(Dated: May 31, 2024)

We identify emergent hydrodynamics governing charge transport in Brownian random time evolution with various symmetries, constraints, and ranges of interactions. This is accomplished via a mapping between the averaged dynamics and the low-energy spectrum of a Lindblad operator, which acts as an effective Hamiltonian in a doubled Hilbert space. By explicitly constructing dispersive excited states of this effective Hamiltonian using a single-mode approximation, we provide a comprehensive understanding of diffusive, subdiffusive, and superdiffusive relaxation in many-body systems with conserved multipole moments and variable interaction ranges. Our approach further allows us to identify exotic Krylov-space-resolved diffusive relaxation despite the presence of dipole conservation, which we verify numerically. Therefore, we provide a general and versatile framework to qualitatively understand the dynamics of conserved operators under random unitary time evolution.

Introduction. Recent years have seen a surge of interest in the nonequilibrium dynamics of quantum manybody systems, driven by rapid advancements in quantum simulation capabilities across diverse physical platforms. In particular, significant attention has been devoted to understanding the thermalization process of interacting many-body systems $[1–7]$ $[1–7]$. A vital theoretical tool that provides key insights into the dynamics of thermalizing quantum systems is the study of random unitary time evolution. While retaining analytical tractability, such methods can successfully capture universal properties of non-integrable many-body dynamics such as transport, operator spreading, or entanglement growth [\[8–](#page-5-1)[16\]](#page-5-2). In particular, the application of methods based on random unitary evolution has highlighted the importance of symmetries and constraints in many-body dynamics, unveiling a rich phenomenology of emergent hydrodynamics at late times. Recent results range from transport in long-range interacting systems [\[17](#page-5-3)[–20\]](#page-5-4) to anomalously slow subdiffusion $[21-32]$ $[21-32]$ or even localization due to Hilbert space fragmentation in models with kinetic constraints [\[33–](#page-5-7)[44\]](#page-6-0).

In this work, we introduce a simple, yet powerful method to understand the qualitative behavior of latetime hydrodynamics based on Brownian Hamiltonian evolution, which can be modeled by Markovian dynamics and thus captured by a Lindblad equation [\[45–](#page-6-1)[50\]](#page-6-2). Our approach successfully reproduces results reported in previous literature and allows us to uncover novel, unconventional hydrodynamic relaxation in constrained manybody systems. The key technical step relates dynamical properties such as the auto-correlation of conserved operators to the low-energy spectrum of an emergent effective

FIG. 1. Brownian circuit and effective Hamiltonian. Mapping (a) random operator dynamics to (b) imaginarytime evolution by an effective Hamiltonian $\mathcal L$ in a doubled Hilbert space. On the left, an operator ρ is evolved by a local Hamiltonian $H_t \equiv \sum_i h_i dB_{i,t}$ with Brownian random variable dB. Overlapping blocks for forward/backward evolution (dark/light) share the same Brownian variable, but all other Brownian variables are independently drawn from Gaussian distributions. On the right, we average over random variables while taking timesteps to zero; this produces imaginary-time Schrodinger evolution by a Lindbladian operator.

Hamiltonian in a *doubled Hilbert space* [\[51,](#page-6-3) [52\]](#page-6-4). The lowenergy excitation spectrum of the latter thus dictates the long-time dynamics of such correlations. Accordingly, this mapping allows us to utilize well-established techniques in condensed matter physics, such as the singlemode approximation, to analyze our problem. Here, we apply this method to various scenarios: We show that systems conserving U(1) global charge as well as higher multipole moments exhibit diverse hydrodynamic relaxation depending on their symmetries and ranges of interactions. Then, we extend our approach to understand Krylov-subspace-resolved hydrodynamics, where we uncover general conditions under which relaxation is diffusive despite the presence of dipole conservation. We verify this diffusive relaxation numerically in lattice models

in both one and two spatial dimensions.

Brownian Circuits. We consider time evolution by a time-dependent Hamiltonian $H_t \equiv \sum_i h_i \, dB_{i,t}$, defined via interaction terms h_i with $h_{\mathbf{x},\lambda} = h_{\mathbf{x}+1,\lambda}$ and Brownian random variables $dB_{t,i}$ at each time slice $[t, t + \delta)$. Here, the label $i = (\mathbf{x}, \lambda)$ encodes both the spatial support and operator type of h_i . The random variables have vanishing mean $\mathbb{E}[d\overline{B}] = 0$ and finite variance $\mathbb{E}[dB^2] = 1/\delta$.

Under this time evolution, a density matrix $\rho(t)$ evolves as $\rho(t+\delta) \equiv e^{-iH_t\delta} \rho(t) e^{iH_t\delta}$. Averaging the infinitesimal time evolution over the random variables, the leading order operator evolution becomes [\[53\]](#page-6-5)(Sec. B):

$$
\mathbb{E}[\partial_t \rho] = -\frac{1}{2} \sum_i (h_i^2 \rho - 2h_i \rho h_i + \rho h_i^2) = \mathcal{L}[\rho], \qquad (1)
$$

where $\mathcal L$ is a superoperator called the Lindblandian.

We now construct an alternative description of the operator dynamics Eq. [\(1\)](#page-1-0) by employing the Choi isomorphism, a mapping from an operator acting on the Hilbert space H to a state defined on the doubled Hilbert space $\mathcal{H}_u \otimes \mathcal{H}_l$, where subscripts u, l are introduced to distinguish two copies of H . For a given operator O , the mapping reads $O \mapsto ||O|| \equiv \sum_i |i\rangle \otimes (O|i\rangle)$, where the summation is over all basis states of the original Hilbert space $[53]$ (Sec. A). Under this mapping, the Lindbladian superoperator $\mathcal L$ maps to a linear operator $\mathcal H_{\mathcal L}$ acting on the doubled Hilbert space:

$$
\hat{\mathcal{H}}_{\mathcal{L}} = \frac{1}{2} \sum_{i} \left| h_i^T \otimes \mathbb{I} - \mathbb{I} \otimes h_i \right|^2 =: \frac{1}{2} \sum_{x,\lambda} \mathcal{O}_{x,\lambda}^\dagger \mathcal{O}_{x,\lambda}. \tag{2}
$$

where $|\dots|^2$ should be understood as $(\dots)^{\dagger}(\dots)$, and $\mathcal{O}_{\bm{x},\lambda} = (h_{\bm{x},\lambda}^T \otimes \mathbb{I} - \mathbb{I} \otimes h_{\bm{x},\lambda}).$ The average dynamics in Eq. (1) can then be recast into an imaginary time evolution generated by the effective Hamiltonian $\hat{\mathcal{H}}_{\mathcal{L}}$:

$$
\partial_t \| O \rangle = -\hat{\mathcal{H}}_{\mathcal{L}} \| O \rangle \quad \Rightarrow \quad \| O(t) \rangle = e^{-t\hat{\mathcal{H}}_{\mathcal{L}}} \| O_0 \rangle. \tag{3}
$$

We are interested in the dynamics of a local operator O under Brownian evolution, which we characterize by the averaged auto-correlation function $\mathbb{E}\langle O_{\bm{y}}(0)O_{\bm{x}}(t)\rangle_{\rho}$ [\[54\]](#page-6-6) with respect to the maximally mixed state $\rho = \frac{1}{D} \mathbb{I}$, where D is the dimension of the many-body Hilbert space.

Note that Eq. [\(2\)](#page-1-1) inherits translation invariance from the interaction terms, $h_{\mathbf{x},\lambda} = h_{\mathbf{x+1},\lambda}$. Therefore, we can label the eigenstates of $\mathcal{H}_{\mathcal{L}}$ by their momentum; let $\|\mathbf{k}, \nu\|$ be the eigenstates of $\mathcal{H}_{\mathcal{L}}$ with energy $E_{\mathbf{k},\nu}$, carrying momentum k and an additional label ν . Inserting a completeness relation, we obtain

$$
\mathbb{E}\langle O_{\mathbf{y}}(0)O_{\mathbf{x}}(t)\rangle_{\rho} = \frac{1}{D} \langle \langle O_{\mathbf{y}}(0) \| e^{-t\hat{\mathcal{H}}_{\mathcal{L}}} \| O_{\mathbf{x}}(0) \rangle \rangle
$$

$$
= \frac{1}{D} \sum_{\mathbf{k},\nu} e^{-tE_{\mathbf{k},\nu}} e^{i\mathbf{k} \cdot (\mathbf{y} - \mathbf{x})} |\langle \langle \mathbf{k}, \nu \| O_{\mathbf{x}} \rangle \rangle|^2. \tag{4}
$$

Consider a d-dimensional system. Assuming a gapless dispersion $\min_{\nu} \{ E_{\mathbf{k},\nu} \} \sim k^n$ at low momentum $\mathbf{k} \to 0$, as

well as a finite overlap $|\langle k, \nu | O_x \rangle|^2$ of the operator of interest $||O_x||$ with these gapless modes [\[55\]](#page-6-7), the autocorrelation at $x = y$ decays algebraically as

$$
\mathbb{E}\langle O_{\bm{x}}(t)O_{\bm{x}}(0)\rangle_{\rho} \underset{t \to \infty}{\sim} \int_{k} e^{-tk^{n}} \mathrm{d}^{d} \bm{k} \sim t^{-d/n}, \qquad (5)
$$

implying that the dynamical exponent $z = n$. Therefore, the study of late-time operator dynamics in the Brownian evolution reduces to the identification of gapless dispersing states in the effective Hamiltonian $\mathcal{H}_{\mathcal{L}}$.

Charge Conservation. We now assume that each h_i in the original Hamiltonian exhibits a U(1) charge conservation symmetry. In the doubled Hilbert space, the symmetry is doubled as well, and the effective Hamiltonian $\mathcal{H}_{\mathcal{L}}$ in Eq. [\(2\)](#page-1-1) must be symmetric under $G = U(1)_u \times U(1)_l$. We denote by G_{diag} and G_{off} the diagonal and offdiagonal subgroups of G, generated by $g_{\text{diag}/\text{off}} = \hat{Q}_u \otimes \mathbb{I}$ $\mathbb{I} \otimes \hat{Q}_l$, where \hat{Q} is the total charge operator [\[53\]](#page-6-5)(Sec. A).

First, we examine the ground states of $\mathcal{H}_\mathcal{L}$, which is positive semidefinite. The Choi state of the identity operator $\|I\|\$ satisfies $\mathcal{H}_{\mathcal{C}}\|I\|\$ = 0 and is thus a ground state of $\mathcal{H}_{\mathcal{L}}$. Due to U(1) symmetry, I decomposes into the summation over projectors onto different charge sectors: $\mathbb{I} = \sum_m \mathcal{P}_m$, where \mathcal{P}_m is the projector onto a $\mathbf{U}(1)$ sector of charge m. For a system with $N = L^d$ sites and local Hilbert space dimension $M, m \in \{0, 1, ..., ML^d\}$. We denote $\|m\|\rangle$ as the Choi state of \mathcal{P}_m . As such, $\|m\|\rangle$ is also a ground state of $\mathcal{H}_{\mathcal{L}}$ with vanishing G_{diag} charge and a G_{off} -charge of 2m. Note that $\langle\!\langle m||m\rangle\!\rangle = \dim[\mathcal{H}_m]$, the dimensionality of the charge-m sector. Moving forward, we renormalize $||m\rangle\!\rangle$ to $\langle\!\langle m||m\rangle\!\rangle = 1$.

