and discussion about some of the main results, including suggestions concerning possible extensions of the presented work.

2 Related work

Hubel and Wiesel (1959, 1962, 1968, 2005) pioneered the study of visual neurons in the primary visual cortex, and introduced the taxonomy of simple and complex cells. Simple cells were simple characterized by their properties of: (i) having distinct excitatory and inhibitory regions, (ii) obeying roughly linear summation properties, (iii) the excitatory and inhibitory regions balance each other in diffuse lighting. Visual neurons that did not obey these properties were referred to as complex cells. The response of a complex cell to a visual stimulus was also reported to be much less sensitive to the position of the stimulus in the visual field than for a simple cell.

More detailed characterizations of the receptive fields of simple cells have then been performed by DeAngelis *et al.* (1995, 2004), Ringach (2002, 2004), Conway and Livingstone (2006), Johnson *et al.* (2008) and De and Horwitz (2021), where specifically the use of multiple white noise stimuli permit a reconstruction of the full receptive field of a visual neuron, based on theoretical results in system identification theory, assuming linearity of the neuron. More specialized methodologies to characterize the response properties of possibly non-linear visual neurons, based on using deep predictive models to generate tailored stimuli for probing and modelling the neurons, have also been more recently developed by Walker *et al.* (2019).

Furthermore, more detailed characterizations of the orientation selectivity of visual neurons have been performed by Watkins and Berkley (1974), Rose and Blakemore (1974), Schiller *et al.* (1976), Albright (1984), Ringach *et al.* (2002), Nauhaus *et al.* (2008), Scholl *et al.* (2013), Sadeh and Rotter (2014), Goris *et al.* (2015), Li *et al.* (2015) and Almasi *et al.* (2020).

While several works have been concerned with biological mechanisms for achieving orientation selectivity in the visual neurons (Somers *et al.* 1995, Sompolinsky and Shapley 1997, Carandini and Ringach 1997, Lampl *et al.* 2001,

Ferster and Miller 2000, Shapley *et al.* 2003, Seriès *et al.* 2004, Hansel and van Vreeswijk 2012, Moldakarimov *et al.* 2014, Gonzalo Cogno and Mato 2015, Priebe 2016, Pattadkal *et al.* 2018, Nguyen and Freeman 2019, Merkt *et al.* 2019, Wei *et al.* 2022, Wang *et al.* 2024) as well as characterizing properties of cortical maps (Bonhoeffer and Grinvald 1991, Blasdel 1992, Maldonado *et al.* 1997, Koch *et al.* 2016, Kremkow *et al.* 2016, Najafian *et al.* 2022, Jung *et al.* 2022, Fang *et al.* 2022, Vita *et al.* 2024), the focus of this work is, however, not on such specific biological implementation mechanisms, but instead on purely *functional properties of individual neurons*, that will constitute the effective results from such underlying computational mechanisms between different neurons.

A detailed study of how the orientation selective of neurons in the primary visual cortex can be modulated for cats that wear permanently mounted goggles, that alter the directional distribution of the incoming visual stimuli, has been presented by Sasaki *et al.* (2015), showing that long exposure to such stimuli affects the elongation of receptive fields, and how such elongation affects the orientational selectivity.

Mathematical models of simple cells have been formulated, in terms of Gabor filters (Marcelja 1980; Jones and Palmer 1987a, 1987b; Porat and Zeevi 1988) or Gaussian derivatives (Koenderink and van Doorn 1984, 1987, 1992; Young and his co-workers 1987, 2001, 2001, Lindeberg 2013, 2021). Specifically, theoretical models of early visual processes in terms of Gaussian derivatives have been formulated in Lowe (2000), May and Georgeson (2007), Hesse and Georgeson (2005), Georgeson *et al.* (2007), Hansen and Neumann (2008), Wallis and Georgeson (2009), Wang and Spratling (2016), Pei *et al.* (2016), Ghodrati *et al.* (2017), Kristensen and Sandberg (2021), Abballe and Asari (2022), Ruslim *et al.* (2023) and Wendt and Faul (2024).

Beyond the work by Hubel and Wiesel, the properties of complex cells have been further characterized by Movshon *et al.* (1978), Emerson *et al.* (1987), Martinez and Alonso (2001), Touryan *et al.* (2002, 2005), Rust *et al.* (2005), van Kleef *et al.* (2010) Goris *et al.* (2015), Li *et al.* (2015) and Almasi *et al.* (2020), as well as modelled computationally by Adelson and Bergen (1985), Heeger (1992), Serre and Riesenhuber (2004), Einhäuser *et al.* (2002), Kording *et al.* (2004), Merolla and Boahen (2004), Berkes and Wiscott (2005), Carandini (2006), Hansard and Horaud (2011), Franciosini *et al.* (2019), Lian *et al.* (2021), Oleskiw *et al.* (2024) and Yedjour and Yedjour (2024).

The notion of affine Gaussian smoothing, with its associated notion of affine Gaussian derivatives, was derived axiomatically in (Lindeberg 2011) and was proposed as a spatial model of simple cells in (Lindeberg 2013, 2021). This model has also been extended to complex cells in (Lindeberg 2020 Section 5). Parallel extensions of the affine Gaussian

derivative model for simple cells to spatio-temporal receptive fields have been performed in (Lindeberg 2016, 2021).

3 Receptive field models based on affine Gaussian derivatives

For modelling the response properties of simple cells, we will in this paper make use of the affine Gaussian derivative model for linear receptive fields, which has been theoretically derived in a principled axiomatic manner in (Lindeberg 2011), and then been demonstrated in (Lindeberg 2013, 2021) to well model the spatial properties of simple cells in the primary cortex, as established by neurophysiological measurements by DeAngelis *et al.* (1995, 2004) and Johnson *et al.* (2008); see Figures 16–17 in (Lindeberg 2021) for comparisons between biological receptive fields and computational models in terms of affine Gaussian derivatives, as will be used as a basis for the analysis in this paper.

In this section, we shall review main components of this theory, which we shall then build upon in the theoretical analysis in Section 4, concerning the orientation selectivity properties of these receptive field models, based on the affine Gaussian derivative model for simple cells over a purely spatial domain, as well as a corresponding generalized affine Gaussian derivative model for simple cells over a joint spatio-temporal domain. Based on these models of simple cells, we shall also define models for complex cells, both over a purely spatial image domain and over a joint spatio-temporal domain, where the joint spatio-temporal models are new. Since the analysis to be performed in Section 4 will make use of very specific properties of this receptive field model, while this model may be less known than the Gabor model for visual receptive fields, this review will be rather detailed, so as to be sufficiently self-contained, to support the theoretical analysis that will be later presented in Section 4.

3.1 Purely spatial model of simple cells

If we initially disregard the temporal dependencies of the simple cells, we can formulate a purely spatial model of linear receptive fields with orientation preference according to (Lindeberg 2021 Equation (23)), see (Lindeberg 2021 Figure 7) for illustrations of such receptive fields;

$$\begin{aligned} T_{\text{simple}}(x_1, x_2; \sigma_\varphi, \varphi, \Sigma_\varphi, m) \\ = T_{\varphi^m, \text{norm}}(x_1, x_2; \sigma_\varphi, \Sigma_\varphi) = \sigma_\varphi^m \partial_\varphi^m (g(x_1, x_2; \Sigma_\varphi)), \end{aligned} \quad (1)$$

where

- φ represents the preferred orientation of the receptive field,

- σ_φ represents the amount of spatial smoothing¹ in the direction φ (in units of the spatial standard deviation²),
- $\partial_\varphi^m = (\cos \varphi \partial_{x_1} + \sin \varphi \partial_{x_2})^m$ is an m :th-order directional derivative operator³ in the direction φ ,
- Σ_φ is a symmetric positive definite covariance matrix, with one of its eigenvectors aligned with the direction of φ , and
- $g(x; \Sigma_\varphi)$ is a 2-D affine Gaussian kernel with its shape determined by the covariance matrix Σ_φ

$$g(x; \Sigma_\varphi) = \frac{1}{2\pi \sqrt{\det \Sigma_\varphi}} e^{-x^T \Sigma_\varphi^{-1} x/2} \quad (2)$$

for $x = (x_1, x_2)^T$, and with one of the eigenvectors of Σ_φ parallel to the orientation φ .

For $m = 1$ and $m = 2$, differentiation of the affine Gaussian kernel and introducing the following parameterization of the spatial covariance matrix

$$\Sigma_\varphi = \begin{pmatrix} C_{11} & C_{12} \\ C_{12} & C_{22} \end{pmatrix} \quad (3)$$

with

$$C_{11} = \sigma_1^2 \cos^2 \varphi + \sigma_2^2 \sin^2 \varphi, \quad (4)$$

$$C_{12} = (\sigma_1^2 - \sigma_2^2) \cos \varphi \sin \varphi, \quad (5)$$

$$C_{22} = \sigma_1^2 \sin^2 \varphi + \sigma_2^2 \cos^2 \varphi, \quad (6)$$

as well as reformulating the arguments with respect to this more explicit parameterization, leads to the following ex-

¹ If we let e_φ denote the unit vector in the direction of φ , according to $e_\varphi = (\cos \varphi, \sin \varphi)^T$, then we can determine σ_φ from the spatial covariance matrix Σ_φ according to $\sigma_\varphi = \sqrt{e_\varphi^T \Sigma_\varphi e_\varphi}$.

² In this paper, we parameterize both the spatial and the temporal scale parameters in units of the standard deviations of the corresponding spatial or temporal smoothing kernels. These parameters are related to the corresponding variance-based parameterizations in the earlier work, that we build upon, according to $\sigma_{\text{space}} = \sqrt{s}$ and $\sigma_{\text{time}} = \sqrt{\tau}$. By this change of notation, some equations in this paper will have somewhat different appearance, compared to the previous work that we cite. This change of notation will, however, lead to easier notation in the mathematical analysis that will follow in Section 4

³ Concerning the notation, we write derivatives either in operator form ∂_{x_1} , which constitutes short notation for $\frac{\partial}{\partial x_1}$, or as subscripts, $L_{x_1} = \partial_{x_1} L$, which is also short notation for $\frac{\partial L}{\partial x_1}$. Directional derivatives of functions are also written as subscripts $L_\varphi = \partial_\varphi L$ and can, of course, also be applied repeatedly $L_{\varphi\varphi} = \partial_\varphi^2 L$. Observe, however, that subscripts are also used with a different meaning in connections constants. The notation σ_φ means the σ -value used when computing directional derivatives, as opposed to σ_t , to be introduced later, which means the σ -value that is used when computing temporal derivatives.

explicit expressions, for an arbitrary preferred orientation φ :

$$\begin{aligned} T_{\text{simple}}(x_1, x_2; \sigma_1, \sigma_2, \varphi, 1) &= \\ &= \sigma_1 (\cos(\varphi) \partial_{x_1} + \sin(\varphi) \partial_{x_2}) g(x_1, x_2; \Sigma_\varphi) \\ &= -\frac{(x_1 \cos(\varphi) + x_2 \sin(\varphi))}{2\pi \sigma_1^2 \sigma_2} \times \\ &e^{-\frac{(\sigma_1^2 + \sigma_2^2)(x_1^2 + x_2^2) - (\sigma_1 - \sigma_2)(\sigma_1 + \sigma_2)(2x_1 x_2 \sin(2\varphi) + \cos(2\varphi)(x_1 - x_2)(x_1 + x_2))}{4\sigma_1^2 \sigma_2^2}} \end{aligned} \quad (7)$$

$$\begin{aligned} T_{\text{simple}}(x_1, x_2; \sigma_1, \sigma_2, \varphi, 2) &= \\ &= \sigma_1^2 (\cos^2(\varphi) \partial_{x_1 x_1} + 2 \cos(\varphi) \sin(\varphi) \partial_{x_1 x_2} + \sin^2(\varphi) \partial_{x_2 x_2}) \\ &\quad g(x_1, x_2; \Sigma_\varphi) \\ &= \frac{(x_1^2 + x_2^2 - 2\sigma_1^2 + \cos(2\varphi)(x_1^2 - x_2^2) + 2x_1 x_2 \sin(2\varphi))}{4\pi \sigma_1^3 \sigma_2} \times \\ &e^{-\frac{(\sigma_1^2 + \sigma_2^2)(x_1^2 + x_2^2) - (\sigma_1 - \sigma_2)(\sigma_1 + \sigma_2)(2x_1 x_2 \sin(2\varphi) + \cos(2\varphi)(x_1 - x_2)(x_1 + x_2))}{4\sigma_1^2 \sigma_2^2}} \end{aligned} \quad (8)$$

In the above expressions for the spatial receptive field model T_{simple} , the multiplication of the m -th-order directional derivative operator in the direction φ by the spatial scale parameter σ_φ in the same direction, implements scale-normalized derivatives (Lindeberg 1998) according to

$$\partial_{x_1^{\alpha_1} x_2^{\alpha_2}, \text{norm}} = \sigma^{\gamma(\alpha_1 + \alpha_2)} \partial_{x_1^{\alpha_1} x_2^{\alpha_2}}, \quad (9)$$

where we here, for simplicity, choose the scale normalization power $\gamma = 1$ to simplify the following calculations.

This notion of spatial scale-normalized derivatives implies that we measure the amplitude of local spatial variations with respect to a given scale level, and makes it possible to define scale-invariant feature responses, that assume the same magnitude for input image structures of different spatial extent, provided that the spatial scale levels are adapted to the characteristic length of spatial variations in the image data. Specifically, this spatial scale normalization of the spatial receptive field response implies scale selective properties in the sense that the receptive field will produce its maximum response over spatial scales at a spatial scale proportional to a characteristic length in the image data.

Note that this model for the spatial dependency of simple cells, in terms of affine Gaussian derivatives, goes beyond the previous biological modelling results by Young (1987), in turn with very close relations to theoretical modelling results by Koenderink and van Doorn (1987, 1992), in that the spatial smoothing part of the receptive field is here spatially anisotropic, and thereby allows for higher orientation selectivity compared to defining (regular) Gaussian derivatives from partial derivatives or directional derivatives of rotationally symmetric Gaussian kernels, as used by Young and Koenderink and van Doorn. Direct comparisons with biological receptive fields, see Figures 16–17 in (Lindeberg

2021), also show that biological simple cells are more anisotropic than can be well modelled by directional derivatives of rotationally symmetric Gaussian kernels.

