Knowing the transport properties of iron under realistic conditions present in the Earth's core is essential for the geophysical modeling of Earth's magnetic field generation. Besides by extreme pressures and temperatures, transport may be influenced importantly also by the presence of light elements. Using a combination of molecular dynamics, density functional theory, and dynamical mean-field theory methods we investigate how oxygen impurities influence the electronic correlations and transport in the liquid outer Earth's core. We consider a case with an oxygen content of ∼ 10atomic%, a value that is believed to be close to the composition of the core. We find that the electronic correlations are enhanced but their effect on conductivities is moderate (compared to pure Fe, electrical conductivity drops by 10% and thermal conductivity by 18%). The effect of electron-electron scattering alone, whereas not large, is comparable to effects of the compositional disorder. We reveal the mechanism behind the larger suppression of the thermal conductivity and associated reduction of the Lorenz ratio and discuss its geophysical significance.

## INTRODUCTION

The Earth's magnetic field is generated by a selfexcited dynamo that is driven by convection in the outer core. The thermal conductivity of iron, which determines the amount of heat flow available for convection, and the value of electrical conductivity, which determines the dissipation of the current, are crucial inputs for geophysical models of this geodynamo mechanism. Direct measurements of transport under extreme pressures and temperatures that are relevant to Earth's core are challenging [\[1,](#page-5-0) [2\]](#page-5-1) as one must ensure homogeneous temperature and carefully control the geometry of the samples [\[3\]](#page-5-2).

One can access transport properties also from first principle calculations based on the molecular dynamics (MD)–density functional theory (DFT) method [\[4–](#page-5-3) [6\]](#page-5-4). These calculations have shown that the electrical and thermal conductivities have values that are significantly (2-3 times) higher [\[5,](#page-5-5) [6\]](#page-5-4) than earlier established estimates [\[7,](#page-5-6) [8\]](#page-5-7). These earlier estimates were based on extrapolations that neglected the effects of resistivity saturation [\[9–](#page-5-8)[11\]](#page-5-9). The higher values of thermal conductivity lead to a different geophysical picture, with an inner core that is younger  $\langle \langle 1 \rangle$  billion years, whereas magnetism is known to exist for at least 3.4 billion years [\[12,](#page-5-10) [13\]](#page-5-11) ), and less thermal convective energy to drive the geodynamo, which is known as "the new core paradox" [\[14\]](#page-5-12). Namely, less thermal energy implies that convection must be helped by the chemical convection driven by the exsolution of lighter elements but this was less active before the formation of the inner core.

There has been an ongoing discussion on whether electronic correlations, which have been shown to be significant in iron under Earth's core conditions [\[15,](#page-5-13) [16\]](#page-5-14), can cause a breakdown in the Mott-Ioffe-Regel resistivity saturation [\[9,](#page-5-8) [17\]](#page-5-15). This debate revolves around whether these correlations are strong enough to reduce conductivity values to previously established levels [\[18–](#page-5-16)[20\]](#page-6-0), as suggested in a pioneering work (later retracted)[\[18\]](#page-5-16). Recent findings indicate that electron-electron scattering (EES) plays only a moderate role and represents a small fraction compared to thermal-disorder (electron-phonon) scattering [\[21,](#page-6-1) [22\]](#page-6-2).

One important question remains to be addressed: does alloying with lighter elements significantly enhance correlations, and if so, to what extent are conductivities suppressed? The Earth's core contains a sizable contribution of lighter elements, primarily silicon and oxygen, with recent research indicating a high oxygen concentration [\[23\]](#page-6-3). The influence of these substitutions has been broadly investigated using MD-DFT [\[5,](#page-5-5) [6,](#page-5-4) [24,](#page-6-4) [25\]](#page-6-5), but without accounting for correlation effects. Oxygen might enhance electronic correlations by reducing iron 3d shell occupancy toward half-filling [\[26\]](#page-6-6). Indeed, recent theoretical work [\[27\]](#page-6-7) investigated several ordered FeO structures and found a very strong enhancement of electronelectron scattering (EES). However, the impact of thermal disorder on EES was neglected in that study, and the final effect on thermal conductivity, taking into account both EES and electron-phonon scattering, was not evaluated. Furthermore, the impact of EES on conductivity in liquid iron, which is most relevant for the dynamo

<sup>&</sup>lt;sup>4</sup>Institute of Theoretical and Computational Physics,

<span id="page-0-0"></span><sup>∗</sup> [german.blesio@ijs.si](mailto:german.blesio@ijs.si)

mechanism, was not clarified.