The degenerate groundstate manifold with different G_{off} -charges implies spontaneous symmetry breaking of G_{off} . This can be shown explicitly by constructing a groundstate state $\|\theta\| \equiv \sum_m f(m)e^{im\theta} \|m\|$ such that under the rotation by G_{off} generator, $e^{i\alpha g_{\text{off}}} ||\theta\rangle = ||\theta + \theta||$ $\{\alpha\}\neq \{\theta\}.$ The low-energy excitations of $\mathcal{H}_\mathcal{L}$ must be given by the Nambu-Goldstone modes for the broken continuous symmetry. A standard approach for constructing Goldstone modes is to apply G_{off} density modulations with momentum k on the ground state $||m\rangle$. The variational ansatz for such a state is defined as

$$
||m_{\mathbf{k}}\rangle\!\rangle \equiv \frac{1}{\sqrt{\mathcal{N}_{\mathbf{k}}}}\hat{\rho}_{\mathbf{k}}||m\rangle\!\rangle, \quad \hat{\rho}_{\mathbf{k}} \equiv \sum_{\mathbf{x}} \frac{e^{i\mathbf{k}\cdot\mathbf{x}}}{L^{d/2}}(\hat{\rho}_{\mathbf{x},u} + \hat{\rho}_{\mathbf{x},l}),\tag{6}
$$

where $\hat{\rho}_{x,u/l}$ measures U(1) charge in the layer u or l at position x , and $\mathcal{N}_k \equiv \langle m \vert \vert \hat{\rho}_k^{\dagger} \hat{\rho}_k \vert \vert m \rangle$ is a static structural factor with $\rho_k^{\dagger} = \hat{\rho}_{-k}$. It straightforward to show that $\Vert m_k \rangle$ carries a well-defined momentum k and thus $\langle\langle m_{\mathbf{k}}|m_{\mathbf{k'}}\rangle = \delta_{\mathbf{k},\mathbf{k'}}$ [\[53\]](#page-6-5)(Sec. E). We remark that since $(\hat{\rho}_{x,u} + \hat{\rho}_{x,l})$ measures a local G_{off} -charge, the constructed mode corresponds to the density fluctuations of the G_{off} charge.

What is the energy of this variational state? With orthogonality between $\Vert m_{k}\rangle$ for different momenta, the variational expected energy provides an upper bound for the low-energy dispersion of Eq. (2) :

$$
\langle\!\langle m_{\mathbf{k}} \| \hat{\mathcal{H}}_{\mathcal{L}} \| m_{\mathbf{k}} \rangle\!\rangle = \frac{1}{\mathcal{N}_{\mathbf{k}}} \sum_{\mathbf{x},\lambda} \langle\!\langle m \| [\mathcal{O}_{\mathbf{x},\lambda}, \hat{\rho}_{\mathbf{k}}]^{\dagger} [\mathcal{O}_{\mathbf{x},\lambda}, \hat{\rho}_{\mathbf{k}}] \| m \rangle\!\rangle, \tag{7}
$$

where we used $\mathcal{O}_{\bm{x},\lambda}||m\rangle=0$. By using U(1) symmetry, the commutator in Eq. (7) can be recast as

$$
[\mathcal{O}_{\bm{x},\lambda},\hat{\rho}_{\bm{k}}] = e^{i\bm{k}\cdot\bm{x}} \sum_{\bm{y}\in\mathcal{S}_{\bm{x}}} \sum_{n=1}^{\infty} [\mathcal{O}_{\bm{x},\lambda}, \frac{[i\bm{k}\cdot(\bm{y}-\bm{x})]^n}{n!} \hat{\rho}_{\bm{y}}], \tag{8}
$$

where we used $[\mathcal{O}_{\bm{x},\lambda},\sum_{\bm{y}}\hat{\rho}_{\bm{y}}]=0$, and $\mathcal{S}_{\bm{x}}$ is the *local* support of the operator $\mathcal{O}_{\mathbf{x},\lambda}$ (thus warranting the expansion of $e^{i\mathbf{k}\cdot(\mathbf{y}-\mathbf{x})}$ for small \mathbf{k}). Generally, assuming a finite expectation value of the local dipole fluctuations $\langle\!\langle m|| |[O_{{\bm{x}},\lambda}, \sum_{{\bm{y}}} y_i \hat{\rho}_{\bm{y}}]| \rangle$ 2 ||m\), the expansion Eq. [\(8\)](#page-2-1) does not vanish at $n = 1$, giving rise to a leading order contribution proportional to k:

$$
[\mathcal{O}_{\bm{x},\lambda},\hat{\rho}_{\bm{k}}] \propto k \quad \Rightarrow \quad \langle m_{\bm{k}} || \hat{\mathcal{H}}_{\mathcal{L}} || m_{\bm{k}} \rangle \propto k^2. \tag{9}
$$

Here, we focus on isotropic systems for simplicity; however, dynamical exponents can be obtained similarly for non-isotropic systems. Furthermore, \mathcal{N}_k is a constant, independent of k [\[53\]](#page-6-5)(Sec. E). Therefore, $\Vert m_{\mathbf{k}} \rangle$ generically exhibits a quadratic $(E_k \propto k^2)$ dispersion, regardless of the details of the effective Hamiltonian. Note the similarity of our approach to the single-mode approximation in superfluid or quantum Hall states [\[56–](#page-6-8)[58\]](#page-6-9), where the Feynman-Bijl ansatz [\[53\]](#page-6-5)(Sec. D) provides variational states that capture the dispersion of density fluctuation excitations.

Long-Range Interactions. We extend our preceeding analysis to charge-conserving systems with long-range interactions. Specifically, we consider the effects of longrange terms in our Hamiltonian of the form $h_{x,x'} =$ $|x-x'|^{-\alpha}(\hat{S}_{\bm{x}}^{+}\hat{S}_{\bm{x}'}^{-}+h.c.),$ where $\hat{S}_{\bm{x}}^{\pm}$ are raising and lowering operators for the charge $\hat{\rho}_x$ at site x and $\hat{Q} = \sum_x \hat{\rho}_x$ is conserved. The effective Hamiltonian reads $\hat{\mathcal{H}}_c = \sum_{\mathbf{x}, \mathbf{y}'} \mathcal{O}_{\mathbf{x}, \mathbf{y}'}^{\dagger} \mathcal{O}_{\mathbf{x}, \mathbf{y}'}^{\dagger}$ and the commutator entering Eq. (7) $_{x,x'}\mathcal{O}_{x,x'}^{\dagger}\mathcal{O}_{x,x'}$ and the commutator entering Eq. [\(7\)](#page-2-0) becomes

$$
[\mathcal{O}_{\boldsymbol{x},\boldsymbol{x}'},\hat{\rho}_{\boldsymbol{k}}] = e^{i\boldsymbol{k}\cdot\boldsymbol{x}} \frac{(1 - e^{i\boldsymbol{k}\cdot(\boldsymbol{x}' - \boldsymbol{x})})}{|\boldsymbol{x} - \boldsymbol{x}'|^\alpha} \left[\tilde{\mathcal{O}}_{\boldsymbol{x},\boldsymbol{x}'},\hat{\rho}_{\boldsymbol{x}} \right], \quad (10)
$$

where $x, x' := \mathcal{O}_{x,x'} |x - x'|^{\alpha}$ is now distanceindependent. Assuming $\alpha > d/2$ and a finite expectation value for the square of the commutator on the RHS of Eq. [\(10\)](#page-2-2), the variational energy of $\|m_{\mathbf{k}}\rangle$ is [\[53\]](#page-6-5)(Sec. F)

$$
\langle\!\langle m_{\mathbf{k}} \| \hat{\mathcal{H}}_{\mathcal{L}} \| m_{\mathbf{k}} \rangle\!\rangle \underset{k \to 0}{\propto} C_1(\alpha) |k|^{2\alpha - d} + C_2(\alpha) k^2. \tag{11}
$$

Thus, for $\alpha < 1 + d/2$, the system relaxes superdiffusively with $z = 2\alpha - d$, successfully reproducing previous works on long-range interacting systems [\[17,](#page-5-3) [18,](#page-5-8) [59\]](#page-6-10). Alternatively, for $\alpha \le d/2$ the prefactors $C_1(\alpha)$ and $C_2(\alpha)$

exhibit divergences and the associated modes become gapped $[53]$ (Sec. F); accordingly, the operator decays exponentially fast [\[17\]](#page-5-3), entering an effectively nonlocal "allto-all" interacting regime.

Dipole Conservation. The method outlined above also applies to systems with conserved quantities beyond $U(1)$ charges. Let us focus on one-dimensional models with charge multipole symmetries, as relevant to frac-ton systems [\[60–](#page-6-11)[68\]](#page-6-12), generated by $Q^{(n)} \equiv \sum_{x} x^{n}$ P $\hat{\rho}_x$ = ${}_{x}x^{n}(\hat{\rho}_{x,u} + \hat{\rho}_{x,l})$. Concretely, we consider Brownian time evolution conserving the first two multipole moments $n = 0$ and $n = 1$, i.e. $[h_i, Q^{(0)}] = [h_i, Q^{(1)}] = 0$. This combination of charge and dipole symmetries generally leads to Hilbert space fragmentation [\[33,](#page-5-7) [34,](#page-5-9) [69\]](#page-6-13): For a given symmetry sector $Q^{(0)}, Q^{(1)}$ labeled by the different charge and dipole values, there are numerous distinct Krylov sectors, K , connected by the Hamiltonian evolution. Our goal is to understand the associated Krylov-space-resolved hydrodynamics in such systems. For this purpose, we introduce the operator $\mathcal{P}_\mathcal{K}$ projecting onto an individual Krylov sector, K , and its Choi state $\|\mathcal{K}\rangle$, which we define to be normalized. In the doubled Hilbert space formalism, we thus define new excited states, $\|\mathcal{K}_k\right) = \hat{\rho}_k \|\mathcal{K}\rangle / (\mathcal{N}_k^{\mathcal{K}})^{1/2}$, where $\hat{\mathcal{H}}_{\mathcal{L}} \|\mathcal{K}\rangle = 0$ and $\mathcal{N}_k^{\mathcal{K}} \equiv \langle K \vert \vert \hat{\rho}_k^{\dagger} \hat{\rho}_k \vert \vert \mathcal{K} \rangle$ is the Krylov-resolved structure factor.