3.2 Purely spatial model of complex cells

In (Lindeberg 2020 Section 5) it was proposed that some of the qualitative properties of complex cells, of being both (i) polarity-independent, (ii) approximately phase-independent and (iii) not obeying a superposition principle, as opposed to polarity-dependent as well as strongly phase-dependent, as simple cells are, can modelled by combining first- and second-order directional affine Gaussian derivative responses of the form⁴

$$L = \sqrt{\frac{L_{\varphi, \text{norm}}^2 + C_\varphi L_{\varphi\varphi, \text{norm}}^2}{\sigma_\varphi^2 \Gamma}}, \quad (10)$$

where

- $L_{\varphi, \text{norm}}$ and $L_{\varphi\varphi, \text{norm}}$ represent the results of applying scale-normalized directional affine Gaussian derivative operators of orders 1 and 2, respectively, according to (1), to the input image f :

$$\begin{aligned} L_{\varphi, \text{norm}}(x_1, x_2; \sigma_\varphi, \Sigma_\varphi) &= \\ &= T_{\varphi, \text{norm}}(x_1, x_2; \sigma_\varphi, \Sigma_\varphi) * f(x_1, x_2), \end{aligned} \quad (11)$$

$$\begin{aligned} L_{\varphi\varphi, \text{norm}}(x_1, x_2; \sigma_\varphi, \Sigma_\varphi) &= \\ &= T_{\varphi\varphi, \text{norm}}(x_1, x_2; \sigma_\varphi, \Sigma_\varphi) * f(x_1, x_2), \end{aligned} \quad (12)$$

- $C_\varphi > 0$ is a weighting factor between first and second-order information, and
- $\Gamma \geq 0$ is a complementary scale normalization parameter, that we, however, henceforth will set to zero, to simplify the following treatment.

This model can be seen as an affine Gaussian derivative analogue of the energy model of complex cells proposed by Adelson and Bergen (1985) and Heeger (1992), specifically the fact that receptive fields similar to first- vs. second-order derivatives are reported to occur in pairs (De Valois *et al.* 2000), resembling properties of approximate quadrature pairs, as related by a Hilbert transform (Bracewell 1999, pp. 267–272). The model is also closely related to the proposal by Koenderink and van Doorn (1990) to sum up the squares of first- and second-order derivative response, in a corresponding way as cosine wave and sine wave responses

⁴ In the expressions below, the symbol L denotes the result of pure spatial smoothing of the input image $f(x_1, x_2)$ with an affine Gaussian kernel $g(x_1, x_2; \Sigma)$, i.e., $L(x_1, x_2; \Sigma) = g(x_1, x_2; \Sigma) * f(x_1, x_2)$. In the area of scale-space theory, this representation is referred to as the (affine) spatial scale-space representation of f .

are combined in a Euclidean manner, to get a more phase-independent response.

For a perfect quadrature pair of filters, the sum of the squares of the filter responses will be spatially constant for any sine wave of any frequency and phase. The quasi-quadrature entity will instead have the property that the response will be spatially constant, or alternatively have only relatively moderate ripples, at or near the spatial scale level at which the quasi-quadrature measure assumes its maximum value over spatial scales, provided that the value of the weighting parameter C_φ is properly chosen (see Lindeberg (1998) Figure 21 and Lindeberg (2018) Equation (26)).

In this way, the quasi-quadrature measure combines the responses of the first- and second-order affine Gaussian derivative operators in a complementary manner, where the first-order derivatives correspond to odd filters (antisymmetric under reflection) and the second-order derivatives to even filters (symmetric under reflection).

3.3 Joint spatio-temporal models of simple cells

For modelling the joint spatio-temporal behaviour of linear receptive fields with orientation preference, in (Lindeberg 2021 Section 3.2) the following model is derived from theoretical arguments, see (Lindeberg 2021 Figures 10-11 for illustrations)

$$\begin{aligned} T_{\text{simple}}(x_1, x_2, t; \sigma_\varphi, \sigma_t, \varphi, v, \Sigma_\varphi, m, n) \\ &= T_{\varphi^m, \bar{t}^n, \text{norm}}(x_1, x_2, t; \sigma_\varphi, \sigma_t, v, \Sigma_\varphi) \\ &= \sigma_\varphi^m \sigma_t^n \partial_\varphi^m \partial_t^n (g(x_1 - v_1 t, x_2 - v_2 t; \Sigma_\varphi) h(t; \sigma_t)), \end{aligned} \quad (13)$$

where (for symbols not previously defined in connection with Equation (1))

- σ_t represents the amount of temporal smoothing (in units of the temporal standard deviation),
- $v = (v_1, v_2)^T$ represents a local motion vector, in the direction φ of the spatial orientation of the receptive field,
- $\partial_t^n = (\partial_t + v_1 \partial_{x_1} + v_2 \partial_{x_2})^n$ represents an n :th-order velocity-adapted temporal derivative operator,
- $h(t; \sigma_t)$ represents a temporal smoothing kernel with temporal standard deviation σ_t .

In the case of non-causal time (where the future can be accessed), the temporal kernel can be determined to be a 1-D Gaussian kernel

$$h(t; \sigma_t) = \frac{1}{\sqrt{2\pi}\sigma_t} e^{-t^2/2\sigma_t^2}, \quad (14)$$

whereas in the case of time-causal time (where the future cannot be accessed), the temporal kernel can instead be chosen as the time-causal limit kernel (Lindeberg 2016 Section 5, 2023a Section 3)

$$h(t; \sigma_t) = \psi(t; \sigma_t, c), \quad (15)$$

defined by having a Fourier transform of the form

$$\hat{\Psi}(\omega; \sigma_t, c) = \prod_{k=1}^{\infty} \frac{1}{1 + i c^{-k} \sqrt{c^2 - 1} \sigma_t \omega}, \quad (16)$$

and corresponding to an infinite set of first-order integrators coupled in cascade with specifically chosen time constants to enable temporal scale covariance, where the distribution parameter $c > 1$ describes the ratio between adjacent discrete temporal scale levels in this temporal scale-space model.

In analogy with the spatial scale normalization in the previous purely spatial model, multiplication of the n :th-order velocity-adapted temporal derivative operator ∂_t^n by the temporal standard deviation σ_t raised to the power of n implements scale-normalized velocity-adapted temporal derivatives according to

$$\partial_{t, \text{norm}}^n = \sigma_t^{\gamma n} \partial_t^n, \quad (17)$$

as an extension of Equation (9) from the spatial to the temporal domain, see (Lindeberg 2017). Also here, for simplicity, we restrict ourselves to the specific choice of the scale normalization parameter $\gamma = 1$. By this temporal scale normalization, the temporal component of the spatio-temporal receptive field will have scale selective properties, implying that it will produce its maximum response over temporal scales at a temporal scale proportional to a characteristic temporal duration of the temporal structures in the video data.

In Figure 18 in (Lindeberg 2021), it is demonstrated that this model well captures the qualitative properties of simple cells in the primary visual cortex, as established by neurophysiological cell recordings by DeAngelis *et al.* (1995, 2004), regarding both space-time separable receptive fields and velocity-adapted receptive fields, tuned to particular motion directions in joint space-time.

Note that these spatio-temporal models of simple cells go beyond the previous biological modelling results by Young and his co-workers (2001, 2001) in that: (i) the purely spatial smoothing component of the receptive field model is based on anisotropic Gaussian kernels as opposed to rotationally symmetric Gaussian kernels, (ii) this model also incorporates a truly time-causal model, that takes into explicit account that the future cannot be accessed in a real-world situation, and (iii) the parameterization of the spatio-temporal filter shapes is different, and more closely aligned to the inherent geometry of the imaging situation.

3.4 Joint spatio-temporal models of complex cells

3.4.1 Model based on space-time separable receptive fields

For modelling qualitative properties of complex cells over the joint spatio-temporal domain, we can extend the spatial

quasi-quadrature measure in (10) to the following spatio-temporal quasi-quadrature measure that operates on a combination of spatial directional derivatives and temporal derivatives according to

$$(\mathcal{Q}_{\varphi,\text{sep},\text{norm}}L)^2 = ((L_{\varphi,t,\text{norm}}^2 + C_t L_{\varphi,tt,\text{norm}}^2) + C_{\varphi} (L_{\varphi\varphi,t,\text{norm}}^2 + C_t L_{\varphi\varphi,tt,\text{norm}}^2)) / (\sigma_{\varphi}^{2\Gamma_{\varphi}} \sigma_t^{2\Gamma_t}), \quad (18)$$

where the individual components in this expression are defined from space-time separable receptive fields according to

$$L_{\varphi,t,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) = T_{\varphi,t,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (19)$$

$$L_{\varphi,tt,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) = T_{\varphi,tt,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (20)$$

$$L_{\varphi\varphi,t,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) = T_{\varphi\varphi,t,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (21)$$

$$L_{\varphi\varphi,tt,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) = T_{\varphi\varphi,tt,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (22)$$

with the underlying space-time separable spatio-temporal receptive fields $T_{\varphi^m,t^n,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, 0, \Sigma_{\varphi})$ according to (13) for $v = 0$.

In the expression (18), the quasi-quadrature measure operates on both pairs of first- and second-order directional derivatives as well as pairs of first- and second-order velocity-adapted derivatives simultaneously, aimed at balancing the responses of odd vs. even filter responses over both space or time in parallel.

This (new) spatio-temporal quasi-quadrature measure constitutes an extension of the spatio-temporal quasi-quadrature measure in (Lindeberg 2018 Section 4.2), by being additionally adapted to be selective to particular image orientations over the spatial domain, as opposed to being rotationally isotropic, as well as being based on affine Gaussian derivative operators, as opposed to partial derivatives of rotationally symmetric Gaussian kernels over the spatial domain.

This oriented spatio-temporal quasi-quadrature measure will specifically inherit the qualitative properties of the previously presented purely spatial oriented quasi-quadrature measure (40), in that it will be polarity-independent as well as much less sensitive to the phase in the input video data compared to the above models of simple cells.

3.4.2 Model based on velocity-adapted receptive fields

If we would compute the above spatio-temporal quasi-quadrature measure based on velocity-adapted spatio-temporal receptive fields, then the quasi-quadrature measure would be zero if the velocity vector of the velocity-adapted receptive fields is equal to the velocity-value of the moving sine wave pattern. To define a quasi-quadrature measure that instead will give a maximally strong response if the velocity vector is adapted to the velocity vector of a moving pattern, we do therefore instead define a quasi-quadrature measure for velocity-adapted receptive fields by extending the purely spatial quasi-quadrature measure (10) to operate on spatial receptive fields complemented by a temporal smoothing stage, *i.e.*, velocity-adapted receptive fields for zero order of temporal differentiation ($n = 0$ in (13)):

$$(\mathcal{Q}_{\varphi,\text{vel},\text{norm}}L) = \sqrt{\frac{L_{\varphi,\text{norm}}^2 + C_{\varphi} L_{\varphi\varphi,\text{norm}}^2}{\sigma_{\varphi}^{2\Gamma_{\varphi}}}}, \quad (23)$$

where the individual components in this expression are defined from space-time separable receptive fields according to

$$L_{\varphi,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, v, \Sigma_{\varphi}) = T_{\varphi,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, v, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (24)$$

$$L_{\varphi\varphi,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, v, \Sigma_{\varphi}) = T_{\varphi\varphi,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, v, \Sigma_{\varphi}) * f(x_1, x_2, t), \quad (25)$$

with the underlying space-time separable spatio-temporal receptive fields $T_{\varphi^m,t^n,\text{norm}}(x_1, x_2, t; \sigma_{\varphi}, \sigma_t, v, \Sigma_{\varphi})$ according to (13) for $n = 0$.

Again, the intention behind this (also new) definition is that also this spatio-temporal quasi-quadrature measure should be both polarity-independent with respect to the input and much less sensitive to the phase in the input compared to the velocity-adapted spatio-temporal models of simple cells, while also in conceptual agreement with the energy models of complex cells.

4 Orientation selectivity properties for models of simple cells and complex cells in terms of affine Gaussian derivatives

In this section, we will theoretically analyze the orientation selectivity properties of the above described purely spatial as well as joint spatio-temporal models for receptive fields, when exposed to sine wave patterns with different orientations in relation to the preferred orientation of the receptive field.

4.1 Motivation for separate analyses for the different classes of purely spatial or joint spatio-temporal receptive field models, as well as motivation for studying the orientation selectivity curves for models of both simple cells and complex cells

A main reason for performing separate analyses for both purely spatial and joint spatio-temporal models, is that, *a priori*, it may not be clear how the results from an analysis of the orientation selectivity of a purely spatial model would relate to the results from an orientation selectivity analysis of a joint spatio-temporal model. Furthermore, within the domain of joint spatio-temporal models, it is not *a priori* clear how the results from an orientation selectivity analysis of a space-time separable spatio-temporal model would relate to the results for a velocity-adapted spatio-temporal model. For this reason, we will perform separate individual analyses for these three main classes of either purely spatial or joint spatio-temporal receptive field models.

Additionally, it may furthermore not be *a priori* clear how the results from orientation selectivity analyses of models of simple cells that have different numbers of dominant spatial or spatio-temporal lobes would relate to each other, nor how the results from an orientation selectivity analysis of a model of a complex cell would relate to the analysis of orientation selectivity of models of simple cells. For this reason, we will also perform separate analyses for models of simple and complex cells, for each one of the above three main classes of receptive field models, which leads to a total number of $(2+1) + (2 \times 2+1) + (2+1) = 11$ separate analyses, in the cases of either purely spatial, space-time separable or velocity-adapted receptive spatio-temporal fields, respectively, given that we restrict ourselves to simple cells that can be modelled in terms of either first- or second-order spatial and/or temporal derivatives of affine Gaussian kernels. The reason why there are $2 \times 2 + 1 = 5$ subcases for the space-time separable spatio-temporal model is that we consider all the possible combinations of first- and second-order spatial derivatives with all possible combinations of first- and second-order temporal derivatives.

As will be demonstrated from the results, to be summarized in Table 1, the results from the orientation selectivity of the simple cells will turn out be similar within the class of purely first-order simple cells between the three classes of receptive field models (purely spatial, space-time separable or velocity-adapted spatio-temporal), as well as also similar within the class of purely second-order simple cells between the three classes of receptive field models. Regarding the models of complex cells, the results of the orientation selectivity analysis will be similar between the purely spatial and the velocity-adapted spatio-temporal receptive field models, whereas the results from the space-time separable spatio-temporal model of complex cells will differ from the other

two. The resulting orientation selectivity curves will, however, differ between the sets of (i) first-order simple cells, (ii) second-order simple cells and (iii) complex cells.