In this study, we investigate the transport properties of Fe and FeO alloys in their liquid state at the innercore boundary (ICB) and core-mantle boundary (CMB) conditions. We describe the liquid state using MD-DFT and account for electron-electron scattering (EES) using dynamical mean-field theory (DMFT) [\[20,](#page-6-0) [21,](#page-6-1) [28,](#page-6-8) [29\]](#page-6-9). Specifically, we focus on the  $Fe<sub>0.91</sub>O<sub>0.09</sub>$  composition and observe that its EES rate increases by  $\sim 25\%$  compared to pure iron (Fe ), but the conductivities are affected to a lesser extent with only an  $\approx 10\%$  drop in electrical conductivity  $\sigma$  and an  $\approx 18\%$  drop in thermal conductivity  $\kappa$ . This change is mainly due to band-structure effects rather than a direct increase in EES.

In order to quantify the effects of electronic-correlation on transport we compare the calculated DMFT conductivities with those from the MD-DFT. We find that the inclusion of EES leads to only a moderate reduction of electrical and thermal conductivities by roughly 10% and 20%, respectively. This finding is crucial considering a large body of existing theoretical work that neglects EES [\[5,](#page-5-5) [6,](#page-5-4) [11,](#page-5-9) [24\]](#page-6-4). A related study of Fe-Si alloys has shown similar behavior [\[22\]](#page-6-2). We discuss why the thermal conductivities are suppressed more than the electrical ones and highlight the geophysical implications of our results.

### METHODS

We performed the molecular dynamics calculations using the VASP code [\[30\]](#page-6-10), using the projected augmented wave method [\[31,](#page-6-11) [32\]](#page-6-12) to describe the interactions between the electrons and the ions and expanded the singleparticle orbitals as linear combinations of plane waves (PW), including PW with maximum energies of 400 eV. The molecular dynamics simulations were performed by sampling the Brillouin zone using the Γ point only, and a time step was 1 fs. The temperature was controlled using the Nosé [\[33\]](#page-6-13) thermostat. To compute the DFT electrical and thermal conductivity we used the modified version of VASP by Dejarlais [\[34\]](#page-6-14).

The DFT+DMFT self-consistent calculations were performed with a local density approximation (LDA) approach in the Wien2K code [\[35,](#page-6-15) [36\]](#page-6-16), using the TRIQS library [\[37–](#page-6-17)[40\]](#page-6-18) for the DMFT and transport calculations. We used a local density-density interaction vertex with interaction parameters  $U = 5.0 \text{ eV}, J_H = 0.93 \text{ eV}, \text{ in}$ agreement with the previous studies on pure iron [\[19,](#page-5-17) [21\]](#page-6-1), and solved the impurity problem using the continuoustime hybridization-expansion segment solver [\[41,](#page-7-0) [42\]](#page-7-1). Each calculation was first converged by 25 fully selfconsistent DFT+DMFT iterations, where each Monte Carlo run employed  $2 \times 10^{10}$  Monte Carlo moves and 200 moves/measurement. Using the converged Kohn–Sham Hamiltonian, 10 additional DMFT cycles were performed with the number of Monte Carlo moves increased to  $10^{11}$ . To obtain clean data for analytical continuation

that we performed using Maximum Entropy method, 20 additional runs (with  $2 \times 10^{11}$  moves per run) were carried out starting from the same converged value of the DMFT bath Green's function and resetting the random sequence.