In the presence of both charge and dipole conservation symmetries, the commutator in Eq. [\(8\)](#page-2-1) now vanishes at $n = 1$, and takes a finite value only at order $n \geq 2$. Accordingly, the excited modes $\|\mathcal{K}_k\|$ carry an energy $E_k = \langle K_k || \hat{H}_{\mathcal{L}} || K_k \rangle \rangle \propto \frac{1}{N_k^{\mathcal{K}}} k^4$. For generic dipoleconserving systems featuring \ddot{weak} fragmentation, the largest Krylov sector \mathcal{K}_0 makes up a finite portion of the full Hilbert space (up to a prefactor algebraic in system size). As a consequence, its static structure factor $\mathcal{N}_k^{\mathcal{K}_0} \to \mathcal{O}(1)$ remains finite as $k \to 0$. We thus obtain subdiffusive relaxation with dynamical exponent $z = 4$. The generalization of this result to systems conserving ${Q^{(0)},...,Q^{(m)}}$ multipoles is straightforward: The com-mutator in Eq. [\(8\)](#page-2-1) now vanishes up to order $n = m$, giving rise to a dispersion proportional to $k^{2(m+1)}$ and dynamical exponent $z = 2(m + 1)$, in accordance with previous results [\[22](#page-5-10)[–25,](#page-5-11) [70,](#page-6-14) [71\]](#page-6-15).

Similar to the charge-conserving case, these results can be extended to long-range interacting systems in arbitrary dimensions. For example, consider power-law decaying dipole hopping terms $h_{\mathbf{x},\mathbf{x}'} \sim \frac{1}{|\mathbf{x}-\mathbf{x}'|^\alpha} (D_{\mathbf{x}}^\dagger D_{\mathbf{x}'} + \text{h.c.}),$ where $D_{\mathbf{x}}$ is a local operator lowering the dipole moment. When $\alpha > \frac{d}{2}$, we determine the dispersion to be $E_{\mathbf{k}} \sim C_1(\alpha) k^{2\alpha+2-d} + C_2(\alpha) k^4$ [\[53\]](#page-6-5)(Sec. F). Therefore, if $\alpha < 1 + d/2$, charge spreads faster than the subdiffusive transport $z = 4$ of short-range systems. For $\alpha < \frac{d}{2}$, dipole hopping becomes highly non-local, and charge transport effectively arises from individual local dipole creation/annihilation terms, analogous to systems with conventional charge conservation. In our framework,

FIG. 2. Relaxation dynamics in multipole-conserving systems with long-range interactions. Systems with $\frac{1}{r^{\alpha}}$ power-law decaying hopping of local multipoles of order m exhibit three distinct dynamical regimes. When $\alpha > \frac{d}{2} + 1$ (orange), the dynamics is (sub)diffusive with dynamical exponent $z = 2(m + 1)$. For $\frac{d}{2} + 1 > \alpha > \frac{d}{2}$ (blue), the dynamics is faster, with dynamical exponent $z = 2(m +$ α) – d. When $\alpha \leq \frac{d}{2}$, the system is effectively non-local, thus, relaxation occurs from individual m-th multipole creation/annihilation operators, which are hoppings of $(m-1)$ th multipole charges. This results in (sub)diffusive transport with $z = 2(m - 1) + 2 = 2m$.

after renormalizing the single-mode dispersion to be bounded [\[53\]](#page-6-5)(Sec. F), we obtain $E_k \sim k^2$. We provide a summary of the dynamical exponents emerging in multipole-conserving systems with such long-range hopping of local moments in Fig. [2.](#page-3-0)

Constrained dynamics. Returning to short-range models with dipole-conservation, we may ask whether relaxation differing from the subdiffusive behavior $z = 4$ can emerge in specific Krylov sectors. The presence of the structure factor in the dispersion of Eq. [\(7\)](#page-2-0) suggests this may be the case in Krylov sectors where charge fluctuation follow a sub-volume law with vanishing $\lim_{k\to 0} \mathcal{N}_k^{\mathcal{K}} = 0$. We demonstrate this effect in concrete examples below.

Let us first consider a one-dimensional chain with charge and dipole conservation and introduce bond variables \hat{e}_x defined via $\hat{\rho}_x = \hat{e}_x - \hat{e}_{x-1}$, i.e. $\hat{e}_x = \sum_{i=0}^x \hat{\rho}_i$. For convenience, we define the charge density $\hat{\rho}_x$ relative to its average value within K, i.e. $\sum_{x} \langle \hat{\rho}_x \rangle_{\mathcal{K}} = 0$. We note that the \hat{e}_i can be understood as a local dipole density, with $\sum_{x} \hat{e}_x = Q^{(1)}$ [\[27,](#page-5-12) [72,](#page-6-16) [73\]](#page-6-17). Let us now assume that a sector K exhibits *bounded* fluctuations of these bond variables. Formally, $\lim_{L\to\infty} \langle \hat{e}_k \hat{e}_{-k} \rangle_{\mathcal{K}} \xrightarrow{k\to 0} \sigma_1^2 < \infty$, where $\hat{e}_k = \frac{1}{\sqrt{2}}$ $\frac{1}{L} \sum_{x} e^{ikx} \hat{e}_x$ and σ_1 corresponds to the average fluctuation of the local dipole density. Since $\hat{e}_x = \sum_{i=0}^x \hat{\rho}_i$, the finiteness of \hat{e}_x implies area-law fluctuations of the total charge within any given region. Using that $\hat{\rho}_k = (1 - e^{-ik})\hat{e}_k$ for $k \neq 0$, the structure factor for small k becomes

$$
\mathcal{N}_k^{\mathcal{K}} = \langle \hat{\rho}_k \hat{\rho}_{-k} \rangle_{\mathcal{K}} = k^2 \langle \hat{e}_k \hat{e}_{-k} \rangle \to \sigma_1^2 k^2. \tag{12}
$$

Therefore, for Krylov sectors satisfying Eq. [\(12\)](#page-3-1), the energy of the excited mode $\|\mathcal{K}_k\rangle$ scales as $E_k \propto k^2$ and we expect diffusive relaxation, despite the presence of dipole-conservation. To interpret this result, note that the \hat{e}_x constitute a conserved local density with an effectively finite local state space due to their bounded fluctuations. If \hat{e}_x is bounded, these local dipoles move without additional kinetic constraints and are thus expected to relax diffusively, see also Ref. [\[72\]](#page-6-16). Generalization to systems conserving $\{Q^{(0)},...,Q^{(m)}\}$ is again straightforward: Krylov sectors with bounded multipole densities up to order $p \leq m$ have $\mathcal{N}_k \to \sigma_p^2 k^{2p}$, leading to a dispersion $\propto k^{2(m-p+1)}$ in short-range systems.

As a concrete example of Eq. (12) , we consider random Brownian evolution in a $S = 1$ spin chain with local dipole-conserving terms $h_i = \hat{S}_i^+ (\hat{S}_{i+1}^-)^2 \hat{S}_{i+2}^+ + \text{h.c.}.$ Although these terms induce a strong fragmentation of the Hilbert space, there exist exponentially large, delocalized Krylov sectors [\[33,](#page-5-7) [35\]](#page-5-13). We label the local charge density by $\rho_x = S_x^z \in \{0, \pm\}$ and consider the Krylov sector containing the initial state $|\psi_0\rangle = |...00 + 00...\rangle$. In terms of the variables \hat{e}_x introduced above, $|\psi_0\rangle = |...00111... \rangle$ corresponds to a domain wall, and the $\hat{e}_x \in \{0,1\}$ can be shown to take values in a bounded range [\[33\]](#page-5-7), thus satisfying our condition Eq. [\(12\)](#page-3-1). Diffusive relaxation of this state has indeed been found in Ref. [\[72\]](#page-6-16), and $\mathbb{E}\langle S_{x=L/2}^z(t)\rangle \sim t^{-1/2}$ can be verified numerically using random classical time evolution, as illustrated in $[53]$ (Sec. G).

To illustrate the generality of the condition Eq. [\(12\)](#page-3-1), we consider systems beyond 1D. In analogy to $d=1$, for $d>1$ we write $\hat{\rho}(\boldsymbol{x})=\nabla \cdot \hat{\boldsymbol{e}}(\boldsymbol{x})$, where $\hat{\mathbf{e}}(\mathbf{x}) = (\hat{e}_1(\mathbf{x}), ..., \hat{e}_d(\mathbf{x}))$ is now a d-component vector. We recognize that $\hat{e}(x)$ is not uniquely determined by the charge configuration $\hat{\rho}(\boldsymbol{x})$, and the relation between these variables takes the form of a $U(1)$ Gauss law, where the $\hat{e}(x)$ constitute electric field degrees of freedom. Indeed, area-law charge fluctuations arise in $U(1)$ gauge theories if fluctuations of the electric fields $\hat{e}(x)$ are bounded, as $\int_V dV \hat{\rho}(\boldsymbol{x}) = \int_{\partial V} d\boldsymbol{A} \cdot \hat{\boldsymbol{e}}(\boldsymbol{x})$. Thus, imposing global dipole conservation on $U(1)$ link models [\[74](#page-6-18)[–76\]](#page-6-19) with a finite electric field state space gives rise to diffusive behavior through Eq. (12) . To verify this prediction, we numerically simulate classical, discrete random time evolution in a hard-core dimer model on a square lattice (see Fig. [3a](#page-4-1)), which can be mapped to a $U(1)$ link model [\[77,](#page-6-20) [78\]](#page-6-21). Under this mapping, a site x without any attached dimer carries a charge $\hat{\rho}(\boldsymbol{x}) = (-1)^{x_1+x_2}$ at $\boldsymbol{x} = (x_1, x_2)$, while a site with an attached dimer carries no charge. In the dynamics carried out numerically (see [\[53\]](#page-6-5) Sec. G, as well as Refs. [\[21,](#page-5-5) [24,](#page-5-14) [25,](#page-5-11) [70\]](#page-6-14) for related approaches), we then explicitly incorporate conservation of the dipole moment associated to $\hat{\rho}(\boldsymbol{x})$. Starting from an initial state with an isolated positive charge in the bulk of the system $\hat{\rho}(\mathbf{x}, t=0) = \delta_{x_1,0} \, \delta_{x_2,0}$ (see Fig. [3a](#page-4-1)), we numerically find a diffusive broadening of the resulting charge distribution at late times. As the overall charge density in the system vanishes, and positive and negative charges

FIG. 3. Relaxation dynamics in a dipole-conserving dimer model. a) We numerically consider a classical, discrete random time evolution in a dimer model with hard-core constraint, i.e. maximally one dimer attached to each site in the square lattice. This model can be mapped onto a $U(1)$ link model following Refs. [\[74–](#page-6-18)[76\]](#page-6-19). Under this mapping, vacancies, i.e. sites without attached dimer, carry positive (blue spheres) or negative charge (orange spheres), depending on their sublattice. We explicitly incorporate preservation of the hard-core constraint, the total charge, and the dipole moment associated with these charges in the time evolution. b) Decay of the charge density $\bar{\rho}(0, t)$ for an isolated positive charge initially placed at $x = 0$ in the bulk of the system: see a). The decay is consistent with diffusion in two dimensions. c) Scaling collapse of the charge distribution at different times along $\bar{\rho}(\boldsymbol{x} = (x, 0), t)$, indicating Gaussian diffusion. Numerical results were averaged over 3×10^6 runs of the random time evolution [\[53\]](#page-6-5)(Sec. G).

occupy different sublattices, we consider the quantity $\bar{\rho}(x_1, t) \equiv \hat{\rho}((x_1, 0), t) + \hat{\rho}((x_1 - 1, 0), t)$. We show in Fig. [3c](#page-4-1) that $t\bar{\rho}(x_1,t)$ exhibits a scaling collapse when plotted and $\ell_{\mathcal{P}}(x_1, y)$ cannotes a setting complete with relaxation in two dimensions.