The resulting special handling of the different cases that will arise from this analysis, with their different response characteristics, is particularly important, if one wants to fit parameterized models of orientation selectivity curves to actual neurophysiological data. If we want to relate neurophysiological findings measured for neurons, that are exposed to time-varying visual stimuli, or for neurons that have a strong dependency on temporal variations in the visual stimuli, then our motivation for performing a genuine spatio-temporal analysis for each one of the main classes of spatio-temporal models for simple cells, is to reduce the explanatory gap between the models and actual biological neurons.

4.2 Modelling scenario

For simplicity of analysis, and without loss of generality, we will henceforth align the coordinate system with the preferred orientation of the receptive field, in other words choosing the coordinate system such that the orientation angle $\varphi = 0$. Then, we will expose this receptive field to static or moving sine wave patterns, that are oriented with respect to an inclination angle θ relative to the resulting horizontal x_1 -direction, as illustrated in Figure 1. Figure 2 shows maps of the underlying first-order and second-order Gaussian derivatives for different degrees of elongation of the receptive fields.

By necessity, the presentation that will follow will be somewhat technical, since we will analyze the properties of our mathematical models for the receptive fields of simple and complex cells for three different main cases of either (i) purely spatial receptive fields, (ii) space-time separable spatio-temporal receptive fields and (iii) velocity-adapted spatio-temporal receptive fields.

Readers, who may be more interested in the final results only and their biological implications, while not in the details of the mathematical modelling with its associated theoretical analysis, can without major loss of continuity proceed directly to Section 4.6, where a condensed overview is given of the derived orientation selectivity results.

Readers, who additionally is interested in getting just a brief overview of how the theoretical analysis is carried out, and the assumptions regarding the probing of the receptive fields that it rests upon, would be recommended to additionally read at least one of the theoretical modelling cases, where the purely spatial analysis in the following Section 4.3 then constitutes the simplest case.

Fig. 1 Schematic illustration of the modelling situation studied in the theoretical analysis, where the coordinate system is aligned to the preferred orientation $\varphi = 0$ of the receptive field, and the receptive field is then exposed to a sine wave pattern with inclination angle θ . In this figure, the sine wave pattern is schematically illustrated by a set of level lines, overlaid onto a few level curves of a first-order affine Gaussian derivative kernel. (Horizontal axis: spatial coordinate x_1 . Vertical axis: spatial coordinate x_2 .)

4.3 Analysis for purely spatial models of receptive fields

For the forthcoming purely spatial analysis, we will analyze the response properties of our spatial models of simple and complex cells to sine wave patterns with angular frequency ω and orientation θ of the form

$$f(x_1, x_2) = \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 + \beta). \quad (27)$$

4.3.1 First-order simple cell

Consider a simple cell that is modelled as a first-order scale-normalized derivative of an affine Gaussian kernel (according to (1) for $m = 1$), and oriented in the horizontal x_1 -direction (for $\varphi = 0$) with spatial scale parameter σ_1 in the horizontal x_1 -direction and spatial scale parameter σ_2 in the vertical x_2 -direction, and thus a spatial covariance matrix of the form $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$:

$$\begin{aligned} T_{0,\text{norm}}(x_1, x_2; \sigma_1, \sigma_2) &= \\ &= \frac{\sigma_1}{2\pi\sigma_1\sigma_2} \partial_{x_1} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2} \right) \\ &= -\frac{x_1}{2\sigma_1^2\sigma_2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2}. \end{aligned} \quad (28)$$

The corresponding receptive field response is then, after solving the convolution integral⁵ in Mathematica,

$$\begin{aligned} L_{0,\text{norm}}(x_1, x_2; \sigma_1, \sigma_2) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} T_{0,\text{norm}}(\xi_1, \xi_2; \sigma_1, \sigma_2) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2) d\xi_1 d\xi_2 \\ &= \omega \sigma_1 \cos(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta)} \\ &\quad \times \cos(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 + \beta), \end{aligned} \quad (29)$$

i.e., a cosine wave with amplitude

$$A_\varphi(\theta, \omega; \sigma_1, \sigma_2) = \omega \sigma_1 |\cos \theta| e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta)}. \quad (30)$$

If we assume that the receptive field is fixed, then the amplitude of the response will depend strongly on the angular frequency ω of the sine wave. The value first increases because of the factor ω and then decreases because of the exponential decrease with ω^2 .

If we assume that a biological experiment regarding orientation selectivity is carried out in such a way that the angular frequency is varied for each inclination angle θ , and then that the result is for each value of θ reported for the angular frequency $\hat{\omega}$ that leads to the maximum response, then we can determine this value of $\hat{\omega}$ by differentiating $A_\varphi(\theta, \omega; \sigma_1, \sigma_2)$ with respect to ω and setting the derivative to zero, which gives:

$$\hat{\omega}_\varphi = \frac{1}{\sqrt{\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta}}. \quad (31)$$

Inserting this value into $A_\varphi(\theta, \omega; \sigma_1, \sigma_2)$, and introducing a scale parameter ratio κ such that

$$\sigma_2 = \kappa \sigma_1, \quad (32)$$

which implies

$$\hat{\omega}_\varphi = \frac{1}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (33)$$

⁵ Note, however, that, since the input signals in this analysis are throughout sine waves, we could also get the receptive field responses to the sine waves by multiplying the amplitudes of the sine waves by the absolute value of the Fourier transforms of the receptive field models, while simultaneously shifting the phases of the sine waves with the phases of the Fourier transforms of the receptive field models. For convenience, we do, however, throughout this treatment solve the convolution integrals as explicit integrals in Mathematica, since symbolic computations are really helpful in this mathematical analysis, when optimizing the scale selectivity properties of the receptive fields, by differentiating the receptive field responses with respect to the angular frequencies of the sine waves, and also to handle the more complex non-linear models of complex cells, considered later in this paper.

Fig. 2 Affine Gaussian derivative receptive fields of orders 1 and 2 for the image orientation $\varphi = 0$, with the scale parameter ratio $\kappa = \sigma_2/\sigma_1$ increasing from 1 to $4\sqrt{2}$ according to a logarithmic distribution, from left to right, with the larger of these scale parameters σ_2 kept constant. (top row) First-order directional derivatives of affine Gaussian kernels according to (1) for $m = 1$. (bottom row) Second-order directional derivatives of affine Gaussian kernels according to (1) for $m = 2$. (Horizontal axes: image coordinate x_1 . Vertical axes: image coordinate x_2 .)

then gives the following orientation selectivity measure

$$A_{\varphi, \max}(\theta, \kappa) = \frac{|\cos \theta|}{\sqrt{e \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}}. \quad (34)$$

Note, specifically, that this amplitude measure is independent of the spatial scale parameter σ_1 of the receptive field, which, in turn, is a consequence of the scale-invariant nature of differential expressions in terms of scale-normalized derivatives for scale normalization parameter $\gamma = 1$.

The left column in Figure 3 shows the result of plotting the measure $A_{\varphi, \max}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. As can be seen from the graphs, the degree of orientation selectivity increases strongly with the value of the spatial scale ratio parameter κ .

4.3.2 Second-order simple cell

Consider next a simple cell that can be modelled as a second-order scale-normalized derivative of an affine Gaussian kernel (according to (1) for $m = 2$), and oriented in the horizontal x_1 -direction (for $\varphi = 0$) with spatial scale parameter σ_1 in the horizontal x_1 -direction and spatial scale parameter σ_2 in the vertical x_2 -direction, and thus again with a spatial covariance matrix of the form $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$:

$$\begin{aligned} T_{00, \text{norm}}(x_1, x_2; \sigma_1, \sigma_2) &= \\ &= \frac{\sigma_1^2}{2\pi\sigma_1\sigma_2} \partial_{x_1 x_1} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2} \right) \\ &= \frac{(x_1^2 - \sigma_1^2)}{2\pi\sigma_1^3\sigma_2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2}. \end{aligned} \quad (35)$$

The corresponding receptive field response is then, again after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{00, \text{norm}}(x_1, x_2; \sigma_1, \sigma_2) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} T_{00, \text{norm}}(\xi_1, \xi_2; \sigma_1, \sigma_2) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2) d\xi_1 d\xi_2 \\ &= -\omega^2 \sigma_1^2 \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta)} \\ &\quad \times \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 + \beta), \end{aligned} \quad (36)$$

i.e., a sine wave with amplitude

$$A_{\varphi\varphi}(\theta, \omega; \sigma_1, \sigma_2) = \omega^2 \sigma_1^2 \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta)}. \quad (37)$$

Again, also this expression first increases and then increases with the angular frequency ω . Selecting again the value of $\hat{\omega}$ at which the amplitude of the receptive field response assumes its maximum over ω gives

$$\hat{\omega}_{\varphi\varphi} = \frac{\sqrt{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (38)$$

and implies that the maximum amplitude over spatial scales as function of the inclination angle θ and the scale parameter ratio κ can be written

$$A_{\varphi\varphi, \max}(\theta; \kappa) = \frac{2 \cos^2 \theta}{e (\cos^2 \theta + \kappa^2 \sin^2 \theta)}. \quad (39)$$

Again, this amplitude measure is also independent of the spatial scale parameter σ_1 of the receptive field, because of the scale-invariant property of scale-normalized derivatives, when the scale normalization parameter γ is chosen as $\gamma = 1$.

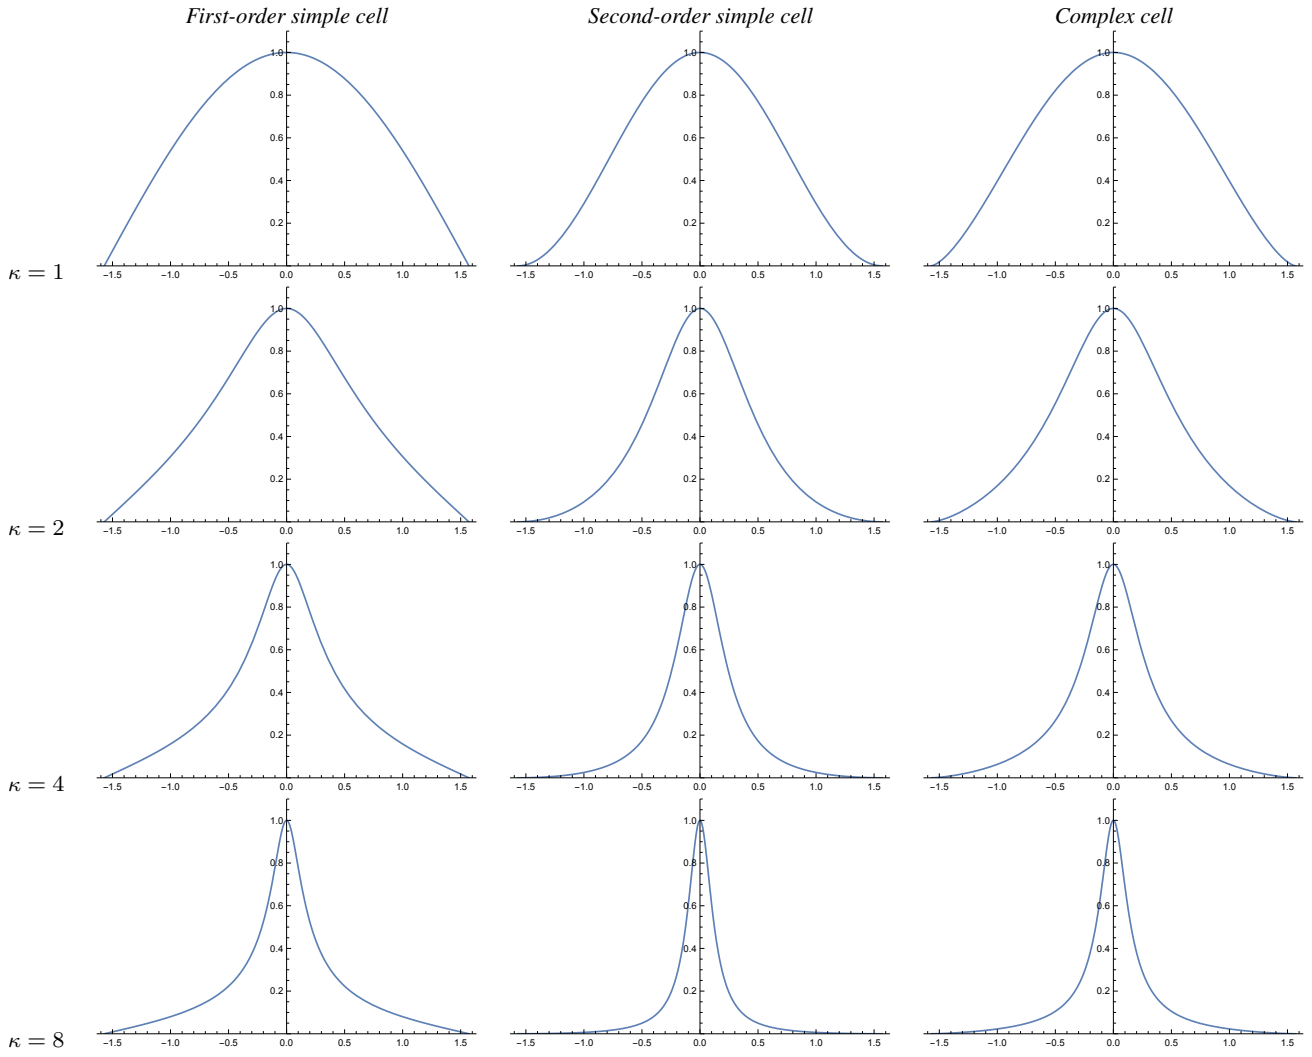

Fig. 3 Graphs of the orientation selectivity for *purely spatial models* of (left column) simple cells in terms of first-order directional derivatives of affine Gaussian kernels, (middle column) simple cells in terms of second-order directional derivatives of affine Gaussian kernels and (right column) complex cells in terms of directional quasi-quadrature measures that combine the first- and second-order simple cell responses in a Euclidean way for $C = 1/\sqrt{2}$, and shown for different values of the ratio κ between the spatial scale parameters in the vertical *vs.* the horizontal directions. Observe how the degree of orientation selectivity varies strongly depending on the eccentricity $\epsilon = 1/\kappa$ of the receptive fields. (top row) Results for $\kappa = 1$. (second row) Results for $\kappa = 2$. (third row) Results for $\kappa = 4$. (bottom row) Results for $\kappa = 8$. (Horizontal axes: orientation $\theta \in [-\pi/2, \pi/2]$. Vertical axes: Amplitude of the receptive field response relative to the maximum response obtained for $\theta = 0$.)

$$\mathcal{Q}_{0,spat,norm}L = \sqrt[4]{2}e^{-\frac{1}{\sqrt{2}}} \frac{|\cos \theta|}{\cos^2 \theta + \kappa^2 \sin^2 \theta} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta \cos^2 \left(\frac{\sqrt[4]{2}}{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}} \left(\frac{x_1 \cos \theta}{\sigma_1} + \frac{x_2 \sin \theta}{\sigma_1} \right) + \beta \right)} \quad (26)$$

Fig. 4 The expression for the oriented spatial quasi-quadrature measure $\mathcal{Q}_{0,spat,norm}L$ in the purely spatial model (40) of a complex cell, when applied to a sine wave pattern of the form (27), for $\omega = \omega_{\mathcal{Q}}$ according to (41).