We calculated the conductivities within the Kubo linear-response neglecting the vertex corrections. The electrical and thermal conductivity read [\[40,](#page-6-18) [43\]](#page-7-2)

<span id="page-1-0"></span>
$$
\sigma_{\alpha\alpha'} = \frac{e^2}{k_B T} K_{\alpha\alpha'}^0 \ , \ \kappa_{\alpha\alpha'} = k_B \left[ K_{\alpha\alpha'}^2 - \frac{\left( K_{\alpha\alpha'}^1 \right)^2}{K_{\alpha\alpha'}^0} \right], \ (1)
$$

where  $\alpha$  is the direction  $(x, y \text{ or } z)$  and  $k_B$  the Boltzmann constant. The kinetic coefficients  $K_{\alpha\alpha}^n$  are

$$
K_{\alpha\alpha'}^{n} = 2\pi\hbar \int d\omega (\beta\omega)^{n} f(\omega) f(-\omega) \Gamma^{\alpha\alpha'}(\omega,\omega), \qquad (2)
$$

where 2 is the spin factor,  $f(\omega)$  is the Fermi function, and the  $\Gamma^{\alpha \alpha'}$  is given by

$$
\Gamma^{\alpha\alpha'}(\omega,\omega') = \frac{1}{V} \sum_{\mathbf{k}} \text{Tr}\left(v_{\mathbf{k}}^{\alpha} A_{\mathbf{k}}(\omega) v_{\mathbf{k}}^{\alpha'} A_{\mathbf{k}}(\omega')\right) \tag{3}
$$

where V is the unit-cell volume,  $A_{\mathbf{k}}(\omega)$  is the DMFT spectral function at momentum **k**, and  $v_{\mathbf{k}}^{\alpha}$  is the corresponding band velocity in the direction  $\alpha$ . We also define the transport distribution

$$
\Gamma(\omega) = \sum_{\alpha} \Gamma^{\alpha\alpha}(\omega, \omega).
$$
 (4)

We also calculated the response at finite frequency  $\Omega$ which yields the optical electrical and thermal conductivity. These are evaluated by Eq[.1](#page-1-0) using the kinetic coefficients evaluated at a finite frequency  $\Omega$ 

$$
K_{\alpha\alpha'}^n(\Omega) = 2\pi\hbar \int d\omega \Gamma^{\alpha\alpha'}(\omega + \Omega/2, \omega - \Omega/2)(\omega + \Omega/2)^n
$$

$$
\beta^{n-1} \frac{f(\omega - \Omega/2) - f(\omega + \Omega/2)}{\Omega}.
$$
(5)

In the momentum sums we retained 14 momentum points. The electron-phonon-only values were calculated using the Kubo-Greeenwood approximation as implemented in VASP [\[34\]](#page-6-14) using 10 momentum points. We checked that upon increasing the number of momentum points further the results vary by less than 1%.

### RESULTS

We calculate the liquid phase for 67 atoms: all iron (Fe) or with oxygen (Fe<sub>0.91</sub>O<sub>0.09</sub>). We study the liquid at CMB conditions for a temperature  $T = 4400$  K, volume  $8.64 \text{\AA}^3/\text{atom}$  (which corresponds to pressure 132) GPa), and ICB conditions  $T = 6350$  K with volume  $7.16 \text{ Å}^3/\text{atom}$  (pressure 330 GPa).

The calculations were performed for three snapshots separated by 5 ps time each and the calculations of transport properties was performed by averaging over the snapshots and spatial directions.

Electronic correlations. Figure [1](#page-2-0) displays the imaginary part of self-energies for a single snapshot in the energy range of  $[-1, 1]$  eV. Each curve represents a different site/orbital/spin index, and the thick lines indicate an average over all of them. Since the electron-electron scattering rate is  $1/\tau = -2\mathrm{Im}\Sigma(\omega \to 0)$ , more negative values of ImΣ indicate stronger electronic correlations. Our results show that the scattering increases significantly in the oxygen-rich case for both ICB and CMB. The distribution of the curves reveals that not only the Fe sites closest to oxygen are affected, but also the spread of the data is wider in the oxygen-rich case, and even the self-energies with the smallest magnitudes are enhanced by oxygen. Overall, the average EES, as given by the average Im $\Sigma$ , increases by 25%.