Conclusion and Outlook. In this work we have established a comprehensive understanding of conserved operator dynamics under Brownian random unitary time evolution through a duality with the spectral properties of an associated effective Hamiltonian. Though the $U(1)$ symmetric Brownian evolution was used for clarity of presentation, these results generalize for any dynamics conserving a continuous global symmetry governed by a Lindblad equation $[53]$ (Sec. C). As the groundstate manifold always exhibits a spontaneous symmetry breaking of a con-

tinuous symmetry, a single-mode approximation could be applied to capture the low energy physics of this effective Hamiltonian to reproduce a number of dynamical universality classes for short- and long-range interacting systems with charge and multipole conservation laws. In addition, our formalism allowed us to study the Krylovspace-resolved hydrodynamics of dipole-conserving systems, establishing diffusive behavior in Krylov spaces with area law charge fluctuations, in contrast to more generic dynamics in the presence of dipole conservation.

We expect that such diffusive relaxation in dipoleconserving systems is valid beyond the specific examples studied numerically here and holds whenever the time evolution proceeds within an effective state space (not necessarily a Krylov space) that fulfills Eq. (12) . In particular, bounded fluctuations of the variables \hat{e}_x can arise from energetics, for example via a term $\sim (\hat{e}_x)^2$ in the Hamiltonian, as appears naturally in standard electromagnetism. In this context, the resulting area-law charge fluctuations can be interpreted as Coulomb repulsion, which consequently leads to diffusive relaxation in dipoleconserving systems. Furthermore, bounded charge fluctuations occur in many other interesting models: It was shown in Refs.[\[73,](#page-6-17) [79\]](#page-6-22) that area law charge fluctuations can arise in dipole-conserving Bose-Hubbard models in low-energy Mott states whenever a finite energy gap exists for charged excitations. It would be interesting to study the relevance of our results to such systems in the future.

Note added: While finalizing this work, we became aware of independent related works [\[80,](#page-6-23) [81\]](#page-6-24). The previous version [\[82\]](#page-6-25) considered an unbounded single-mode dispersion for effectively all-to-all interacting models, leading to ultra-fast relaxation. Renormalizing the dispersion to be bounded results in a finite dynamical exponent for $\alpha_0 \leq d/2$ as shown in Fig. [2.](#page-3-0)

CONTENTS

Appendix A: Doubled Hilbert Space Formalism

In this section, we provide a brief introduction to the Choi isomorphism and doubled Hilbert space formalism. For a given Hermitian operator $O = \sum_j \lambda_j |\psi_j\rangle\langle\psi_j|$ acting on the Hilbert space H (such as a physical observable or density matrix), the Choi state $||O||$ [\[51,](#page-6-3) [52\]](#page-6-4) is defined in a doubled Hilbert space $\mathcal{H}_d = \mathcal{H}_u \otimes \mathcal{H}_l$ as follows:

$$
\|\mathbb{I}\rangle := \sum_{i} |i\rangle_{u} \otimes |i\rangle_{l}
$$

$$
\|\mathcal{O}\rangle := (\mathbb{I} \otimes \mathcal{O})\|\mathbb{I}\rangle = \sum_{i} |i\rangle_{u} \otimes \mathcal{O}|i\rangle_{l}
$$

$$
= \sum_{f} \lambda_{j} |\psi_{j}^{*}\rangle_{u} \otimes |\psi_{j}\rangle_{l} = (\mathcal{O}^{T} \otimes \mathbb{I})\|\mathbb{I}\rangle_{h}, \qquad (A1)
$$

where subscripts u, l is introduced to distinguish two copies of H. Also, note that $(A \otimes B) \parallel \mathbb{I} \rangle = (AB^T \otimes \mathbb{I}) \parallel \mathbb{I} \rangle =$ (^I [⊗] BA^T)∥I⟩⟩. Therefore, under Choi Isomorphism, $AOB \rightarrow (B^T \otimes A) \parallel O \rangle$. Note that, for a given Choi state $||O\rangle$, its operator form can then be obtained by taking an overlap with a states $||i, j|| \equiv |i\rangle \otimes |j\rangle \in \mathcal{H}_d$:

$$
\langle\!\langle i,j| | O \rangle\!\rangle = \langle j| O | i \rangle. \tag{A2}
$$

The Choi state automatically respects the following symmetry:

$$
SWAP^* \equiv \mathcal{C} \circ SWAP,\tag{A3}
$$

where the SWAP symmetry exchanges \mathcal{H}_u and \mathcal{H}_l , and $\mathcal C$ is the complex-conjugation symmetry. This operation corresponds to Hermitian conjugation in the operator language.

Similarly, under the Choi isomorphism, a quantum channel acting on the space of linear operators defined on H would map into a linear operator (not necessarily Hermitian) defined on \mathcal{H}_d , namely the *Choi operator*. For a generic quantum channel $\mathcal E$ with Kraus representation $\{K_i\}$ ($\mathcal{E} : \rho \mapsto \sum_i K_i \rho K_i^{\dagger}$), its Choi operator form is defined as the following:

$$
\mathcal{E} \mapsto \hat{\mathcal{E}} \equiv \sum_{i} K_i^* \otimes K_i. \tag{A4}
$$

For example, the averaged action of the Brownian time evolution in Eq.(1) from the main text would be mapped into a Lindbladian operator acting on the doubled Hilbert space under the Choi isomorphism.

Turning to symmetry constraints, let G be the symmetry group acting on the original Hilbert space H . Then, the Choi state will enjoy a doubled symmetry group $G_u \times G_l$. We remark that the symmetry representation of $g \in G$ in the upper Hilbert space, \mathcal{H}_u , is defined as a complex-conjugated version of the original representation, $U^*(g)$. Accordingly,

$$
|\Psi\rangle \mapsto (U^*(g_u) \otimes U(g_l))|\Psi\rangle \quad \forall g_u \cdot g_l \in G_u \times G_l. \tag{A5}
$$

Appendix B: Brownian Circuit and the Lindbladian

In the body of this paper, we chose a specific type of Brownian circuit in order to demonstrate charge transport in a clear manner. Here, we will derive the Choi operator for the averaged dynamics of a general Brownian circuit. The most general Brownian circuit employs random variables $\{dB_i\}$ for the timeslice $[t, t + \Delta)$ such that the first moment $\mathbb{E}[dB_i] = \mu_i$ and the second moment $\mathbb{E}[dB_idB_j] = \mu_i\mu_j + \delta_{ij}/\Delta$. Using these variables, the Hamiltonian at time slice $[t, t + \Delta)$ is defined as $H_t \equiv \sum_i h_i dB_{i,t}$, so that a density matrix ρ_t evolves as

$$
e^{-iH_t\Delta}\rho_t e^{iH_t\Delta} = \rho_t - i\Delta \sum_i [h_i, \rho_t] dB_i
$$

$$
-\frac{\Delta^2}{2} \sum_{i,j} [h_i, [h_j, \rho_t]] dB_i dB_j + \cdots. \tag{B1}
$$

This allows one to characterize the expected continuoustime dynamics of ρ_t as

$$
\mathbb{E}[\partial_{\tau}\rho] \equiv \lim_{\Delta \to 0} \frac{\mathbb{E}[\rho_{t+\Delta} - \rho_t]}{\Delta} \n= \sum_{i} \left(-i\mu_i[h_i, \rho] - \frac{1}{2}[h_i, [h_i, \rho]] \right) \n= \sum_{i} \left(-i\mu_i(h_i \rho - \rho h_i) - \frac{1}{2}(h_i^2 \rho - 2h_i \rho h_i + \rho h_i^2) \right).
$$
\n(B2)

Employing the Choi isomorphism explained in the previous section, we can recast the operator ρ_t as a state vector in a doubled Hilbert space, $\|\rho_t\|$. Similarly, the above action of averaged time evolution, which can be understood as a quantum channel, can be recast into a linear operator $\mathcal{H}_{\mathcal{L}}$ acting on the doubled state as $\partial_{\tau} || \rho \rangle = -\mathcal{H}_{\mathcal{L}} || \rho \rangle$ where

$$
\hat{\mathcal{H}}_{\mathcal{L}} = \sum_{i} i\mu_{i} (h_{i}^{T} \otimes \mathbb{I} - \mathbb{I} \otimes h_{i}) + (h_{i}^{T} \otimes \mathbb{I} - \mathbb{I} \otimes h_{i})^{2}
$$

$$
= \sum_{i} (i\mu_{i} \mathcal{O}_{i} + \mathcal{O}_{i}^{\dagger} \mathcal{O}_{i}), \tag{B3}
$$

where $\mathcal{O}_i \equiv h_i^T \otimes \mathbb{I} - \mathbb{I} \otimes h_i$. At $\mu_i = 0$, we recover Eq.(3) in the main text.

In fact, a similar structure is obtained from the master equation in Lindblad from, where the time evolution of the density matrix (or operator) is given as

$$
\dot{\rho} = -i[H, \rho] + \sum_{i} \gamma_i \left(L_i \rho L_i^{\dagger} - \frac{1}{2} \{ L_i^{\dagger} L_i, \rho \} \right). \tag{B4}
$$

Under the Choi isomorphism, the RHS can be expressed as the action of the following linear operator $\mathcal{H}_{\mathcal{L}}$ on $\|\rho\|$:

$$
\hat{\mathcal{H}}_{\mathcal{L}} = -i \left(H^T \otimes \mathbb{I} - \mathbb{I} \otimes H \right) \n- \sum_{i} \frac{\gamma_i}{2} \left(2L_i^* \otimes L_i - (L_i^{\dagger} L_i)^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i^{\dagger} L_i \right),
$$
\n(B5)

where H is the system Hamiltonian, L_i are the jump operators, and $\gamma_i \geq 0$ are the damping weights. When the jump operators are Hermitian up to a phase, i.e. $L_i^{\dagger} =$ $e^{i\theta}L_i$, and we set $H=0$, we see a familiar form:

$$
\hat{\mathcal{H}}_{\mathcal{L}} = \sum_{i} \frac{\gamma_i}{2} |L_i^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i|^2 = \frac{1}{2} \sum_{\mathbf{x},\nu} \tilde{\mathcal{O}}_{\mathbf{x},\nu}^\dagger \tilde{\mathcal{O}}_{\mathbf{x},\nu}, \quad (B6)
$$

where $\tilde{O}_{i=(\bm{x},\nu)} = L_i^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i$. Thus, in a system obeying Lindbladian dynamics governed by hermitian jump operators, our results should hold. The intuition about why such a system would imitate random Brownian evolution comes from the fact that these conditions imply that the relevant system dynamics all come from interactions with an infinite-temperature environmental bath.