The middle column in Figure 3 shows the result of plotting the measure $A_{\varphi,\max}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. Again, the degree of orientation selectivity increases strongly with the value of κ , as for the first-order model of a simple cell.

4.3.3 Complex cell

To model the spatial response of a complex cell according to the spatial quasi-quadrature measure (10), we combine the responses of the first- and second-order simple cells for $\Gamma = 0$:

$$\mathcal{Q}_{0,\text{spat},\text{norm}}L = \sqrt{L_{0,\text{norm}}^2 + C_\varphi L_{00,\text{norm}}^2}, \quad (40)$$

with $L_{0,\text{norm}}$ according to (29) and $L_{00,\text{norm}}$ according to (36). Choosing the angular frequency $\hat{\omega}$ as the geometric average of the angular frequencies for which the first- and second-order components of this entity assume their maxima over angular frequencies, respectively,

$$\hat{\omega}_{\mathcal{Q}} = \sqrt{\hat{\omega}_\varphi \hat{\omega}_{\varphi\varphi}} = \frac{\sqrt[4]{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (41)$$

with $\hat{\omega}_\varphi$ according to (33) and $\hat{\omega}_{\varphi\varphi}$ according to (38). Again letting $\sigma_1 = \kappa \sigma_1$, and setting⁶ the relative weight between first- and second-order information to $C_\varphi = 1/\sqrt{2}$ according to (Lindeberg 2018), gives the expression according to Equation (26) in Figure 4.

For inclination angle $\theta = 0$, that measure is spatially constant, in agreement with previous work on closely related isotropic purely spatial isotropic quasi-quadrature measures (Lindeberg 2018). Then, the spatial phase dependency increases with increasing values of the inclination angle θ . To select a single representative of those differing representations, let us choose the geometric average of the extreme values, which then assumes the form

$$A_{\mathcal{Q},\text{spat}}(\theta; \kappa) = \frac{\sqrt[4]{2} |\cos \theta|^3}{\sqrt{e} (\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}}. \quad (42)$$

⁶ Concerning the choice of the weighting factor C_φ between first- and second-order information, it holds that $C_\varphi = 1/\sqrt{2}$ implies that the spatial quasi-quadrature measure will assume a constant value (be phase independent) for a sine wave at the scale level that is the geometric average of the scale levels at which the scale-normalized amplitudes of the first- and the second-order components in the quasi-quadrature measure assume their maxima over scale, for the specific choice of $\gamma = 1$ and $\Gamma = 0$. We will later see manifestations of this property, in that the responses of the different quasi-quadrature measures, that we use for modelling complex cells, will be phase independent for inclination angle $\theta = 0$, for an angular frequency that is the geometric average of the angular frequencies for which the first- and second-order components in the quasi-quadrature measures will assume their maximum amplitude over scales (see Equations (26), (115) and (43)).

The right column in Figure 3 shows the result of plotting the measure $A_{\mathcal{Q},\text{spat}}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. As can be seen from the graphs, the degree of orientation selectivity increases strongly with the value of κ also for this model of a complex cell, and in a qualitatively similar way as for the simple cell models.

4.4 Analysis for space-time separable models of spatio-temporal receptive fields

To simplify the main flow through the paper, the detailed analysis of the orientation selectivity properties for the space-time separable models for the receptive fields of simple and complex cells is given in Appendix A.1, with the main results summarized in Section 4.6. Readers, who are mainly interested in understanding the principles by which the theoretical analysis is carried out, can proceed directly to Section 4.5, without major loss of continuity.

The main conceptual difference with the analysis of the space-time separable receptive spatio-temporal field models in Appendix A.1, compared to the purely spatial models in Section 4.3 or the velocity-adapted spatio-temporal receptive field models in Section 4.5, is that the space-time separable spatio-temporal receptive field models in Appendix A.1 do additionally involve derivatives with respect to time.

4.5 Analysis for velocity-adapted spatio-temporal models of receptive fields

Let us next analyze the response properties of non-separable velocity-adapted spatio-temporal receptive fields to a moving sine wave of the form (87)

$$f(x_1, x_2, t) = \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - u t + \beta). \quad (44)$$

Based on the observation that the response properties of temporal derivatives will be zero, if the velocity v of the spatio-temporal receptive field is adapted to the velocity u of the moving sine wave, we will study the case when the temporal order of differentiation n is zero.

4.5.1 First-order simple cell

Consider a velocity-adapted receptive field corresponding to a *first-order* scale-normalized Gaussian derivative with scale parameter σ_1 and velocity v in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a zero-order Gaussian derivative

Fig. 5 Graphs of the orientation selectivity for *velocity-adapted spatio-temporal models* of (left column) simple cells in terms of first-order directional derivatives of affine Gaussian kernels combined with zero-order temporal Gaussian kernels, (middle column) simple cells in terms of second-order directional derivatives of affine Gaussian kernels combined with zero-order temporal Gaussian kernels and (right column) complex cells in terms of directional quasi-quadrature measures that combine the first- and second-order simple cell responses in a Euclidean way for $C_\varphi = 1/\sqrt{2}$ shown for different values of the ratio κ between the spatial scale parameters in the vertical *vs.* the horizontal directions. Observe how the degree of orientation selectivity varies strongly depending on the eccentricity $\epsilon = 1/\kappa$ of the receptive fields. (top row) Results for $\kappa = 1$. (second row) Results for $\kappa = 2$. (third row) Results for $\kappa = 4$. (bottom row) Results for $\kappa = 8$. (Horizontal axes: orientation $\theta \in [-\pi/2, \pi/2]$. Vertical axes: Amplitude of the receptive field response relative to the maximum response obtained for $\theta = 0$.)

$$\mathcal{Q}_{0,\text{vel,norm}}L = \sqrt[4]{2} e^{-\frac{1}{\sqrt{2}}} \frac{|\cos \theta|}{\cos^2 \theta + \kappa^2 \sin^2 \theta} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta \cos^2 \left(\frac{2^{3/4} (\cos(\theta) (x_1 - vt) + \sin(\theta) x_2)}{\sigma_1 \sqrt{1 + \kappa^2 - (\kappa^2 - 1) \cos 2\theta}} + \beta \right)} \quad (43)$$

Fig. 6 The expression for the oriented spatio-temporal quasi-quadrature measure $\mathcal{Q}_{0,\text{vel,norm}}L$ in the velocity-adapted spatio-temporal model (23) of a complex cell, when applied to a sine wave pattern of the form (44), for $\omega = \omega_Q$ according to (58) and $u = u_Q$ according to (59).

with scale parameter σ_t in the temporal direction, corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 1$ and $n = 0$ in (13):

$$\begin{aligned} T_{0,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \frac{\sigma_1}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \Big|_{x_1 \rightarrow x_1 - vt} \\ &= \frac{(x_1 - vt)}{(2\pi)^{3/2} \sigma_1^2 \sigma_2 \sigma_t} e^{-(x_1 - vt)^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \end{aligned} \quad (45)$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{0,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \int_{\xi_1 = -\infty}^{\infty} \int_{\xi_2 = -\infty}^{\infty} \int_{\zeta = -\infty}^{\infty} T_{0,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\ &= \omega \sigma_1 \cos \theta \\ &\quad \times e^{-\frac{\omega^2}{2} ((\sigma_1^2 + \sigma_t^2 v^2) \cos^2(\theta) + \sigma_2^2 \sin^2 \theta - 2\sigma_t^2 uv \cos \theta + \sigma_t^2 u^2)} \\ &\quad \times \cos(\cos(\theta) x_1 + \sin(\theta) x_2 - \omega u t + \beta), \end{aligned} \quad (46)$$

i.e., a cosine wave with amplitude

$$\begin{aligned} A_\varphi(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \omega \sigma_1 \cos \theta \\ &\quad \times e^{-\frac{\omega^2}{2} (\cos^2 \theta (\sigma_1^2 + \sigma_t^2 v^2) + \sigma_2^2 \sin^2 \theta - 2\sigma_t^2 uv \cos \theta + \sigma_t^2 u^2)}. \end{aligned} \quad (47)$$

Assume that a biological experiment regarding the response properties of the receptive field is performed by varying both the angular frequency ω and the image velocity u to get the maximum value of the response over these parameters. Differentiating the amplitude A_φ with respect to ω and u and setting these derivative to zero then gives

$$\hat{\omega}_\varphi = \frac{1}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (48)$$

$$\hat{u}_\varphi = v \cos \theta. \quad (49)$$

Inserting these values into $A_\varphi(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t)$ then gives the following orientation selectivity measure

$$A_{\varphi,\text{max}}(\theta, \kappa) = \frac{\cos \theta}{\sqrt{e} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}. \quad (50)$$

The left column in Figure 5 shows the result of plotting the measure $A_{\varphi,\text{max}}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. As we can see from the graphs, as for the previous purely spatial models of the receptive fields, as well as for the previous space-time separable model of the receptive fields, the degree of orientation selectivity increases strongly with the value of κ .

4.5.2 Second-order simple cell

Consider next a velocity-adapted receptive field corresponding to a *second-order* scale-normalized Gaussian derivative with scale parameter σ_1 and velocity v in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a zero-order Gaussian derivative with scale parameter σ_t in the temporal direction, corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 2$ and $n = 0$ in (13):

$$\begin{aligned} T_{00,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \frac{\sigma_1^2}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1 x_1} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \Big|_{x_1 \rightarrow x_1 - vt} \\ &= \frac{((x_1 - vt)^2 - \sigma_1^2)}{(2\pi)^{3/2} \sigma_1^3 \sigma_2 \sigma_t} e^{-(x_1 - vt)^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \end{aligned} \quad (51)$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{00,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \int_{\xi_1 = -\infty}^{\infty} \int_{\xi_2 = -\infty}^{\infty} \int_{\zeta = -\infty}^{\infty} T_{00,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\ &= -\omega^2 \sigma_1^2 \cos^2 \theta \\ &\quad \times e^{-\frac{\omega^2}{2} ((\sigma_1^2 + \sigma_t^2 v^2) \cos^2 \theta + \sigma_2^2 \sin^2 \theta - 2\sigma_t^2 uv \cos \theta + \sigma_t^2 u^2)} \\ &\quad \times \cos(\sin(\theta) x_1 + \sin(\theta) x_2 - \omega u t + \beta), \end{aligned} \quad (52)$$

i.e., a sine wave with amplitude

$$\begin{aligned} A_{\varphi\varphi}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \omega^2 \sigma_1^2 \cos^2 \theta \\ &\quad \times e^{-\frac{\omega^2}{2} (\cos^2 \theta (\sigma_1^2 + \sigma_t^2 v^2) + \sigma_2^2 \sin^2 \theta - 2\sigma_t^2 uv \cos \theta + \sigma_t^2 u^2)}. \end{aligned} \quad (53)$$

Assume that a biological experiment regarding the response properties of the receptive field is performed by varying both the angular frequency ω and the image velocity u to get the maximum value of the response over these parameters. Differentiating the amplitude $A_{\varphi\varphi}$ with respect to ω and u and setting these derivative to zero then gives

$$\hat{\omega}_{\varphi\varphi} = \frac{\sqrt{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (54)$$

$$\hat{u}_{\varphi\varphi} = v \cos \theta. \quad (55)$$

Inserting these values into $A_{\varphi\varphi}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t)$ then gives the following orientation selectivity measure

$$A_{\varphi\varphi,\text{max}}(\theta, \kappa) = \frac{2 \cos^2 \theta}{e (\cos^2 \theta + \kappa^2 \sin^2 \theta)}. \quad (56)$$

The middle column in Figure 5 shows the result of plotting the measure $A_{\varphi\varphi,\max}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. Again, the degree of orientation selectivity increases strongly with the value of κ .

4.5.3 Complex cell

To model the spatial response of a complex cell according to the spatio-temporal quasi-quadrature measure (23) based on velocity-adapted spatio-temporal receptive fields, we combine the responses of the first- and second-order simple cells (for $\Gamma = 0$)

$$(\mathcal{Q}_{0,\text{vel},\text{norm}}L) = \sqrt{\frac{L_{0,\text{norm}}^2 + C_\varphi L_{00,\text{norm}}^2}{\sigma_\varphi^{2\Gamma}}}, \quad (57)$$

with $L_{0,\text{norm}}$ according to (46) and $L_{00,\text{norm}}$ according to (52).

Selecting the angular frequency as the geometric average of the angular frequency values at which the above spatio-temporal simple cell models assume their maxima over angular frequencies, as well as using the same value of u ,

$$\hat{\omega}_{\mathcal{Q}} = \sqrt{\hat{\omega}_\varphi \hat{\omega}_{\varphi\varphi}} = \frac{\sqrt{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (58)$$

with $\hat{\omega}_\varphi$ according to (48) and $\hat{\omega}_{\varphi\varphi}$ according to (54), as well as choosing the image velocity \hat{u} as the same value as for which the above spatio-temporal simple cell models assume their maxima over the image velocity ((49) and (55))

$$\hat{u}_{\mathcal{Q}} = v \cos \theta, \quad (59)$$

as well as letting $\sigma_1 = \kappa \sigma_1$, and setting the relative weights between first- and second-order information to $C_\varphi = 1/\sqrt{2}$ and $C_t = 1/\sqrt{2}$ according to (Lindeberg 2018), then gives the expression according to Equation (43) in Figure 6.