<span id="page-2-0"></span>FIG. 1. Imaginary part of the calculated self-energies on the real axis. In the top and middle panels, we show the individual self-energies (blue lines) and their average  $\langle Im \Sigma \rangle$  (black thick). In the bottom panel, the four average self-energies are shown, at the ICB (full) and CMB (dashed) conditions.

Conductivities. The calculated optical conductivities are shown in Fig. [2](#page-2-1) for the case of electrical and thermal current on the top and bottom panels, respectively. The  $\omega \rightarrow 0$  values indicate the dc-transport values. One sees that quantitatively the effect of oxygen on transport is somewhat weaker than on the EES. Also shown in that figure are the results of a simplified calculation where one uses the  $\langle \Sigma \rangle$  instead of the individual self-energies. One sees a "self-averaging" effect: the results of such a calculation are almost indistinguishable from the full calculation. This also tells that statistical uncertainties of the individual self-energies will not affect the calculated conductivities.

<span id="page-2-1"></span>FIG. 2. Optical electrical (top) and thermal (bottom) conductivity for pure Fe and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$ . The ICB and CMB cases are shown on the left and right, respectively. The dashed lines (that overlap closely with the filled ones) indicate a simplified calculation using fully (site, orbital, and spin) averaged self-energies.

<span id="page-2-2"></span>FIG. 3. Thermal conductivity for pure Fe and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$  for the ICB (top) and CMB cases (bottom). We show the results obtained with orbitally and site-resolved self-energies (dots) as well as those calculated using the average self-energy (full line). The latter was first averaged over all sites and orbitals on the Matsubara grid and then analytically continued. The differences between the two are very small. With dash-dotted line, we show results calculated by exchanging the average self-energy between the Fe and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$ .

To what extent is the suppression of conductivities in the oxygen-rich case due to the increase of EES documented in Fig. [1?](#page-2-0) It turns out that, as suggested in the earlier work [\[21\]](#page-6-1) iron under Earth's core conditions is in a thermal-disorder dominated case where the changes of EES impact transport weakly. In Fig. [3](#page-2-2) we demonstrate this by additional calculations where we compute the conductivity of the  $Fe<sub>0.91</sub>O<sub>0.09</sub>$  case by using the scattering information from  $\langle \Sigma \rangle$  corresponding to pure Fe calculation and vice versa for the other case. Quite strikingly, these "exchanged" calculations are at small frequencies almost indistinguishable from the "non-exchanged" ones. This tells that the oxygen affects the results through a structurally induced change in the band dispersions and that the changes in the EES play an insignificant role. This is further demonstrated in Appendix [B](#page-5-18) where the scattering is artificially increased and only a weak effect on transport is seen.

Fig. [4](#page-3-0) shows the calculated values of resistivity (top) and thermal conductivity (bottom) along with data from the literature. Thermal disorder dominates, and perfect crystalline lattices have much higher conductivities. The additional influence of compositional disorder is moderate, and the magnitude of the change is similar to that of including EES on top of the thermal disorder for a given composition.

<span id="page-3-0"></span>FIG. 4. Resistivity (top) and thermal conductivity (bottom) for Fe and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$  for the ICB and CMB cases calculated using DMFT (including both electron-electron and e. ph scattering) and DFT (e.-ph. only). Previous calculations (extracted from Ref. [\[21\]](#page-6-1)) for supercell and perfect lattice bcc/hcp are shown for the solid case.