Appendix C: Generalization

In the main body of the paper, we have discussed the Brownian dynamics essentially captured by Eq. [\(B4\)](#page-8-3) with $H = 0$ and $L = e^{i\theta} L^{\dagger}$. In the following, we relax this condition and investigate how this gives rise to non-Hermitian effective Hamiltonian.

1. Discrete Evolution

First, we remark that the averaged dynamics in the doubled Hilbert space can be expressed as

$$
e^{-\hat{\mathcal{H}}_{\mathcal{L}}dt} := \int dB_t p(dB_t) \big(e^{-ih^T(dB_t)dt} \otimes e^{-ih(dB_t)dt} \big)
$$
\n(C1)

where $p(dB_t)$ is the probability distribution for the Brownian random variable dB_t . The above expression can be immediately extended to any random local-unitary ensemble $\mathcal{U} = \{(p(U), U)\}\$ where each U conserves a desired symmetry (e.g. $U(1)$) by replacing a continuous time evolution by a discrete-time evolution, where its averaged dynamics for each time step is captured as

$$
e^{-\mathcal{H}} = \int dU p(U) (U^T \otimes U). \tag{C2}
$$

Note that the RHS has its eigenvalue magnitudes always equal or smaller than 1, implying that $\mathcal{H} \geq 0$. Now, the late-time averaged dynamics of this random ensemble U is captured by the low energy spectrum of the effective Hamiltonian H , since after the application of this random unitary circuit layers $T \gg 1$ times, the Choi states with small eigenvalues against H would survive.

2. Quantum Coherent Terms

Second, for more generic Lindbladian evolution, we loosen the restrictions imposed by Brownian evolution and add quantum-coherent terms to our Lindbladian to examine the effects on our dynamics. To do so, we re-turn to Eq. [\(B3\)](#page-8-4) with $\mu_i \neq 0$ or Eq. [\(B4\)](#page-8-3) with $H \neq 0$. Treating each term separately, we get

$$
\hat{\mathcal{H}}_{\mathcal{L}} = iH_1 + H_2
$$
\n
$$
H_1 = -(H^T \otimes \mathbb{I} - \mathbb{I} \otimes H)
$$
\n
$$
H_2 = \sum_i \frac{\gamma_i}{2} \left(L_i^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i \right)^{\dagger} \left(L_i^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i \right)
$$
\n(C3)

where H_1 and H_2 are Hermitian operators. Note that H_2 is positive semi-definite and [∥]I⟩⟩ is the ground state with zero energy, i.e., $H_1 \parallel \mathbb{I} \rangle = H_2 \parallel \mathbb{I} \rangle = 0$. This is because

$$
(O \otimes \mathbb{I}) \|\mathbb{I}\rangle = (\mathbb{I} \otimes O^T) \|\mathbb{I}\rangle. \tag{C4}
$$

When $H_2 = 0$, and H_1 respects translational symmetry strongly [\[83\]](#page-6-26), the evolution is entirely coherent, and we would expect charge dynamics to be ballistic due to momentum conservation. However, when $H_1 = 0$, as shown in the main text, charge dynamics would be diffusive.

Although we cannot apply variational estimates for the non-Hermitian Hamiltonian, let us attempt to understand what would happen if both coherent (H_1) and stochastic (H_2) terms are present. We would assume that each component is independently symmetry preserving: $[H_{1,2}, Q_{\text{diag}}] = 0$ (this condition is equivalent to $[H,Q] = [L_i, Q] = 0$. These two components may not commute; however, due to translation invariance, they should still have a spectrum parameterized by momentum eigenstates as $E_{\mathbf{k},\nu} = if_1(\mathbf{k},\nu) + f_2(\mathbf{k},\nu)$. As such, the autocorrelation function should take the form:

$$
\mathbb{E}\langle O_{\mathbf{y}}(t)O_{\mathbf{x}}(0)\rangle_{\rho} \propto \sum_{\mathbf{k},\nu} e^{i\mathbf{k}\cdot\Delta\mathbf{x}-if_1(\mathbf{k},\nu)t} e^{-tf_2(\mathbf{k},\nu)} |\langle\langle \mathbf{k},\nu||O_{\mathbf{x}}\rangle\rangle|^2
$$
 (C5)

where $\Delta x = y - x$. Now if we assume that $f_1(\mathbf{k}, \nu) \approx$ $c_{\nu} \mathbf{k} + \dots$ is approximately linear for small k, and $f_2(\mathbf{k}, \nu) \sim k^{\beta}$, then we obtain just what we might expect: a decay determined by the real part, yielding an expected decay, but with one operator in the autocorrelation shifted by distance $\Delta x = c_{\nu} t$

$$
\mathbb{E}\langle O_{\bm{x}-\bm{c}_{\bm{\nu}}\bm{t}}(t)O_{\bm{x}}(0)\rangle_{\rho} \underset{t\to\infty}{\sim} \int_{k} e^{-t(E_{0}+k^{\beta})} \mathrm{d}^{d}\bm{k} \sim \frac{e^{-tE_{0}}}{|t|^{d/\beta}}.
$$
\n(C6)

Now, let us evaluate real and imaginary components using variational states defined in the main text:

$$
\langle m_{\mathbf{k}} || \hat{\mathcal{H}}_{\mathcal{L}} || m_{\mathbf{k}} \rangle = i \langle m_{\mathbf{k}} || H_1 || m_{\mathbf{k}} \rangle + \langle m_{\mathbf{k}} || H_2 || m_{\mathbf{k}} \rangle
$$

\n
$$
= i \langle m || \rho_{-k} [H_1, \rho_k] || m \rangle
$$

\n
$$
+ \sum_{i, \lambda} \langle m || [\mathcal{O}_{i, \lambda}, \rho_k]^{\dagger} [\mathcal{O}_{i, \lambda}, \rho_k] || m \rangle
$$

\n
$$
\approx_{k \to 0} i C_1 k + C_2 k^2
$$
 (C7)

The first term is linear in k for a generic H_1 because $[H_1, \rho_k] = \sum_{n,x} \frac{(ikx)^n}{n!}$ $\frac{f(x)}{n!}[H_1,\rho_x],$ and the $n=0$ term vanishes due to symmetry. Naively, this would seem to give a ballistically spreading front; however, we have to be careful when applying our variational estimate. While it is still true that our variational modes may bound the real spectrum arising from H_2 , the imaginary component coming from H_1 should not have any such bound. Instead, the imaginary component of the spectrum will generically either be gapped or have a linear dispersion. Expanding to the lowest order, we have $f_1(\mathbf{k}, \nu) \approx c_{0,\nu} + c_{\nu} \mathbf{k} + \dots$, where $c_{0,\nu}$ can be zero.

A non-zero $c_{0,\nu}$ is generically expected, resulting in diffusion with some form of oscillating phase factor:

$$
\mathbb{E}\langle O_{\mathbf{y}}(t)O_{\mathbf{x}}(0)\rangle_{\rho} \underset{t \to \infty}{\sim} \int_{k} e^{i(k\Delta x - C_{1}t)} e^{-tC_{2}k^{2}} dk \quad \text{(C8)}
$$

$$
\sim e^{-iC_{1}t} \frac{e^{-\frac{(\Delta x)^{2}}{4C_{2}t}}}{\sqrt{C_{2}t}}.
$$

To make this more precise, we need to bring up an important fact about Lindbladians. Because they preserve hermiticity (as encoded by the SWAP symmetry in Sec. A, which is complex-conjugation symmetry in the operator

formalism), any complex-valued eigenstates of our effective Hamiltonian, $\hat{\mathcal{H}}_{\mathcal{L}}$, must come in conjugate pairs. As such, there will always exist an index ν' such that, at lowest order, the spectrum is $E_{\mathbf{k},\nu'} = iC_{1,\nu'} + C_{2,\nu'}k^2$, where $C_{1,\nu'} = -C_{1,\nu}, C_{2,\nu'} = C_{2,\nu}.$ Thus, we obtain multiple spreading fronts, so that, summing over these pairs

$$
\mathbb{E}\langle O_{\mathbf{y}}(t)O_{\mathbf{x}}(0)\rangle_{\rho} \underset{t \to \infty}{\sim} \sum_{\nu \neq \nu'} \frac{\cos\left(C_{1,\nu}t\right)e^{-\frac{(\Delta x)^2}{4C_{2,\nu}t}}}{\sqrt{C_{2,\nu}t}}, \quad \text{(C9)}
$$

which gives a diffusive dynamics with an oscillating prefactor.

3. Non-Hermitian Jump Operators

Finally, what if $L_i^{\dagger} \neq e^{i\theta} L_i$ for any θ ? To proceed, we have to understand the non-Hermitian nature of $\hat{H}_{\mathcal{L}}$ better. As a non-Hermitian Hamiltonian, $\mathcal{H}_{\mathcal{L}}$ will generically have different left and right eigenvectors $\langle L_{\alpha} \rangle$ and $\|R_{\alpha}\rangle$ for the shared eigenvalue ϵ_{α} . Although generically right (left) eigenvectors are not orthogonal to each other, they satisfy a biorthonormality:

$$
\langle L_{\alpha} || R_{\beta} \rangle = \delta_{\alpha\beta}.
$$
 (C10)

Thus, if we wish to describe to the evolution of an operator $\langle O(t) \rangle = \text{tr}(O\rho(t)) = \langle O||e^{-t\hat{H}_{\mathcal{L}}}||\rho \rangle$, we may choose to study late-time dynamics in the Schrodinger picture by focusing on right eigenvectors with ground state $\|\rho_{eq}\rangle$, or in the Heisenberg picture by focusing on left eigenvectors with ground state ⟨⟨I∥.

To carry out further analysis, we switch from density matrix evolution to operator evolution. This is because the steady state for density matrix evolution is generically not the maximally mixed state I, yet that of operator evolution always is due to the trace-preserving nature of the Lindbladian dynamics.

$$
\text{tr}(\rho(t)) = \langle \langle \mathbb{I} \| \rho(t) \rangle \rangle = 1
$$

\n
$$
\Rightarrow \partial_t \langle \langle \mathbb{I} \| \rho \rangle \rangle = \langle \langle \mathbb{I} \| \mathcal{H}_\mathcal{L} \| \rho \rangle \rangle = 0
$$
 (C11)

Since this holds for any density matrix, $\|\rho\|$, it is clear that ⟨⟨I[∥] is a left-ground state. This ground state structure greatly simplifies our analysis, and since we care about the rates of decay, not the exact form of the equilibrium density matrix, we focus on operator evolution.