For inclination angle $\theta = 0$, that measure is spatially constant, in agreement with our previous purely spatial analysis, as well as in agreement with previous work on closely related isotropic spatio-temporal quasi-quadrature measures (Lindeberg 2018). When the inclination angle increases, the phase dependency of the quasi-quadrature measure will, however, increase. To select a single representative of those differing representations, let us choose the geometric average of the extreme values, which then assumes the form

$$A_{\mathcal{Q},\text{vel},\max}(\theta; \kappa) = \frac{\sqrt[4]{2} |\cos \theta|^{3/2}}{e^{1/\sqrt{2}} (\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/2}}. \quad (60)$$

The right column in Figure 5 shows the result of plotting the measure $A_{\mathcal{Q},\text{vel},\max}(\theta; \kappa)$ of the orientation selectivity

as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. Again, the degree of orientation selectivity increases strongly with the value of κ .

4.6 Resulting models for orientation selectivity

Table 1 summarizes the results from the above theoretical analysis of the orientation selectivity for our idealized models of simple cells and complex cells, based on the generalized Gaussian derivative model for visual receptive fields, in the cases of either (i) purely spatial models, (ii) space-time separable spatio-temporal models and (iii) velocity-adapted spatio-temporal models. The overall methodology that we have used for deriving these results is by exposing each theoretical receptive field model to either purely spatial or joint spatio-temporal sine wave patterns, and measuring the response properties for different inclination angles θ , at the angular frequency of the sine wave, as well as the image velocity of the spatio-temporal sine wave, at which these models assume their maximum response over variations of these probing parameters.

As can be seen from the table, the form of the orientation selectivity curve is similar for all the models of first-order simple cells, which correspond to first-order derivatives of affine Gaussian kernels over the spatial domain. The form of the orientation selectivity curve is also similar for all the models of second-order simple cells, which correspond to second-order derivatives of affine Gaussian kernels over the spatial domain. For complex cells, the form of the orientation selectivity curve for the space-time separable model is, however, different from the form of the orientation selectivity curve for the purely spatial model and the velocity-adapted spatio-temporal model, which both have a similar form for their orientation selectivity curves.

Note, in particular, that common for all these models is the fact that the degree of orientation selectivity increases with the scale parameter ratio $\kappa = \sigma_2/\sigma_1$, which is the ratio between the scale parameter σ_2 in the direction $\perp\varphi$ perpendicular to the preferred orientation φ of the receptive field and the scale parameter σ_1 in the preferred orientation φ of the receptive field. In other words, for higher values of κ , the form of the orientation selectivity curve is more narrow than the form of the orientation selectivity curve for a lower value of κ . The form of the orientation selectivity curve is also more narrow for a simple cell that can be modelled as a second-order directional derivative of an affine Gaussian kernel, than for a simple cell that can be modelled as a first order derivative of an affine Gaussian kernel.

In this respect, the theoretical analysis supports the conclusion that the degree of orientation selectivity of the receptive fields increases with the degree of anisotropy or elonga-

	Purely spatial model	Space-time separable spatio-temporal model	Velocity-adapted spatio-temporal model
First-order simple cell	$\frac{ \cos \theta }{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}$	$\frac{ \cos \theta }{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}$	$\frac{ \cos \theta }{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}$
Second-order simple cell	$\frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta}$	$\frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta}$	$\frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta}$
Complex cell	$\frac{ \cos \theta ^{3/2}}{(\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}}$	$\frac{ \cos \theta \sqrt{2 + \kappa^2 + (2 - \kappa^2) \cos 2\theta}}{\cos^2 \theta + \kappa^2 \sin^2 \theta}$	$\frac{ \cos \theta ^{3/2}}{(\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}}$

Table 1 Summary of the forms of the orientation selectivity functions derived from the theoretical models of simple cells and complex cells based on the generalized Gaussian derivative model for visual receptive fields, in the cases of either (i) purely spatial models, (ii) space-time separable spatio-temporal models and (iii) velocity-adapted spatio-temporal models. Concerning the notation, the term “first-order simple cell” means a model of a simple cell that corresponds to a first-order directional derivative of an affine Gaussian kernel over the spatial domain, whereas the term “second-order simple cell” means a model of a simple cell that corresponds to a second-order directional derivative of an affine Gaussian kernel over the spatial domain. As we can see from the table, the form of the orientation selectivity function is similar for all the models of first-order simple cells. The form of the orientation selectivity function is also similar for all the models of second-order simple cells. For complex cells, the orientation selectivity function of the space-time separable model is, however, different from the orientation selectivity function of the purely spatial model and the velocity-adapted spatio-temporal model, which both have similar orientation selectivity functions. Note, in particular, that common for all these models is the fact that the degree of orientation selectivity increases with the scale parameter ratio $\kappa = \sigma_2/\sigma_1$, which is the ratio between the scale parameter σ_2 in the direction $\perp \varphi$ perpendicular to the preferred orientation φ of the receptive field and the scale parameter σ_1 in the preferred orientation φ of the receptive field. The shapes of the theoretically derived orientation selectivity curves do, however, notably differ between the classes of (i) first-order simple cells, (ii) second-order simple cells and (iii) complex cells.

tion of the receptive fields, specifically the fact that highly anisotropic or elongated affine Gaussian derivative based receptive fields have higher degree of orientation selectivity than more isotropic affine Gaussian derivative based receptive fields.

The shapes of the resulting orientation selectivity curves do, however, notably differ between the classes of (i) first-order simple cells, (ii) second-order simple cells and (iii) complex cells. This property is important to take into account, if one aims at fitting parameterized models of orientation selectivity curves to neurophysiological measurements of corresponding data.

5 Orientation selectivity analysis for an affine Gabor model of simple cells

In this section, we will perform an orientation selectivity analysis, as analytically similar as possible, for idealized receptive fields according to an affine Gabor model for purely spatial receptive fields.

Given two spatial scale parameters σ_1 and σ_2 and an angular frequency ν , consider an affine Gabor model with a pair of purely spatial receptive fields of the form

$$T_{\text{even}}(x_1, x_2; \sigma_1, \sigma_2, \nu) = \frac{1}{2\pi\sigma_1\sigma_2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2} \cos(\nu x_1), \quad (61)$$

$$T_{\text{odd}}(x_1, x_2; \sigma_1, \sigma_2, \nu) = \frac{1}{2\pi\sigma_1\sigma_2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2} \sin(\nu x_1). \quad (62)$$

Let us, in analogy with the treatment in Section 4.3, subject these receptive fields to test probes of the form (27)

$$f(x_1, x_2) = \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 + \beta) \quad (63)$$

for different inclination angles θ . The responses of the even and odd components of the Gabor pair to such test functions are given by

$$\begin{aligned} L_{\text{even}}(x_1, x_2; \sigma_1, \sigma_2, \nu) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} T_{\text{even}}(\xi_1, \xi_2; \sigma_1, \sigma_2, \nu) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2) d\xi_1 d\xi_2, \end{aligned}$$

$$\begin{aligned} L_{\text{odd}}(x_1, x_2; \sigma_1, \sigma_2, \nu) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} T_{\text{odd}}(\xi_1, \xi_2; \sigma_1, \sigma_2, \nu) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2) d\xi_1 d\xi_2. \quad (64) \end{aligned}$$

Solving these convolution integrals in Mathematica then gives

$$\begin{aligned} L_{\text{even}}(x_1, x_2; \sigma_1, \sigma_2, \nu) &= \\ &= \frac{1}{2} \left(e^{2\nu\omega\sigma_1^2 \cos \theta} + 1 \right) \sin(\beta + \omega x_1 \cos \theta + \omega x_2 \sin \theta) \times \\ &\quad e^{\frac{1}{2}(-\nu^2\sigma_1^2 - 2\nu\omega\sigma_1^2 \cos \theta - \omega^2\sigma_1^2 \cos^2 \theta - \omega^2\sigma_2^2 \sin^2 \theta)}, \quad (65) \end{aligned}$$

$$\begin{aligned} L_{\text{odd}}(x_1, x_2; \sigma_1, \sigma_2, \nu) &= \\ &= -\frac{1}{2} \left(e^{2\nu\omega\sigma_1^2 \cos \theta} - 1 \right) \cos(\beta + \omega x_1 \cos \theta + \omega x_2 \sin \theta) \times \\ &\quad e^{\frac{1}{2}(-\nu^2\sigma_1^2 - 2\nu\omega\sigma_1^2 \cos \theta - \omega^2\sigma_1^2 \cos^2 \theta - \omega^2\sigma_2^2 \sin^2 \theta)}. \quad (66) \end{aligned}$$

Unfortunately, it is hard to analytically determine the angular frequency ω of the test function that gives the strongest amplitude for the Gabor response obtained with a given frequency ν . Therefore, we will in the following simply set $\omega = \nu$, implying that this analysis for the Gabor model will not be methodologically identical to the previous analysis for the affine Gaussian derivative model, in the sense that we will not optimize the angular frequency ω of the test probe for each inclination angle θ .

Fig. 7 Graphs of the orientation selectivity of *purely spatial models* of a simple cell, using the *even component of the affine Gabor model* according to (61) and (62). Observe how the degree of orientation selectivity depends on the scale parameter ratio κ , in a qualitatively similar manner as for the affine Gaussian derivative model for purely spatial receptive fields. For the affine Gabor model, the degree of orientation selectivity does, however, also depend strongly on the product of the two remaining parameters $\sigma_1 \nu$ in the model. (top row) Results for $\kappa = 1$. (second row) Results for $\kappa = 2$. (third row) Results for $\kappa = 4$. (bottom row) Results for $\kappa = 8$. (left column) Results for $\sigma_1 \nu = 1/2$. (middle column) Results for $\sigma_1 \nu = 1$. (right column) Results for $\sigma_1 \nu = 2$. (Horizontal axes: orientation $\theta \in [-\pi/2, \pi/2]$. Vertical axes: Amplitude of the receptive field response relative to the maximum response obtained for $\theta = 0$.)

Letting additionally $\sigma_2 = \kappa \sigma_1$ for $\kappa > 1$, we obtain that the amplitudes of the two Gabor responses can be written:

$$A_{\text{even}} = \frac{1}{2} \left(e^{2\nu^2 \sigma_1^2 \cos \theta} + 1 \right) e^{-\nu^2 \sigma_1^2 \cos^2(\frac{\theta}{2})(\kappa^2 - 1)(1 - \cos \theta)}, \quad (67)$$

$$A_{\text{odd}} = \frac{1}{2} \left(e^{2\nu^2 \sigma_1^2 \cos \theta} - 1 \right) e^{-\nu^2 \sigma_1^2 \cos^2(\frac{\theta}{2})(\kappa^2 - 1)(1 - \cos \theta)}. \quad (68)$$

In contrast to the previous analysis for affine Gaussian derivative models of simple cells, where we determined the angular frequency of the probing sine wave, to maximize the response given a value of the spatial scale parameter, and

in this way eliminated the dependency of the orientation selectivity on the size of the spatial scale parameter in the idealized receptive field model, and in this way reduced the explicit orientation dependency to only depend on the ratio κ between the scale parameters, we cannot, however, here eliminate the remaining parameters of the idealized Gabor model from the orientation selectivity analysis.

The affine Gabor model comprises three internal parameters for the receptive fields (the spatial scale parameters σ_1 and σ_2 , the angular frequency ν as well as the here not explicitly modelled orientation angle φ), while the purely spatial affine Gaussian derivative model comprises only three internal parameters (the spatial scale parameters σ_1 and σ_2

as well as the in Section 4 neither explicitly modelled orientation angle φ).

The affine Gabor model, thus, comprises one more parameter than the affine Gaussian derivative model. The dependency on the remaining degrees of freedom (beyond the orientation φ), due to variations in σ_1 and ν , is, however, of a special form, in the respect that the dependency only depends on the product between σ_1 and ν . Therefore, we will have to, beyond a variability with respect to the scale parameter ratio κ , also investigate the behaviour with respect to variations of the product of the angular frequency ν and the remaining spatial scale parameter σ_1 .

Figure 7 shows orientation selectivity curves for the even component of the affine Gabor pair for different combinations of the scale parameter ratio $\kappa = 1, 2, 4$ or 8 , and the product $\sigma_1\nu = 1/2, 1$ or 2 . As can be seen from these graphs, the orientation selectivity becomes more narrow with increasing values of the scale parameter ratio κ , as for the affine Gaussian derivative model. The orientation selectivity does, however, also become more narrow when the product $\sigma_1\nu$ increases.

Hence, from the conceptual background of whether one could possibly infer that the receptive fields ought to be more elongated, when the orientation selectivity becomes more narrow, one would not be able to make such a logical inference from a population of neurons according to the affine Gabor model, if the only *a priori* would be that the population would be generated from an expansion over all the four internal parameters σ_1, κ, ν and the orientation φ . If it, on the other hand, would be *a priori* known that the relationship between the angular frequency ν and the remaining spatial scale parameter σ_1 would be fixed to a fixed to their product being held constant, then one would, in principle, be able to make such a logical inference.

To save space, we do not show the graphs for the corresponding orientation selectivity curves for the odd component of the Gabor pair, nor for the idealized model of a complex cell, obtained by squaring the responses from the odd and even components and then adding them, and finally taking the square root of the result:

$$\begin{aligned} Q^2 &= L_{\text{even}}^2 + L_{\text{odd}}^2 \\ &= \frac{1}{4} e^{-\nu^2 \sigma_1^2 (\kappa^2 \sin^2 \theta + \cos^2 \theta + 2 \cos \theta + 1)} \times \\ &\quad \left(1 + e^{4\nu^2 \sigma_1^2 \cos \theta} \right. \\ &\quad \left. - 2 e^{2\nu^2 \sigma_1^2 \cos \theta} \cos(2(\beta + \nu x_1 \cos \theta + \nu x_2 \sin \theta)) \right). \end{aligned} \quad (69)$$

The qualitative results, that receptive fields become more narrow as the scale parameter ratio κ increases, or the product $\sigma_1\nu$ of the two remaining parameters increases, are, however, similar. So are the results that the orientation selectivity

of the receptive fields, however, also depends strongly upon the product $\sigma_1\nu$.

We refrain from extending the analysis to possible spatio-temporal models, since it may not be fully clear how the spatio-temporal Gabor models should then be defined.