The operator evolution is given as

$$
\dot{O} = i[H, O] + \sum_{i} \gamma_{i} \left(L_{i}^{\dagger} O L_{i} - \frac{1}{2} \{ L_{i}^{\dagger} L_{i}, O \} \right)
$$

$$
= i[H, O] + \sum_{i} \frac{\gamma_{i}}{2} \left(\{ L_{i}^{h}, [O, L_{i}^{a}] \} - \{ L_{i}^{a}, [O, L_{i}^{h}] \} \right)
$$

$$
+ \sum_{i} \frac{\gamma_{i}}{2} \left([L_{i}^{h}, [O, L_{i}^{h}]] + [L_{i}^{a}, [O, L_{i}^{a}]] \right) \tag{C12}
$$

Where we have split the jump operator into hermitian and antihermitian components, $L_i = L_i^h + iL_i^a$,

where both L^h and L^a are hermitian. Using the Choi-Isomorphism, this can be translated into an effective Hamiltonian of the form

$$
\hat{\mathcal{H}}_{\mathcal{L}} = iH_1 + H_2
$$
\n
$$
H_1 = (H^T \otimes \mathbb{I} - \mathbb{I} \otimes H)
$$
\n
$$
+ \sum_{i} \frac{\gamma_i}{2} ((L_i^h)^T \otimes \mathbb{I} + \mathbb{I} \otimes L_i^h) (\mathbb{I} \otimes (L_i^a)^T - L_i^a \otimes \mathbb{I})
$$
\n
$$
- \sum_{i} \frac{\gamma_i}{2} ((L_i^a)^T \otimes \mathbb{I} + \mathbb{I} \otimes L_i^a) (\mathbb{I} \otimes (L_i^h)^T - L_i^h \otimes \mathbb{I})
$$
\n
$$
H_2 = \sum_{i} \frac{\gamma_i}{2} ((L_i^h)^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i^h)^2
$$
\n
$$
+ \sum_{i} \frac{\gamma_i}{2} ((L_i^a)^T \otimes \mathbb{I} - \mathbb{I} \otimes L_i^a)^2, \qquad (C13)
$$

where H_1 and H_2 are both Hermitian. Using [\(C4\)](#page-8-5), it quickly follows that $H_1 \parallel \mathbb{I}$ = $H_2 \parallel \mathbb{I}$ = 0. Given this, using the same logic as above, we see that the new iH_1 will generically contribute to an oscillating amplitude, now with additional influence from the jump operators L_i . Naively applying the variational estimate from the previous subsection, H_2 , the sum of two locally squared operators, will once more result in diffusion. However, a rigorous understanding of diffusive dynamics with this non-Hermitian effective Hamiltonian would require further study.

Appendix D: Feynman-Bijl Formula

The collective excitations described in the body of this paper closely mirror variational density fluctuation modes in bosonic systems, as described by the Feynman-Bijl formula [\[56–](#page-6-8)[58\]](#page-6-9). In this literature, low-lying modes are described by the variational wavefunction in the first quantized form,

$$
\psi_{\mathbf{k}} = \frac{1}{L^{d/2}} \hat{\rho}_{\mathbf{k}} \phi_0 = \frac{1}{L^{d/2}} \sum_{\mathbf{x}} e^{i\mathbf{k} \cdot \mathbf{x}} \phi_0, \quad (D1)
$$

where ϕ_0 is the exact ground state wavefunction. The difference between this original formulation and our construction is that our dispersing mode is written in second quantized form, where $\rho_k = \frac{1}{L^{d/2}} \sum_{\mathbf{x}} e^{i\mathbf{k} \cdot \mathbf{x}} \hat{\rho}_{\mathbf{x}}$. In addition, we chose to describe excitations over a specific ground state of fixed charge $||m\rangle$ or a Krylov sector $||\mathcal{K}\rangle$. Carrying on with the Feynman-Bijl derivation, the variational estimate for the energy of density fluctuation excitations is given by

$$
\epsilon_{\mathbf{k}} = \frac{\langle \psi_{\mathbf{k}} | H - E_0 | \psi_{\mathbf{k}} \rangle}{\langle \psi_{\mathbf{k}} | \psi_{\mathbf{k}} \rangle} = \frac{f(\mathbf{k})}{s(\mathbf{k})},\tag{D2}
$$

where E_0 is the exact ground state energy (which we set to zero). $f(\mathbf{k})$ is called the oscillator strength, which can be evaluated as

$$
f(\mathbf{k}) = \frac{1}{2L^d} \langle \phi_0 | \left[\hat{\rho}_{\mathbf{k}}^{\dagger}, [H, \hat{\rho}_{\mathbf{k}}] \right] | \phi_0 \rangle, \tag{D3}
$$

and $s(\mathbf{k})$ is the static structure factor:

$$
s(\mathbf{k}) = \langle \psi_{\mathbf{k}} | \psi_{\mathbf{k}} \rangle = \frac{1}{L^d} \langle \phi_0 | \hat{\rho}_{\mathbf{k}}^\dagger \hat{\rho}_{\mathbf{k}} | \phi_0 \rangle.
$$
 (D4)

In the context of superfluid Helium [\[56,](#page-6-8) [57\]](#page-6-27), the oscillator strength $f(\mathbf{k}) \sim k^2$ while the structural factor $s(\mathbf{k}) \sim k$, giving rise to the linear dispersion of the density fluctuation modes $E_k \sim k$.

For our problems of interest, the oscillator strength under the presence of m -th multipole conservation symmetry is given as $f(\mathbf{k}) \sim k^{2(m+1)}$ for short-range interactions, and $f(\mathbf{k}) \sim k^{2(m+\alpha)-d}$ for long-range interactions falling off as $1/r^{\alpha}$ when $\frac{d}{2} + 1 > \alpha > \frac{d}{2}$. On the other hand, the static structural factor is generically constant, as elaborated in the next section, unless there is a constraint on the magnitude of local multipole density fluctuations.

Appendix E: Orthonormal Basis States

In this section, we examine the orthonormality of constructed density fluctuation modes. Specifically, we examine the orthonormality of the excitations in a Krylov sector, $\mathcal{K},$

$$
\|\mathcal{K}_{\mathbf{k}}\rangle = \frac{1}{\sqrt{\mathcal{N}_{\mathbf{k}}^{\mathcal{K}}}} \hat{\rho}_{\mathbf{k}} \|\mathcal{K}\rangle. \tag{E1}
$$

As mentioned in the body of this paper, orthonormality plays an essential role in the construction of our variational modes in two respects. First, if orthogonality breaks down such that $\|\mathcal{K}_k\|$ has significant overlap with the ground state, our variational modes may display a gapless dispersion even when the spectrum of our effective Hamiltonian, $\mathcal{H}_{\mathcal{L}}$, is gapped. Next, as was explained in the section on constrained dynamics, the dispersion of $\|\mathcal{K}_k\|$ may depend on the normalization by its static structure factor, $\mathcal{N}_{k}^{\mathcal{K}}$

We begin by discussing a concrete example where a failure in orthonormality would result in incorrectly predicted relaxation times. Consider a charge conserving effective Hamiltonian that has a gapped spectrum. Due to the finite spectral gap, ΔE , the relaxation should occur in $\mathcal{O}(1)$ time. However, it is possible for the expected energy of our collective modes to still yield a gapless, quadratic dispersion: $\langle m_{\mathbf{k}} || \hat{\mathcal{H}}_{\mathcal{L}} || m_{\mathbf{k}} \rangle \sim_{k \to 0} k^2$, which would predict diffusive transport.

This situation can arise if $\Vert m_k \rangle$ is formed from the superposition of the ground state and a small portion of a gapped excitation, $||e_1\rangle$. For example, we can consider the following imagined decomposition at small k:

$$
||m_{\mathbf{k}}\rangle\!\rangle \underset{k \to 0}{=} \sqrt{1 - |c\mathbf{k}|^2} ||m\rangle\!\rangle + c|\mathbf{k}||e_1\rangle\!\rangle \quad \text{(E2)}
$$

$$
\langle\!\langle m_{\mathbf{k}} | m_{\mathbf{k'}} \rangle\!\rangle \underset{k \to 0}{\approx} 1 - \frac{|c|^2}{2} |\mathbf{k} - \mathbf{k'}|^2 \tag{E3}
$$

$$
\langle\!\langle m_{\mathbf{k}} \| \hat{\mathcal{H}}_{\mathcal{L}} \| m_{\mathbf{k}} \rangle\!\rangle \underset{k \to 0}{\propto} k^2 \langle\!\langle e_1 \| \hat{\mathcal{H}}_{\mathcal{L}} \| e_1 \rangle\!\rangle \propto k^2 \Delta E. \tag{E4}
$$

Where c is some $\mathcal{O}(1)$ constant, and ΔE is the energy gap associated with $||e_1\rangle$.

However, overlap with the ground state is not the only way for orthogonality to fail. When considering individual Krylov sectors, if K is translation invariant and its dimension is at least extensive in system size, momentum is well-defined, and orthogonality of variational states $\|\mathcal{K}_k\|$ follows directly. However, in general, a Krylov subspace, K, may not be translation symmetric, i.e., $T_r \mathcal{K} T_r^{\dagger} \neq \mathcal{K}$ because multipole conservation and translation symmetries do not commute. In this case, our variational mode $\|\mathcal{K}_{k}\rangle$ will not be a momentum eigenstate, and orthogonality does not follow. In order to circumvent this issue, we consider the *symmetrized* Krylov subspace, \mathcal{K}^s , as the following:

$$
\mathcal{K}^s \equiv \bigoplus_{\mathbf{r}} T_{\mathbf{r}} \mathcal{K} T_{\mathbf{r}}^{\dagger}.
$$
 (E5)

We can thus define a new momentum eigenmode $\|\mathcal{K}_{\mathbf{k}}^s\| =$ $\sum_{\mathbf{r}} T_{\mathbf{r}} ||\mathcal{K}_{\mathbf{k}}\rangle / L^{d/2}$. The translation invariance of the Lindbladian ensures that the modes $\|\mathcal{K}_k\|$ have the same energy expectation value as that of the symmetrized space:

$$
\langle\!\langle \mathcal{K}_{\mathbf{k}}^s \Vert \mathcal{L} \Vert \mathcal{K}_{\mathbf{k}}^s \rangle\!\rangle = \sum_{\mathbf{r}} \frac{\langle\!\langle \mathcal{K}_{\mathbf{k}} \Vert T_{\mathbf{r}}^{\dagger} \hat{\mathcal{H}}_{\mathcal{L}} T_{\mathbf{r}} \Vert \mathcal{K}_{\mathbf{k}} \rangle\!\rangle}{L^d} = \langle\!\langle \mathcal{K}_{\mathbf{k}} \Vert \hat{\mathcal{H}}_{\mathcal{L}} \Vert \mathcal{K}_{\mathbf{k}} \rangle\!\rangle,
$$
(E6)

where we use the fact that Krylov sectors are preserved under the action of \mathcal{L} , but not translation, so that $\langle K_{\mathbf{k}} || T_r^{\dagger} \hat{\mathcal{H}}_{\mathcal{L}} T_{r'} || \mathcal{K}_{\mathbf{k}} \rangle \rangle \sim \delta_{r,r'}$. As such, we must now interpret k in $\|\mathcal{K}_k\|$ as a label for the eigenstate that is distinct from the momentum. However, since $\|\mathcal{K}_k\|$ shares the same spectral properties as $\|\mathcal{K}_{\mathbf{k}}^s\|$, we may exploit the translation invariance of $\|\mathcal{K}_{\mathbf{k}}^{s}\|$ to derive the compact form of Eq. (4) from the main text. Still, a similar expression should exist for $\|\mathcal{K}_k\|$, with k effectively entering as a mere integration variable.