6 Relations to compact quantitative measures of the degree of orientation selectivity

In (Ringach *et al.* 2002), two compact measures of the orientation selectivity of biological receptive fields are used, in terms of either the circular variance (Mardia 1972)

$$V = 1 - |R|, \quad (70)$$

where the complex-valued resultant R is given by

$$R = \frac{\int_{\theta=-\pi}^{\pi} r(\theta) e^{2i\theta} d\theta}{\int_{\theta=-\pi}^{\pi} r(\theta) d\theta}, \quad (71)$$

or the orientation bandwidth B , defined as the value of B for which

$$\frac{r(B)}{r(0)} = \frac{1}{\sqrt{2}}. \quad (72)$$

In the following, we will compute these compact measures for the orientation selectivity curves derived from the affine-Gaussian-derivative-based models of visual receptive fields, as summarized in Table 1.

6.1 The resultants R of the orientation selectivity curves computed for the affine-Gaussian-derivative-based models of simple and complex cells

Due to the symmetry of the orientation selectivity curves in Table 1, the purely imaginary component of the resultant R will be zero for all the considered models of simple and complex cells in terms of affine-Gaussian-derivative-based receptive fields. In the following, we therefore focus solely on the purely real component of the resultants.

For the first-order simple cells, we obtain, after solving the resulting integrals in Mathematica:

$$\begin{aligned} R_{\text{simple},1} &= \frac{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos \theta}{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}} \cos 2\theta d\theta}{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos \theta}{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}} d\theta} \\ &= \frac{\kappa (\kappa \cosh^{-1} \kappa - \sqrt{\kappa^2 - 1})}{(\kappa^2 - 1) \cosh^{-1} \kappa}, \end{aligned} \quad (77)$$

and for the second-order simple cells:

$$\begin{aligned} R_{\text{simple},2} &= \frac{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta} \cos 2\theta d\theta}{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta} d\theta} \\ &= \frac{\kappa}{\kappa + 1}. \end{aligned} \quad (78)$$

$$R_{\text{complex}} = \frac{\kappa^2 \left(48 (\kappa^2 - 1)^{3/4} \Gamma\left(\frac{5}{4}\right) {}_2F_1\left(\frac{1}{2}, 1; \frac{3}{4}; \frac{1}{\kappa^2}\right) - 16 (\kappa^2 - 1)^{3/4} \Gamma\left(\frac{5}{4}\right) + 3\sqrt{2\pi} \kappa \Gamma\left(-\frac{1}{4}\right) \right)}{2 (\kappa^2 - 1) \left(16 (\kappa^2 - 1)^{3/4} \Gamma\left(\frac{5}{4}\right) {}_2F_1\left(\frac{1}{2}, 1; \frac{3}{4}; \frac{1}{\kappa^2}\right) + \sqrt{2\pi} \kappa \Gamma\left(-\frac{1}{4}\right) \right)} \quad (73)$$

Fig. 8 Explicit expression for the resultant R for (i) the purely spatial model of complex cells based on affine Gaussian derivatives, as well as for (ii) the velocity-adapted spatio-temporal model of complex cells based on affine Gaussian derivatives. The function ${}_2F_1(a, b; c; z)$ is the hypergeometric function `Hypergeometric2F1[a, b, c, z]` in Mathematica, while $\Gamma(z)$ denotes Euler's Gamma function.

$$B_{\text{complex}} = \cos^{-1} \left(\sqrt{\frac{A}{\kappa^6 - 3\kappa^4 + 3\kappa^2 + 3}} \right) \quad (74)$$

where

$$A = \kappa^2 - 2\kappa^4 + \kappa^6 + \sqrt[3]{2} \sqrt[3]{\kappa^{12} (\kappa^6 - 3\kappa^4 + 3\kappa^2 + 3)^2 - \kappa^6 (\kappa^6 - 3\kappa^4 + 3\kappa^2 - 5)} + C \quad (75)$$

and

$$C = - \frac{2 \times 2^{2/3} \kappa^4 (\kappa^2 - 1)}{\sqrt[3]{-\kappa^{12} + 3\kappa^{10} - 3\kappa^8 + 5\kappa^6} + \sqrt{\kappa^{12} (\kappa^6 - 3\kappa^4 + 3\kappa^2 + 3)^2}} \quad (76)$$

Fig. 9 Explicit expression for the orientation selectivity bandwidth B for (i) the purely spatial model of complex cells based on affine Gaussian derivatives, as well as for (ii) the velocity-adapted spatio-temporal model of complex cells based on affine Gaussian derivatives.

Fig. 10 Graphs of the *resultant* R of the orientation selectivity curves as function of the scale parameter ratio κ for the different models of visual receptive fields based on affine Gaussian derivatives. (left) First-order model of simple cell. (middle) Second-order model of complex cell. (right) Purely spatial model of complex cell or velocity-adapted model of complex cell. (Horizontal axes: scale parameter ratio κ . Vertical axes: resultant R .)

Fig. 11 Graphs of the *orientation bandwidth* B of the orientation selectivity curves as function of the scale parameter ratio κ for the different models of visual receptive fields based on affine Gaussian derivatives. (left) First-order model of simple cell. (middle) Second-order model of complex cell. (right) Purely spatial model of complex cell or velocity-adapted model of complex cell. (Horizontal axes: scale parameter ratio κ . Vertical axes: orientation bandwidth B .)

For both the purely spatial model of complex cells based on affine Gaussian derivatives, as well as for the velocity-adapted model of complex cells based on affine Gaussian derivatives, we do in a similar manner get

$$R_{\text{complex}} = \frac{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos^{3/2} \theta}{(\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}} \cos 2\theta d\theta}{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos^{3/2} \theta}{(\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}} d\theta} \quad (79)$$

with the explicit expression for that result in Figure 8.

For the space-time separable model of complex cells, the corresponding formulation

$$R_{\text{complex-sep}} = \frac{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos \theta \sqrt{2+\kappa^2+(2-\kappa^2)\cos 2\theta}}{\cos^2 \theta + \kappa^2 \sin^2 \theta} \cos 2\theta d\theta}{\int_{\theta=-\pi/2}^{\pi/2} \frac{\cos \theta \sqrt{2+\kappa^2+(2-\kappa^2)\cos 2\theta}}{\cos^2 \theta + \kappa^2 \sin^2 \theta} d\theta} \quad (80)$$

can be handled in closed form in Mathematica, but does unfortunately lead to an explicit expression for the result that is too complex to be reported here.

Figure 10 shows the resulting resultants of the orientation selectivity curves obtained in this way, for the first-order models of simple cells, the second-order models of simple cells as well as for the purely spatial model of complex cells and the velocity-adapted models of complex cells.

6.2 The orientation bandwidths B of the orientation selectivity curves computed for the affine-Gaussian-derivative-based models of simple and complex cells

To measure the orientation selectivity bandwidth for the first-order simple cells, we solve the equation

$$\frac{\cos \theta}{\sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}} = \frac{1}{\sqrt{2}}, \quad (81)$$

which gives the bandwidth measure

$$B_{\text{simple},1} = \cos^{-1} \left(\frac{\kappa}{\sqrt{\kappa^2 + 1}} \right). \quad (82)$$

Correspondingly, to determine the orientation selectivity bandwidth for the second-order simple cells, we solve the equation

$$\frac{\cos^2 \theta}{\cos^2 \theta + \kappa^2 \sin^2 \theta} = \frac{1}{\sqrt{2}}, \quad (83)$$

which gives the bandwidth measure

$$B_{\text{simple},2} = 2 \tan^{-1} \left(\sqrt{\frac{-2\sqrt{2}\kappa^2 + 2\sqrt{2}\sqrt{\kappa^2 + \sqrt{2} - 1}\kappa + \sqrt{2} - 2}{\sqrt{2} - 2}} \right)$$

To determine the corresponding orientation selectivity measure for the purely spatial model of complex cells based on affine Gaussian derivatives, as well as for the velocity-adapted model of complex cells based on affine Gaussian derivatives, we solve the equation

$$\frac{|\cos \theta|^{3/2}}{(\cos^2 \theta + \kappa^2 \sin^2 \theta)^{3/4}} = \frac{1}{\sqrt{2}}, \quad (85)$$

which gives the explicit result for the bandwidth measure B_{complex} shown in Figure 9.

Figure 11 shows the resulting orientation bandwidths of the orientation selectivity curves obtained in this way, for the first-order models of simple cells, the second-order models of simple cells as well as for the purely spatial model of complex cells and the velocity-adapted models of complex cells.

7 Summary and discussion

We have presented an in-depth theoretical analysis of the orientation selectivity for the spatial and spatio-temporal receptive fields according to the generalized Gaussian derivative model for visual receptive fields, summarized in Sections 3.1 and 3.3. This model for visual receptive fields has been previously derived in an axiomatic manner, from symmetry properties of the environment, in combination with requirements of internal consistency between image representations over multiple spatial and temporal scales. This model has notably also been demonstrated to well capture the properties of biological simple cells in the primary visual cortex. Building upon that theory for linear receptive fields, we have also analysed the orientation selectivity for (some of them new) non-linear models of complex cells, summarized in Sections 3.2 and 3.4, based on energy models that combine the output from such models for simple cells for different orders of spatial differentiation.

Specifically, we have in Section 4, with the details concerning the analysis of the space-time separable spatio-temporal models in Appendix A.1, analyzed how the orientation selectivity depends on a scale parameter ratio κ , between the scale parameters in the image orientations perpendicular to vs. parallel with the preferred orientation of the receptive fields. Explicit expressions for the resulting orientation tuning curves have been derived, based on closed form theoretical analysis, and it has been shown that, for all these models of visual receptive fields, the degree of orientation selectivity becomes more narrow with increasing values of the scale parameter ratio κ . Additionally, we have in Section 6 derived closed-form expressions for the resultant and the bandwidth of the orientation selectivity curves, which can be used for interpreting previous compact characterizations of neurophysiological measurements of orientation

selectivity to parameters in the idealized models for visual receptive fields.

To compare the theoretical predictions obtained based on the affine Gaussian derivative model for visual receptive fields, to what would be obtained from basing the theoretical analysis on other types of receptive field models, we have furthermore in Section 5 presented a detailed orientation selectivity analysis for an affine Gabor model of visual receptive fields. The results obtained from the affine Gabor model are consistent with the results obtained from the affine Gaussian derivative model, in the sense that the orientation selectivity becomes more narrow, as we widen the receptive fields in the direction perpendicular to preferred orientation of the receptive fields.

The results from the affine Gabor model do, on the other hand, also differ from the results obtained from the affine Gaussian derivative model, in the respect that the parameter space of the affine Gabor model comprises one more degree of freedom, compared to the parameter space of the affine Gaussian derivative model. Specifically, a variability along that additional degree of freedom does also strongly affect the orientation selectivity of the receptive fields according to the affine Gabor model. The connections between the degree of orientation selectivity and the elongation of the receptive fields obtained from the affine Gaussian derivative model are in this respect more specific than for the affine Gabor model. This points to a both a qualitative similarity and a qualitative difference between the affine Gaussian derivative model and the affine Gabor model.

We have also in Appendix A.2 shown that a generalized version of the affine Gabor model also supports affine covariance, as the affine Gaussian derivative model does.

Concerning extensions of the approach, we have in the present treatment regarding receptive fields according to the generalized Gaussian derivative model for visual receptive fields, limited ourselves to receptive fields corresponding to only first- and second-order derivatives over the spatial domain. Modelling results by Young (1987) have, however, demonstrated that receptive fields up to fourth order of spatial differentiation may be present in the primary visual cortex. It is straightforward to extend our analysis to third- and fourth-order directional derivatives, which would then give other closed-form expressions for the orientation selectivity of the receptive fields (and more narrow than the orientation selectivity for first- and second-order derivatives). Models of complex cells involving third- and fourth-order spatial derivatives could also be formulated and be theoretically analyzed, although experimental support for such extended models of complex cells may currently not be available.

A more conceptual way of extending the modelling work would also be to incorporate a complementary spatial smoothing step in model of complex cells, as used in (Lindeberg 2020 Section 5). In the models for complex cells used in the

theoretical analysis in this paper, the responses of first- and second-order spatial derivative based receptive fields have been throughout combined in a pointwise manner, over both space and time. A more general approach would, however, be to perform weighted integration of such pointwise contributions over a wider support region over space and time, with the size over the spatial image domain and the duration over the temporal domain proportional to the local spatial and temporal scales at which the spatial and temporal derivatives are computed. In the present treatment, we have, however, not extended the complex cell models in that way, although it could be well motivated, mainly to simplify the treatment, and to limit the complexity of the theoretical analysis. If the orientation selectivity curves obtained from theoretical analysis are to be fitted to data from actual neurophysiological measurements, it does, however, seem advisable to complement the models for complex cells by explicit spatial integration, as done in Equation (46) in (Lindeberg 2020).

Concerning the spatio-temporal models of the receptive fields, we have also limited ourselves to performing a non-causal temporal analysis, where the temporal smoothing kernels are 1-D Gaussian kernels. To perform a corresponding time-causal temporal analysis, based on using the time-causal limit kernel (15) for temporal smoothing, one can perform a Fourier analysis to determine how the probing sine wave will be affected, using the closed-form expression for the Fourier transform of the time-causal limit kernel, in a similar way as in the temporal scale selection analysis in (Lindeberg 2017 Section 5.2).

Concerning the way that the orientation selectivity curves are defined, we have in the above theoretical analysis for the affine Gaussian derivative model throughout⁷ in Section 4 assumed that the wavelength $\hat{\omega}$ (and for the spatio-temporal analysis also the image velocity \hat{u}) of the probing sine wave is optimized for each image orientation separately. Another possibility is to instead assume that the wavelength is only optimized for the preferred orientation of the receptive field only, and then held constant for all the other inclination angles θ . Changing the probing method in such a way would change the shapes of the orientation selectivity curves, but could be easily performed, based on the principles for theoretical analysis outlined in the above treatment.

One could possibly also consider extending the analysis to different values of the scale normalization powers γ and Γ , than using the maximally scale invariant choices $\gamma = 1$ and $\Gamma = 0$ used for simplicity in this treatment. Then, however, some type of post-normalization may, however, also be necessary, to make it possible to appropriately compare re-

⁷ In the orientation selectivity analysis for receptive fields according to the affine Gabor model in Appendix 5, we did, however, not optimize the angular frequency ω of the probing sine wave for each inclination angle θ , because that was harder to accomplish, in terms of closed-form mathematical expressions.

ceptive field responses between multiple spatial and temporal scales, which otherwise are perfectly comparable when using $\gamma = 1$ and $\Gamma = 0$.

Concerning possible limitations of the approach, it should be emphasized that the models for visual receptive fields in the generalized Gaussian derivative model are highly idealized. They have been derived from mathematical analysis based on idealized theoretical assumptions, regarding symmetry properties of the environment, while they have not been quantitatively adjusted to the receptive field shapes of actual biological neurons. Hence, the results from the presented theoretical analysis should be interpreted as such, as the results of a maximally idealized model, and not with specific aims of providing a numerically accurate representation of actual biological neurons. The receptive field models also constitute pure feed-forward models with no feed-back mechanisms, which are otherwise known to be important in biological vision.

In view of such a background, it is, however, highly interesting to see how well the derived orientation selectivity curves in Figures 3, 5 and 12 reflect the qualitative shapes of the biologically established orientation selectivity curves recorded in the primary visual cortex by Nauhaus *et al.* (2008), as reflected in the qualitative comparison to those results in our companion paper (Lindeberg 2024a).

Additionally, it is interesting to note that corresponding closed-form calculations of the resultant, for the orientation selectivity curves for the idealized models of simple cells based on affine Gaussian derivatives, lead to predictions that are qualitatively very similar to the experimentally obtained histograms of the resultant for the orientation selectivity curves, accumulated for biological simple cells by Goris *et al.* (2015), if extended to models of simple cells in terms of affine Gaussian derivatives up to order 4, see (Lindeberg 2024a) for further details.

It is also known that the distinction between simple and complex cells may not be as distinct as proposed in the initial work by Hubel and Wiesel, where there could instead be a scale of gradual transitions between simple and complex cells, see Alonso and Martinez (1998), Mechler and Ringach (2002) and Li *et al.* (2015) for treatments with different views on this topic. Considering that the forms of the derived orientation selectivity are often similar for our models of simple and complex cells (as summarized in Table 1), one may speculate that the presented results could be relevant with respect to such a wider contextual background.

It may also be worth stating that we do not in any way exclude the possibility of deriving corresponding prediction results for other possible models of receptive fields, or for models of neural mechanisms that lead to the formation of visual receptive fields. A motivation, for in this paper restricting the analysis in this paper to the idealized receptive fields according to the generalized Gaussian derivative

model and to the idealized receptive fields according to the Gabor model, is that these models may be regarded the most commonly used and well-established idealized functional models for linear receptive fields in the primary visual cortex. These receptive field models do specifically reasonably well reproduce the qualitative shape of many receptive fields in the primary visual cortex, as have been established by neurophysiological measurements. The formulation of possible Gabor models for spatio-temporal receptive fields does, however, appear as a more open topic, why we have restricted the analysis of the affine Gabor model to purely spatial receptive fields.

Considering also that the relationship between the orientation selectivity and the degree of elongation of the receptive fields is more direct for the affine-Gaussian-derivative-based model than for the affine Gabor model, an overall conclusion from this work is therefore that the affine-Gaussian-derivative-based model for visual receptive fields is conceptually much easier to analyze with regard to orientation selectivity properties than the affine Gabor model.

A Appendix

A.1 Analysis for space-time separable models of spatio-temporal receptive fields

To investigate the directional selectivity of our spatio-temporal models for simple and complex cells, we will analyze their response properties to a moving sine wave of the form

$$f(x_1, x_2, t) = \sin(\omega \cos(\theta)(x_1 - u_1 t) + \omega \sin(\theta)(x_2 - u_2 t) + \beta), \quad (86)$$

where we choose the velocity vector $(u_1, u_2)^T$ parallel to the inclination angle θ of the grating according to $(u_1, u_2)^T = (u \cos \theta, u \sin \theta)^T$, which, in turn, implies the form

$$f(x_1, x_2, t) = \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - u t + \beta). \quad (87)$$

Let us initially perform such an analysis for space-time separable models of simple and complex cells, in which the velocity vector v in the spatio-temporal receptive field models is set to zero.

For simplicity, we initially perform the theoretical analysis for non-causal spatio-temporal receptive field models, where the temporal components are given as scale-normalized temporal derivatives of 1-D temporal Gaussian kernels.

In the following, we will name our models of spatio-temporal receptive fields according to the orders of differentiation with respect to space and time.

A.1.1 First-order first-order simple cell

Consider a space-time separable receptive field corresponding to a *first-order* scale-normalized Gaussian derivative with scale parameter σ_1 in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a *first-order* scale-normalized Gaussian derivative with scale parameter σ_t in the temporal direction,

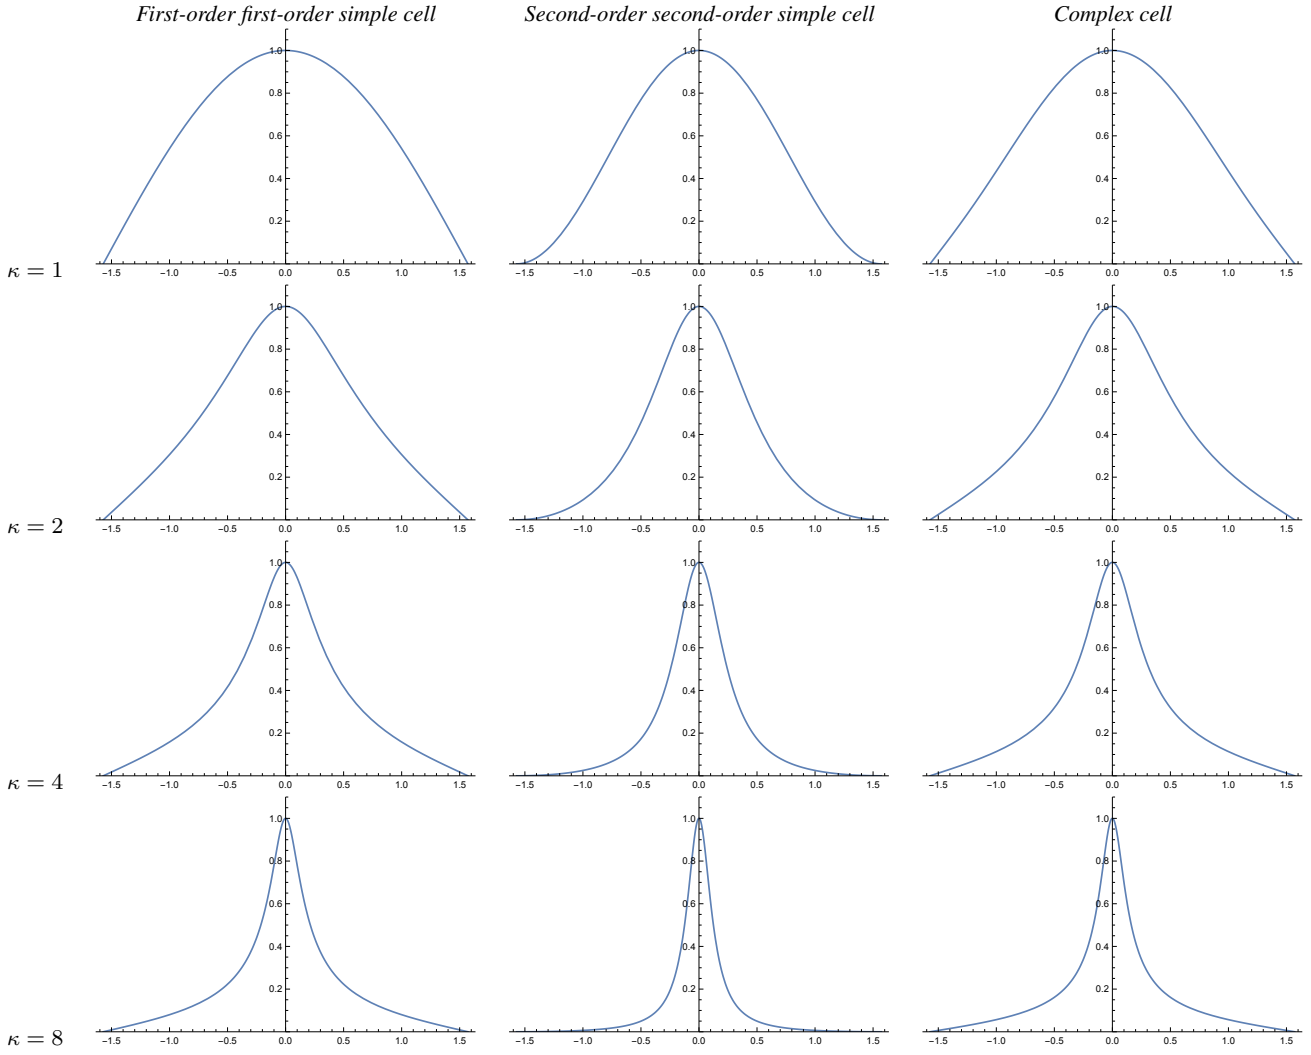

Fig. 12 Graphs of the orientation selectivity for *space-time separable spatio-temporal models* of (left column) simple cells in terms of first-order directional derivatives of affine Gaussian kernels combined with first-order temporal derivatives of temporal Gaussian kernels, (middle column) simple cells in terms of second-order directional derivatives of affine Gaussian kernels combined with second-order temporal derivatives of temporal Gaussian kernels and (right column) complex cells in terms of directional quasi-quadrature measures that combine the first- and second-order simple cell responses in a Euclidean way for $C_\varphi = 1/\sqrt{2}$, and $C_t = 1/\sqrt{2}$ shown for different values of the ratio κ between the spatial scale parameters in the vertical vs. the horizontal directions. Observe how the degree of orientation selectivity varies strongly depending on the eccentricity $\epsilon = 1/\kappa$ of the receptive fields. (top row) Results for $\kappa = 1$. (second row) Results for $\kappa = 2$. (third row) Results for $\kappa = 4$. (bottom row) Results for $\kappa = 8$. (Horizontal axes: orientation $\theta \in [-\pi/2, \pi/2]$. Vertical axes: Amplitude of the receptive field response relative to the maximum response obtained for $\theta = 0$.)

corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 1$ and $n = 1$ in (13):

$$\begin{aligned}
 T_{0,t,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\
 &= \frac{\sigma_1 \sigma_t}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1} \partial_t \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \\
 &= \frac{x_1 t}{(2\pi)^{3/2} \sigma_1^2 \sigma_2 \sigma_t^2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \tag{88}
 \end{aligned}$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned}
 L_{0,t,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\
 &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} \int_{\zeta=-\infty}^{\infty} T_{0,t,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\
 &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\
 &= \omega^2 \sigma_1 \sigma_t u \cos(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)} \\
 &\quad \times \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - u t + \beta), \tag{89}
 \end{aligned}$$

i.e., a sine wave with amplitude

$$A_{\varphi,t}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) = \omega^2 \sigma_1 \sigma_t u \cos(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)}. \quad (90)$$

This expression first increases and then decreases with respect to both the angular frequency ω and the velocity u of the sine wave. Selecting the values of $\hat{\omega}$ and \hat{u} at which this expression assumes its maximum over ω and u

$$\hat{\omega}_{\varphi,t} = \frac{1}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (91)$$

$$\hat{u}_{\varphi,t} = \frac{\sigma_1}{\sigma_t} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}, \quad (92)$$

and again reparameterizing the other spatial scale parameter σ_2 as $\sigma_2 = \kappa \sigma_1$, gives that the maximum amplitude measure over spatial and temporal scales is

$$A_{\varphi,t,\max}(\theta; \kappa) = \frac{\cos \theta}{e \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}. \quad (93)$$

Note that again this directional selectivity measure is independent of the spatial scale parameter σ_1 as well as independent of the temporal scale parameter σ_t , because of the scale-invariant property of scale-normalized derivatives for scale normalization power $\gamma = 1$.

The left column in Figure 12 shows the result of plotting the measure $A_{\varphi,t,\max}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. As we can see from the graphs, as for the previous purely spatial model of the receptive fields, the degree of orientation selectivity increases strongly with the value of κ .

A.1.2 First-order second-order simple cell

Consider a space-time separable receptive field corresponding to a *first-order* scale-normalized Gaussian derivative with scale parameter σ_1 in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a *second-order* scale-normalized Gaussian derivative with scale parameter σ_t in the temporal direction, corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 1$ and $n = 2$ in (13):

$$\begin{aligned} T_{0,tt,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \frac{\sigma_1 \sigma_t^2}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1} \partial_{tt} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \\ &= -\frac{x_1(t^2 - \sigma_t^2)}{(2\pi)^{3/2} \sigma_1^2 \sigma_2 \sigma_t^3} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \end{aligned} \quad (94)$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{0,tt,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} \int_{\zeta=-\infty}^{\infty} T_{0,tt,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\ &= -\omega^3 \sigma_1 \sigma_t^2 u^2 \cos(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)} \\ &\quad \times \cos(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - u t + \beta), \end{aligned} \quad (95)$$

i.e., a cosine wave with amplitude

$$A_{\varphi,tt}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) = \omega^3 \sigma_1 \sigma_t^2 u^2 \cos(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)}. \quad (96)$$

This entity assumes its maximum over the angular frequency ω and the image velocity u at

$$\hat{\omega}_{\varphi,tt} = \frac{1}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (97)$$

$$\hat{u}_{\varphi,tt} = \frac{\sqrt{2}\sigma_1}{\sigma_t} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}, \quad (98)$$

and again reparameterizing the other spatial scale parameter σ_2 as $\sigma_2 = \kappa \sigma_1$, gives that the maximum amplitude measure over spatial and temporal scales is

$$A_{\varphi,tt,\max}(\theta; \kappa) = \frac{2 \cos \theta}{e^{3/2} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (99)$$

i.e., of a similar form as the previous measure $A_{\varphi,tt,\max}(\theta; \kappa)$, while being multiplied by another constant.