Finally, the dispersion of our variational modes depends on a normalizing structure factor. In general, this may be difficult to calculate explicitly; however, in a charge conserving system, it can be directly calculated as

$$
\mathcal{N}_{\mathbf{k}} = \sum_{\mathbf{x}, \mathbf{x}'} \frac{e^{i\mathbf{k} \cdot (\mathbf{x}' - \mathbf{x})}}{L^d} \langle m \| \hat{\rho}_{\mathbf{x}} \hat{\rho}_{\mathbf{x}'} \| m \rangle
$$

\n
$$
= \sum_{\mathbf{x} = \mathbf{x}'} \frac{\langle m \| \hat{\rho}_{\mathbf{x}}^2 \| m \rangle}{L^d} + \sum_{\mathbf{x} \neq \mathbf{x}'} \frac{e^{i\mathbf{k} \cdot (\mathbf{x}' - \mathbf{x})}}{L^d} \langle m \| \hat{\rho}_{\mathbf{x}} \hat{\rho}_{\mathbf{x}'} \| m \rangle
$$

\n
$$
= \langle m \| \hat{\rho}_{\mathbf{x}_0}^2 \| m \rangle - \langle m \| \hat{\rho}_{\mathbf{x}_0} \hat{\rho}_{\mathbf{x}_0 + \mathbf{a}} \| m \rangle, \qquad (E7)
$$

where x_0 and $a \neq 0$ are arbitrary vectors. Here, we employ the fact that $\Vert m \Vert$ is the projection onto the sector of total charge m, and $||m\rangle$ has no notion of distance. More precisely, it is invariant under the permutation of local sites. Accordingly, correlations between charges at different sites are the same for any two sites that are distinct.

Thus, for a charge conserving system, the static structure factor, as given above, is a constant, independent of k. Alternatively, if ρ_x can be written as a mth-order derivative, $\hat{\rho}_x = \partial_x^m \hat{e}_{m,x}$, the structure factor becomes

$$
\mathcal{N}_{\mathbf{k}} = \sum_{\mathbf{x}, \mathbf{x}'} \frac{e^{i\mathbf{k} \cdot (\mathbf{x}' - \mathbf{x})}}{L^d} \langle m \| \partial_{\mathbf{x}}^m \hat{e}_{\mathbf{m}, \mathbf{x}} \partial_{\mathbf{x}'}^m \hat{e}_{\mathbf{m}, \mathbf{x}'} \| m \rangle
$$

$$
\propto k^{2p} \sum_{\mathbf{x}, \mathbf{x}'} \frac{e^{i\mathbf{k} \cdot (\mathbf{x}' - \mathbf{x})}}{L^d} \langle m \| \hat{e}_{\mathbf{m}, \mathbf{x}} \hat{e}_{\mathbf{m}, \mathbf{x}'} \| m \rangle
$$

$$
= k^{2p} \langle m \| \hat{e}_{\mathbf{m}, \mathbf{k}} \hat{e}_{\mathbf{m}, -\mathbf{k}} \| m \rangle. \tag{E8}
$$

Thus, if a system has bounded fluctuations of pth order moments, as described by variables, $\hat{e}_{m,k}$, the structure factor will scale as $\mathcal{N}_k \sim k^{2p}$.

Appendix F: Long-Range Interactions

In this section, we discuss the derivation of the lowenergy dispersion of our Lindbladian induced effective Hamiltonians, $\mathcal{H}_{\mathcal{L}}$, with long-range interactions that respect charge, dipole, or higher moment symmetries.

1. Charge Conservation

Recalling the expression in the main text in Eq. (10) , the expected variational energy with charge conservation is

$$
\langle\!\langle m_{\mathbf{k}}||\hat{\mathcal{H}}_{\mathcal{L}}||m_{\mathbf{k}}\rangle\!\rangle \propto \sum_{\mathbf{x},\mathbf{x}'} \frac{(1-\cos\mathbf{k}\cdot(\mathbf{x}'-\mathbf{x}))}{|\mathbf{x}-\mathbf{x}'|^{2\alpha}} \times \langle\!\langle m_{\mathbf{k}}||\left[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\right]^{\dagger}\left[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\right]||m_{\mathbf{k}}\rangle\!\rangle
$$

$$
\propto \int d^{d} \mathbf{r} \frac{(1-\cos\mathbf{k}\cdot\mathbf{r})}{|\mathbf{r}|^{2\alpha}} \times \int d\Omega_{d-2} \int_{1}^{\infty} dr \int_{1}^{-1} du \frac{(1-\cos(ukr))}{|r|^{2\alpha-d+1}} \times \int_{1}^{\infty} \frac{dr}{|r|^{2\alpha-d+1}} \left(2-\frac{\sin kr}{kr}\right) \times \frac{dr}{2\alpha-d+1} \left(2-\frac{\sin kr}{kr}\right) \times \frac{d}{2\alpha-d+1} \times \Gamma(-1-2\alpha+\frac{3}{2},\frac{d}{2}+1-\alpha;\frac{k^{2}}{2})-2 \times \frac{d}{2\alpha-d+1} \times \Gamma(-1-2\alpha+d)\cos\left(\pi\alpha-\frac{d\pi}{2}\right)|k|^{2\alpha-d+1} \times \int_{k\to 0}^{\infty} (C_{1}(\alpha)|k|^{2\alpha-d}+C_{2}(\alpha)k^{2}), \qquad \text{(F1)}
$$

where we have performed the spatial integral for $d \geq 3$, making use of the form of the angular integral. However, the asymptotic scaling form in the last line of Eq. $(F1)$ also holds for $d = 1, 2$. Above, we used the substitution $u = \cos \theta$ with θ the angle between **k** and **r**, $_1F_2(a; b_1, b_2; z)$ is a hypergeometric function, and $C_1(\alpha)$

and $C_2(\alpha)$ are $\mathcal{O}(1)$ coefficients obtained from this function that are smooth except at $\alpha = d/2$ and $1 + d/2$. At $\alpha \leq d/2$, the spatial integral above exhibits IR divergences scaling with $\log L$ at $\alpha = d/2$ and with $L^{(d-2\alpha)}$ at $\alpha < d/2$, where L is the linear system size. Such a divergence of the single mode dispersion would lead to ultra-fast relaxation in the thermodynamic limit. However, for physical systems, we should renormalize the resulting dispersion to be bounded. In order to do so, we have to rescale the interaction strength with the diverging expression, which we label by $C_0(\alpha \leq \frac{d}{2}, L)$ = $\int_{|\mathbf{r}| < L} d^d \mathbf{r} \frac{(1-\cos \mathbf{k} \cdot \mathbf{r})}{|\mathbf{r}|^{2\alpha}}$. This rescaling leads to a fin $\frac{\cos \kappa \cdot r}{|r|^{2\alpha}}$. This rescaling leads to a finite energy gap at low k, and thus, relaxation within an $\mathcal{O}(1)$ time when $\alpha < d/2$.

Additionally, in this derivation, we assumed that the expectation $\langle\!\langle m_{\mathbf{k}}\vert\vert\big[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\big]^\dagger\big[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\big]\vert\vert m_{\mathbf{k}}\rangle\!\rangle$ did not depend on the distance, $x - x'$. This is true due to the same special property of the position-space representation of the $\|m\|$ state that allowed us to simplify Eq. $(E7)$: The correlation of two local operators acting on ∥m⟩⟩ only depends on whether the operators are at the same or distinct sites because the state $||m\rangle$ is invariant under the permutation of local sites. This is the case for $\langle\!\langle m_{\mathbf{k}}\vert\vert\big[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\big]^\dagger\big[\tilde{\mathcal{O}}_{\mathbf{x},\mathbf{x}'},\hat{\rho}_{\mathbf{x}}\big]\vert\vert m_{\mathbf{k}}\rangle\!\rangle$, and the quantity is independent of the distance $x - x'$.

2. Dipole Conservation

Next, we turn to the case of dipole conservation. Here, we look at generic dipole hoppings of the form

$$
h_{\boldsymbol{x},\boldsymbol{x}',\boldsymbol{n}} = \frac{\hat{S}_{\boldsymbol{x}}^{+}\hat{S}_{\boldsymbol{x}+\boldsymbol{n}}^{-}\hat{S}_{\boldsymbol{x}'}^{-}\hat{S}_{\boldsymbol{x}'+\boldsymbol{n}}^{+} + \text{h.c.}}{| \boldsymbol{x} - \boldsymbol{x}' |^{\alpha_0} | \boldsymbol{n}|^{\alpha_1}}.
$$
 (F2)

Accordingly, our effective Hamiltonian will be of the form $\hat{\mathcal{H}}_{\mathcal{L}} = \sum_{\bm{x}, \bm{x}', \bm{n}} \mathcal{O}_{\bm{x}, \bm{x}', \bm{n}} \mathcal{O}_{\bm{x}, \bm{x}', \bm{n}}^{\dagger}$. With this, we return to calculate the commutator from the main ext in Eq.(8).

$$
[\mathcal{O}_{\boldsymbol{x},\boldsymbol{x}',\boldsymbol{n}},\hat{\rho}_{\boldsymbol{k}}] = \sum_{\boldsymbol{y}\in\mathcal{S}_{\boldsymbol{x}}} e^{i\boldsymbol{k}\cdot\boldsymbol{x}} [\mathcal{O}_{\boldsymbol{x},\boldsymbol{x}',\boldsymbol{n}},e^{i\boldsymbol{k}\cdot(\boldsymbol{y}-\boldsymbol{x})}\hat{\rho}_{\boldsymbol{y}}]
$$

$$
= e^{i\boldsymbol{k}\cdot\boldsymbol{x}} \frac{(1-e^{ik\boldsymbol{n}})(1-e^{i\boldsymbol{k}\cdot(\boldsymbol{x}'-\boldsymbol{x})})}{|\boldsymbol{x}-\boldsymbol{x}'|^{\alpha_0}|\boldsymbol{n}|^{\alpha_1}} \left[\tilde{\mathcal{O}}_{\boldsymbol{x},\boldsymbol{x}',\boldsymbol{n}},\hat{\rho}_{\boldsymbol{x}}\right], \quad \text{(F3)}
$$

where $\tilde{\mathcal{O}}_{\bm{x},\bm{x}',\bm{n}} = \mathcal{O}_{\bm{x},\bm{x}',\bm{n}} |\bm{x}-\bm{x}'|^{\alpha_0} |\bm{n}|^{\alpha_1}$ moves the powerlaw variation to the commutator prefactor. Note that this prefactor now carries the dependence on the displacement, $\mathbf{r} = \mathbf{x} - \mathbf{x}'$, and dipole size, \mathbf{n} . Repeating the same analysis as in the charge conserving case,

$$
\langle K_{\mathbf{k}} \| \hat{\mathcal{H}}_{\mathcal{L}} \| K_{\mathbf{k}} \rangle \propto \sum_{\mathbf{r}} \frac{(1 - \cos \mathbf{k} \cdot (\mathbf{r}))}{|\mathbf{r}|^{2\alpha_0}} \sum_{\mathbf{n}} \frac{(1 - \cos \mathbf{k} \cdot \mathbf{n})}{|\mathbf{n}|^{2\alpha_1}} \times \begin{cases} C_0(\alpha_0, L) \int_{\mathbf{n}} \frac{(1 - \cos \mathbf{k} \cdot \mathbf{n})}{|\mathbf{n}|^{2\alpha_1}}, & \alpha_0 \le \frac{d}{2} \\ \int_{\mathbf{r}} \frac{(1 - \cos \mathbf{k} \cdot \mathbf{r})}{|\mathbf{r}|^{2\alpha_0}} \int_{\mathbf{n}} \frac{(1 - \cos \mathbf{k} \cdot \mathbf{n})}{|\mathbf{n}|^{2\alpha_1}} & \alpha_0 > \frac{d}{2}, \end{cases} (F4)
$$

where $C_0(\alpha, L)$ is a constant diverging with system size as discussed below Eq. $(F1)$. Now, we proceed with the above integration for each range of α_0 :

$$
(\alpha_0 \le d/2) :\nE_k \propto C_0(\alpha_0) (C_1(\alpha_1)|k|^{2\alpha_1 - d} + C_2(\alpha_1)k^2) \underset{\alpha_1 \to \infty}{\propto} k^2 \n(\alpha_0 > d/2) :\nE_k \propto (C_1(\alpha_0)|k|^{2\alpha_0 - d} + C_2(\alpha_0)k^2) \n\times (C_1(\alpha_1)|k|^{2\alpha_1 - d} + C_2(\alpha_1)k^2),\n\times (C_1(\alpha_0)|k|^{2\alpha_0 + 2 - d} + C_1(\alpha_0)k^4),
$$
\n(F5)

where $C_1(\alpha_{0/1})$ and $C_2(\alpha_{0/1})$ are the same as before.

When $\alpha_1 \to \infty$, the effective Hamiltonian can be understood as describing long-ranged hopping of 2-local dipoles, $D_x \equiv S_x^+ S_{x+1}^-$, where 1 is a unit vector. This case was discussed in the main text, with the α dependent phase diagram for transport behavior shown in Fig.2 in the main text. On the other hand, if both $\alpha_{1/0} \leq \frac{d}{2}$, we have diverging integrals for both r and n, which results in finite-time relaxation after renormalizing the divergence. Aside from this fast relaxation, we identify four distinct regimes (note that the physics is symmetric under the exchange of $\alpha_0 \leftrightarrow \alpha_1$):

1. $\alpha_0, \alpha_1 > \frac{d}{2} + 1$:

This regime contains the limiting case $\alpha_{0/1} \rightarrow \infty$, corresponding to local dipoles with nearest neighbor hopings, and yields a dispersion $E_{\mathbf{k}} \sim k^4$.

2. $\alpha_1 > \frac{d}{2} + 1$ and $\frac{d}{2} < \alpha_0 < \frac{d}{2} + 1$:

Local dipoles with long-range hoppings result in a dispersion $E_{\mathbf{k}} \sim k^{2(\alpha_0+1)-d}$

3. $\alpha_1 > \frac{d}{2} + 1$ and $\alpha_0 < \frac{d}{2}$:

Hoppings of local dipoles become so long-ranged that local charge transport arises from individual dipole creation/annihilation terms, equivalent to conventional charge conservation. This yields a dispersion $E_{\mathbf{k}} \sim k^2$.

4. $\frac{d}{2} < \alpha_0, \alpha_1 < \frac{d}{2} + 1$,

Large dipoles with long-range hoppings yield a dispersion of $E_k \sim k^{(2\alpha_0-d)+(2\alpha_1-d)}$. This gives rise to a dynamical exponent $z \in (0, 4)$.

3. Multipole Conservation

The extension of this to systems conserving ${Q^{(0)},...,Q^{(m)}}$ multipoles is straightforward. Interactions are composed of hoppings that scale as $\prod_{p=0}^m \frac{1}{|r_p|^{\alpha_p}}$, where r_p indicates the hopping distance between $(m - p)$ -th moment charges. Therefore, $\alpha_0, \ldots, \alpha_{m-2}, \alpha_{m-1}, \alpha_m$ control the locality of m-th moment hoppings $((m + 1)$ -th moment lengths), ..., quadrupole hoppings (octopole lengths), dipole hoppings (quadrupole lengths), and charge hoppings (dipole lengths), respectively. From the above derivation, when all $\alpha_p > \frac{d}{2}$, our variational modes produce a dispersion of

$$
\langle K_{\mathbf{k}} || \hat{\mathcal{H}}_{\mathcal{L}} || K_{\mathbf{k}} \rangle \!\rangle \underset{k \to 0}{\propto} \prod_{p=0}^{m} \left(C_1(\alpha_p) |k|^{2\alpha_p - d} + C_2(\alpha_p) k^2 \right).
$$
\n(F6)

Whenever $\alpha_p < \frac{d}{2}$, the *p*-th term in this product is replaced by $C_0(\alpha_p, L)$, effectively acting as a constant upon renormalization of the divergence. As in the previous case, we enumerate four regimes:

1. $\alpha_0, \ldots, \alpha_m > \frac{d}{2} + 1$

Local m -th moment charges with nearest neighbor hopings yield a dispersion of $E_{\mathbf{k}} \sim k^{2(m+1)}$

2. $\alpha_1, \ldots, \alpha_m > \frac{d}{2} + 1$ and $\frac{d}{2} < \alpha_0 < \frac{d}{2} + 1$,

Local *m*-th moment charges with long-range hoppings yield a dispersion of $E_{\mathbf{k}} \sim k^{2(\alpha_0+m)-d}$

3. $\alpha_1, \ldots, \alpha_m > \frac{d}{2} + 1$ and $\alpha_0 < \frac{d}{2}$,

Local *m*-th moment charges with extensive hoppings yield a dispersion of $E_{\mathbf{k}} \sim k^{2m}$

4. $\frac{d}{2} < \alpha_0, \ldots, \alpha_m < \frac{d}{2} + 1$,

Extended m -th moment charges with long-range hoppings yield a dispersion $E_k \sim k^{\sum_{p=0}^m (2\alpha_p - d)}$. Since $0 < 2\alpha_i - d < 2$, the dynamical exponent $z = \sum_{p} (2\alpha_p - d) \in (0, 2(m + 1))$ covers the entire range between finite-time relaxation and conventional multipole subdiffusion.

In the main text, we focus on cases 1-3, where transport can be accounted for by local excitations, however, our method accounts for dynamics for all ranges of different α_p , where case 4 corresponds to a particular example.

Appendix G: Numerical Details

In the main text, we derived diffusive relaxation in dipole-conserving systems within Krylov sectors satisfying a charge area law (see Eq. (12) in the main text). In order to verify this prediction, we numerically evaluated the relaxation of classical systems exhibiting these constraints under discrete random time evolution. We emphasize that due to the universality of hydrodynamic transport, the same qualitative relaxation behavior is expected in thermalizing quantum many-body systems, see also Refs. [\[21,](#page-5-5) [24,](#page-5-14) [25,](#page-5-11) [70\]](#page-6-14) for related approaches.

As the first example described in the main text, we time evolve the initial state $|\psi_0\rangle = |...00 + 00...\rangle$ of a $S = 1$ spin chain with local Hilbert space $\hat{\rho}_x \in \{0, \pm\}.$ The time evolution is performed by applying local threesite updates that conserve both the charge $\sum_{x} \hat{\rho}_x$ and

FIG. 4. Numerical simulation of dipole-conserving dynamics. a) We simulate the relaxation dynamics of a classical, discrete random time evolution, in which dipoleconserving updates of a given spatial range are performed randomly. b) For evolution with 3-site updates, the charge excitation of the initial state shown in a) decays diffusively as $t^{-1/2}$ (red curve). In contrast, dynamics under 4-site updates lead to subdiffusive decay $t^{-1/4}$ expected for generic systems (green curve). c) Profile $\hat{\rho}(x,t)$ of the charge density at time $t = 60$ of the evolution defined in a) with 3-site updates. The red curve corresponds to an enveloping function. d) Enveloping functions of the charge density at different times. e) Diffusive scaling collapse of the enveloping functions shown in b). Numerical results were averaged over 2×10^5 runs of the random time evolution in a chain of length $L = 1000$.

dipole moment $\sum_{x} x \hat{\rho}_x$ of the local three-site configuration. These updates are arranged in a brickwall pattern as depicted in Fig. [4a](#page-13-1). Furthermore, the updates are random, i.e. the updated charge configuration on the three sites is chosen randomly from all configurations within the same three-site charge and dipole sector. In Fig. [4b](#page-13-1), we show the time evolution of $\mathbb{E}\langle \hat{\rho}_{x=L/2}(t) \rangle \sim t^{-1/2}$, confirming diffusive behavior. This is contrasted with the generic, subdiffusive decay $\sim t^{-1/4}$ seen when evolving the same initial state with similar local four-site updates, for which the associated Krylov sector no longer follows a charge area law. In Fig. [4e](#page-13-1), we provide a scaling collapse of the full spatial profile of $\mathbb{E} \langle \hat{\rho}_x(t) \rangle$, again in agreement with diffusion. We note that the diffusive behavior in this Krylov sector has previously been reported in Ref. [\[72\]](#page-6-16). Within the framework developed in our work, the emergence of diffusion in dipole conserving systems is explained as a consequence of the more general charge area-law constraint Eq. (12) , from the main text.

To illustrate the generality of this result, in the main text we extended our analysis to systems beyond one spatial dimension. As a concrete example, we studied the dynamics of a two-dimensional dimer-vacancy model, subject to the hard-core constraint of maximally one dimer attached to each lattice site, see Fig.3a of the main text. Vacancies, i.e. sites without an attached dimer, carry a charge $\hat{\rho}(\boldsymbol{x}) = (-1)^{x_1+x_2}$. The constraint of either zero or one dimer on each bond of the lattice is equivalent to a finite electric field state space in a $U(1)$ link model formulation of this system [\[77,](#page-6-20) [78\]](#page-6-21), ensuring area law charge fluctuations. We then explicitly demand the conservation of both the total charge and dipole moment under time evolution.

To verify the emergence of diffusive relaxation in this setup, we implemented a random, discrete classical time evolution similar to the previous example. Here, as depicted schematically in Fig.3a of the main text, we first apply plaquette updates which randomly update the state of elementary square plaquettes that contain either a horizontal or vertical pair of parallel dimers, or four charges. This process conserves the total charge and dipole moment. Then, we apply random dipole hoppings of neighboring ±-charge pairs. Note that due to the sublattice structure of the local charge density $\hat{\rho}_x$, conservation of the dipole moment implies that these charge pairs may only hop along displacement vectors $\mathbf{r} = (r_x, r_y)$ that satisfy $(r_x + r_y) \mod 2 = 0$. In our numerical implementation, we take into account $(|r_x| = 2, r_y = 0)$, $(r_x = 0, |r_y| = 2)$, and $(|r_x| = 1, |r_y| = 1)$.