A.1.3 Second-order first-order simple cell

Consider a space-time separable receptive field corresponding to a *second-order* scale-normalized Gaussian derivative with scale parameter σ_1 in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a *first-order* scale-normalized Gaussian derivative with scale parameter σ_t in the temporal direction, corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 2$ and $n = 1$ in (13):

$$\begin{aligned} T_{00,t,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \frac{\sigma_1^2 \sigma_t}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1 x_1} \partial_t \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \\ &= -\frac{(x_1^2 - \sigma_1^2)t}{(2\pi)^{3/2} \sigma_1^3 \sigma_2 \sigma_t^2} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \end{aligned} \quad (100)$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{00,t,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} \int_{\zeta=-\infty}^{\infty} T_{00,t,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\ &= -\omega^3 \sigma_1^2 \sigma_t u \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)} \\ &\quad \times \cos(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - u t + \beta), \end{aligned} \quad (101)$$

i.e., a cosine wave with amplitude

$$A_{\varphi\varphi,t}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) = \omega^3 \sigma_1^2 \sigma_t u \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)}. \quad (102)$$

This entity assumes its maximum over spatial scale σ_1 and over temporal scale σ_t at

$$\hat{\omega}_{\varphi\varphi,t} = \frac{\sqrt{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (103)$$

$$\hat{u}_{\varphi,t} = \frac{\sigma_1}{\sqrt{2}\sigma_t} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}, \quad (104)$$

and again reparameterizing the other spatial scale parameter σ_2 as $\sigma_2 = \kappa \sigma_1$, gives that the maximum amplitude measure over spatial and temporal scales is

$$A_{\varphi,t,\max}(\theta; \kappa) = \frac{2 \cos^2 \theta}{e^{3/2} (\cos^2 \theta + \kappa^2 \sin^2 \theta)}. \quad (105)$$

A.1.4 Second-order second-order simple cell

Consider a space-time separable receptive field corresponding to a *second-order* scale-normalized Gaussian derivative with scale parameter σ_1 in the horizontal x_1 -direction, a zero-order Gaussian kernel with scale parameter σ_2 in the vertical x_2 -direction, and a *second-order* scale-normalized Gaussian derivative with scale parameter σ_t in the temporal direction, corresponding to $\varphi = 0$, $v = 0$, $\Sigma_0 = \text{diag}(\sigma_1^2, \sigma_2^2)$, $m = 2$ and $n = 2$ in (13):

$$\begin{aligned} T_{00,tt,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \frac{\sigma_1^2 \sigma_t^2}{(2\pi)^{3/2} \sigma_1 \sigma_2 \sigma_t} \partial_{x_1 x_1} \partial_{tt} \left(e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2} \right) \\ &= \frac{(x_1^2 - \sigma_1^2)(t^2 - \sigma_t^2)}{(2\pi)^{3/2} \sigma_1^3 \sigma_2 \sigma_t^3} e^{-x_1^2/2\sigma_1^2 - x_2^2/2\sigma_2^2 - t^2/2\sigma_t^2}. \end{aligned} \quad (106)$$

The corresponding receptive field response is then, after solving the convolution integral in Mathematica,

$$\begin{aligned} L_{00,tt,\text{norm}}(x_1, x_2, t; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \int_{\xi_1=-\infty}^{\infty} \int_{\xi_2=-\infty}^{\infty} \int_{\zeta=-\infty}^{\infty} T_{00,tt,\text{norm}}(\xi_1, \xi_2, \zeta; \sigma_1, \sigma_2, \sigma_t) \\ &\quad \times f(x_1 - \xi_1, x_2 - \xi_2, t - \zeta) d\xi_1 d\xi_2 d\zeta \\ &= \omega^4 \sigma_1^2 \sigma_t^2 u^2 \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)} \\ &\quad \times \sin(\omega \cos(\theta) x_1 + \omega \sin(\theta) x_2 - \omega t + \beta), \end{aligned} \quad (107)$$

i.e., a sine wave with amplitude

$$\begin{aligned} A_{\varphi,t,t}(\theta, u, \omega; \sigma_1, \sigma_2, \sigma_t) &= \\ &= \omega^4 \sigma_1^2 \sigma_t^2 u^2 \cos^2(\theta) e^{-\frac{1}{2}\omega^2(\sigma_1^2 \cos^2 \theta + \sigma_2^2 \sin^2 \theta + \sigma_t^2 u^2)}. \end{aligned} \quad (108)$$

This entity assumes its maximum over spatial scale σ_1 and over temporal scale σ_t at

$$\hat{\omega}_{\varphi,t,t} = \frac{\sqrt{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (109)$$

$$\hat{u}_{\varphi,t,t} = \frac{\sigma_1}{\sigma_t} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}, \quad (110)$$

and again reparameterizing the other spatial scale parameter σ_2 as $\sigma_2 = \kappa \sigma_1$, gives that the maximum amplitude measure over spatial and temporal scales is

$$A_{\varphi,t,t,\max}(\theta; \kappa) = \frac{4 \cos^2 \theta}{e^2 (\cos^2 \theta + \kappa^2 \sin^2 \theta)}. \quad (111)$$

The middle column in Figure 12 shows the result of plotting the measure $A_{\varphi,t,t,\max}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value is equal to 1. Again, the degree of orientation selectivity increases strongly with the value of κ , as for the first-order first-order model of a simple cell.

A.1.5 Complex cell

To model the spatio-temporal response of a complex cell according to the directional sensitive spatio-temporal quasi-quadrature measure (13) based on space-time separable spatio-temporal receptive fields, we combine the responses of the first-order first-order simple cell (89), the first-order second-order cell (95), the second-order first-order simple cell (101) and the second-order second order cell (107) for $v = 0$, $\Gamma_\varphi = 0$ and $\Gamma_t = 0$ according to

$$\begin{aligned} &(\mathcal{Q}_{0,\text{sep},\text{norm}}L)^2 \\ &= L_{0,t,\text{norm}}^2 + C_\varphi L_{00,t,\text{norm}}^2 + \\ &\quad + C_t (L_{0,tt,\text{norm}}^2 + C_\varphi L_{00,tt,\text{norm}}^2). \end{aligned} \quad (112)$$

Selecting the angular frequency $\hat{\omega}$ as the geometric average of the angular frequencies where the above spatio-temporal simple cell models assume their maximum amplitude responses over spatial scales

$$\hat{\omega}_{\mathcal{Q}} = \sqrt{\hat{\omega}_{\varphi,t} \hat{\omega}_{\varphi,tt} \hat{\omega}_{\varphi,t} \hat{\omega}_{\varphi,tt}} = \frac{\sqrt[4]{2}}{\sigma_1 \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}}, \quad (113)$$

and selecting the image velocity \hat{u} of the sine wave as the geometric average of the image velocities where the above spatio-temporal simple cell models assume their maximum amplitude responses over image velocities

$$\hat{u}_{\mathcal{Q}} = \sqrt{\hat{u}_{\varphi,t} \hat{u}_{\varphi,tt} \hat{u}_{\varphi,t} \hat{u}_{\varphi,tt}} = \frac{\sigma_1}{\sigma_t} \sqrt{\cos^2 \theta + \kappa^2 \sin^2 \theta}, \quad (114)$$

as well as choosing the spatial and temporal weighting factors C_φ and C_t between first- and second-order information as $C_\varphi = 1/\sqrt{2}$ and $C_t = 1/\sqrt{2}$ according to (Lindeberg 2018), then implies that the spatio-temporal quasi-quadrature measure assumes the form

$$A_{\mathcal{Q},\text{sep}}(\theta; \kappa) = \frac{e^{-\sqrt{2}|\cos \theta|} \sqrt{2 + \kappa^2 + (2 - \kappa^2) \cos 2\theta}}{\cos^2 \theta + \kappa^2 \sin^2 \theta}. \quad (115)$$

Note that this expression is independent of both the spatial scale parameter σ_1 and the temporal scale parameter σ_t , because of the scale-invariant properties of scale-normalized derivatives for scale normalization parameter $\gamma = 1$. Moreover, this expression is also independent of the phase of the signal, as determined by the spatial coordinates x_1 and x_2 , the time moment t and the phase angle β .

The right column in Figure 12 shows the result of plotting the measure $A_{\mathcal{Q},\text{sep}}(\theta; \kappa)$ of the orientation selectivity as function of the inclination angle θ for a few values of the scale parameter ratio κ , with the values rescaled such that the peak value for each graph is equal to 1. As can be seen from the graphs, the degree of orientation selectivity increases strongly with the value of κ also for this spatio-temporal model of a complex cell, and in a qualitatively similar way as for the simple cell models, regarding both the purely spatial as well as the joint spatio-temporal models of the simple cells.

A.2 Affine transformation property for receptive fields according to a generalized affine Gabor model for simple cells

Given any positive definite spatial covariance matrix Σ and any angular frequency vector $\omega = (\omega_1, \omega_2)^T$, consider a generalization of the affine Gabor model (61) to a vector-valued affine Gabor function of the form

$$G(x; \Sigma, \omega) = g(x; \Sigma, \omega) e^{i\omega^T x}, \quad (116)$$

where $g(x; \Sigma, \omega)$ denotes a (here) two-dimensional Gaussian kernel

$$g(x; \Sigma) = \frac{1}{2\pi \sqrt{\det \Sigma}} e^{-x^T \Sigma^{-1} x/2}. \quad (117)$$

In the case when the angular frequency vector ω is parallel to one of the eigenvectors of the spatial covariance matrix Σ , this form of affine Gabor function spans a similar variability as the previously treated affine Gabor model in (61). To make it possible to define a representation that is closed under general affine transformations (affine covariance), we do, however, here, relax the assumption that the orientation of the angular frequency vector ω should be related to the dominant orientations defined by the eigendirections of the spatial covariance matrix Σ .

Let us now assume that we have two spatial images $f(x)$ and $f'(x')$ that are related according to a spatial affine transformation, such that

$$f'(x') = f(x) \quad (118)$$

for

$$x' = Ax. \quad (119)$$

Let us furthermore define affine Gabor representations over the two spatial domains according to

$$\begin{aligned} L(x; \Sigma, \omega) &= (G(\cdot; \Sigma, \omega) * f(\cdot))(x; \Sigma, \omega) \\ &= \int_{\xi \in \mathbb{R}^2} G(\xi; \Sigma, \omega) f(x - \xi) d\xi, \end{aligned} \quad (120)$$

$$\begin{aligned} L'(x'; \Sigma', \omega') &= (G(\cdot; \Sigma', \omega') * f'(\cdot))(x'; \Sigma', \omega') \\ &= \int_{\xi' \in \mathbb{R}^2} G(\xi'; \Sigma', \omega') f(x' - \xi') d\xi'. \end{aligned} \quad (121)$$

We would now like to investigate if the affine Gabor representations over the two domains could be related to each other. To express such a relation, we will perform the change of variables

$$\xi' = A\xi, \quad (122)$$

which gives

$$d\xi' = |\det A| d\xi, \quad (123)$$

in the convolution integrals.

Step I: Let us first consider how the Gaussian function $g'(x'; \Sigma')$ in the Gabor function $G(x'; \Sigma', \omega')$ transforms under the change of variables. If we, in analogy with the transformation property of the spatial covariance matrix in the affine Gaussian derivative model for visual receptive fields (Equation (28) in Lindeberg 2023b) assume that

$$\Sigma' = A \Sigma A^T, \quad (124)$$

which gives

$$\Sigma'^{-1} = A^{-T} \Sigma^{-1} A^{-1} \quad (125)$$

and

$$\det \Sigma' = |\det A|^2 \det \Sigma, \quad (126)$$

then we obtain

$$\begin{aligned} g(\xi'; \Sigma') &= \frac{1}{2\pi\sqrt{\det \Sigma'}} e^{-\xi'^T \Sigma'^{-1} \xi' / 2} \\ &= \frac{1}{2\pi |\det A| \sqrt{\det \Sigma}} e^{-A\xi^T A^{-T} \Sigma^{-1} A^{-1} A\xi / 2} \end{aligned} \quad (127)$$

$$= \frac{1}{|\det A|} \frac{1}{2\pi\sqrt{\det \Sigma}} e^{-\xi^T \Sigma^{-1} \xi / 2} = \frac{1}{|\det A|} g(\xi; \Sigma). \quad (128)$$

Step II: If we further set

$$\omega' = A^{-T} \omega, \quad (129)$$

and combine with the transformation property (128) of the affine Gaussian kernel, then we have that the Gabor functions over the two domains are related according to

$$\begin{aligned} G(\xi'; \Sigma', \omega') &= g(\xi'; \Sigma') e^{i\omega'^T \xi'} = \frac{1}{|\det A|} g(\xi; \Sigma) e^{i(A^{-T} \omega)^T A \xi} \\ &= \frac{1}{|\det A|} g(\xi; \Sigma) e^{i\omega^T \xi} = \frac{1}{|\det A|} G(\xi; \Sigma, \omega). \end{aligned} \quad (130)$$

Step III: Applied to the convolution integrals (120) and (121), the transformation property (130) of the genuinely affine Gabor function (116) thus implies that

$$\begin{aligned} L'(x'; \Sigma', \omega') &= (G(\cdot; \Sigma', \omega') * f'(\cdot))(x'; \Sigma', \omega') \\ &= \int_{\xi' \in \mathbb{R}^2} G(\xi'; \Sigma', \omega') f(x' - \xi') d\xi' \\ &= \int_{\xi \in \mathbb{R}^2} \frac{1}{|\det A|} G(\xi; \Sigma, \omega) f(x - \xi) |\det A| d\xi \\ &= (G(\cdot; \Sigma, \omega) * f(\cdot))(x; \Sigma, \omega) = L(x; \Sigma, \omega). \end{aligned} \quad (131)$$

Summary of main result: To conclude, we have shown that if two images $f(x)$ and $f'(x')$ are related according to an affine transformation

$$f'(x') = f(x) \quad (132)$$

where

$$x' = Ax, \quad (133)$$

then provided that affine Gabor representations are defined over the two spatial domains according to

$$L(x; \Sigma, \omega) = (G(\cdot; \Sigma, \omega) * f(\cdot))(x; \Sigma, \omega), \quad (134)$$

$$L'(x'; \Sigma', \omega') = (G(\cdot; \Sigma', \omega') * f'(\cdot))(x'; \Sigma', \omega'), \quad (135)$$

it then follows that these (genuinely) affine Gabor representations are equal under a similar spatial affine transformation

$$L'(x'; \Sigma', \omega') = L(x; \Sigma, \omega), \quad (136)$$

provided that the values of the receptive field parameters Σ , Σ' , ω and ω' are appropriately matched according to

$$\Sigma' = A \Sigma A^T, \quad (137)$$

$$\omega' = A^{-T} \omega. \quad (138)$$

This affine transformation property constitutes a genuine affine covariance property of the (here) generalized family of affine Gabor functions according to

$$G(x; \Sigma, \omega) = g(x; \Sigma, \omega) e^{i\omega^T x}. \quad (139)$$

In this context, it should, however, be noted that restricted affine Gabor model (61), where the angular frequency vector is restricted to be parallel with one of the eigendirections of the spatial covariance matrix Σ , cannot, however, be expected to be covariant over the complete group of spatial affine transformations. That restricted affine Gabor model will, however, be covariant under similarity transformations (uniform scaling transformations and spatial rotations) as well as to stretching transformations in the orientation of the angular frequency vector.