Suppression of Lorenz ratio. Interestingly, EES suppresses the thermal conductivities more than the electrical ones. Figure [5](#page-3-1) shows the evolution of the Lorenz number  $L = \kappa/(\sigma T)$  with respect to the strength of EES, which is scaled by the factor  $\alpha$ , as described in Appendix [B.](#page-5-18) For pure Fe, the value of  $L$  due to electronphonon scattering is almost identical to the standard value of 2.44 $\cdot 10^{-8}$  (W $\Omega/K^2$ ), whereas it is considerably

<span id="page-3-1"></span>FIG. 5. (left) Lorenz number for Fe (bullets) and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$ (crosses) and for the ICB (full line) and CMB cases (dashed line). We use the parameter  $\alpha$  to artificially change the magnitude of the EES  $\Sigma \to \Sigma_{\alpha} = \text{Re}\Sigma + \alpha i \text{Im}\Sigma$ . One sees that the Lorenz number is reduced by the presence of oxygen. (right) Transport distribution  $\Gamma(\omega)$ . Solid curves are the obtained form the full DMFT self energy, dashed lines from a constant scattering rate approximation.

reduced when EES is taken into account. This reduction occurs because inelastic EES affects  $\kappa$  more strongly than  $\sigma$ . Specifically,  $\kappa$  is determined by integrating  $\Gamma(\omega) \omega^2(-df/d\omega)$ , where  $\Gamma(\omega)$  is the transport distribution function, f is the Fermi function, and  $\omega$  is the frequency. On the other hand,  $\sigma$  is calculated by integrating  $\Gamma(\omega)$ ( $-df/d\omega$ ), which only involves the derivative of the Fermi function. The conductivity is mostly given by states around  $\omega = 0$ , while the dominant contribution to thermal conductivity occurs at finite energies  $1.5T \lesssim |\omega| \lesssim 4T$ .

The right panel of Figure [5](#page-3-1) presents the transport distribution  $\Gamma(\omega)$  for the CMB case, which are evaluated for the actual EES (full) and compared to a calculation where the energy dependence of scattering is suppressed and the self-energy  $\text{Im}\Sigma \rightarrow \text{const}$  is taken (dashed), corresponding to a DFT transport distribution. It is evident that the increase of EES with energy suppresses  $\Gamma$  that becomes smaller at larger energies compared to the DFT transport distribution case. Additionally, a comparison between Fe and Fe-O is interesting, which is evident from the DFT transport distributions. The inclusion of oxygen leads to significant suppression of transport distribution at  $\omega = 2.5$ eV, caused by O-2p hybridization with the 4s iron states. This explains the smaller Lorenz number in the oxygen-rich case.

# DISCUSSION

In summary, our study focused on the impact of oxygen on electronic transport in liquid iron corresponding to the outer Earth's core conditions. Because oxygen diminishes the Fe 3d electronic occupation towards half-filling, it can be expected to strongly enhance electronic correlations. We indeed find that the EES is moderately increased. The numerical values of the conductivities and the Lorenz

<span id="page-4-0"></span>TABLE I. Summary of results for CMB and ICB conditions, both for Fe and  $Fe<sub>0.91</sub>O<sub>0.09</sub>$ .

ratio are given in Table [I.](#page-4-0) The oxygen substitution at ∼ 10% level, which is a plausible content for the outer core, suppresses electrical (thermal) conductivities by about 10(17)% only. In both Fe and Fe-O including electronic correlations diminishes electrical conductivities by less than 10% and thermal conductivities by about 20%. This reduction is consistent with similar studies [\[21,](#page-6-1) [22\]](#page-6-2), which suggests that it can be used as a rule of thumb when direct calculations are not feasible.

What are the geophysical implications of electronic correlations? The first observation is that their effect is moderate. The drastic reduction of conductivity, which was predicted on the basis of EES enhancement in ordered Fe-O structures [\[22\]](#page-6-2), is not observed when thermal disorder effects are simultaneously included. But it is also clear from our study that neither can one neglect electronic correlations, since the reduction of conductivities due to EES is comparable to the reduction of electronphonon scattering due to light elements. Importantly, some models that assume a higher heat flow from the core find a thermally only driven geodynamo for  $\kappa$  below a limiting value that is of order 100W/mK [\[44,](#page-7-3) [45\]](#page-7-4). EES whereas small compared to the thermal disorder, might in the end provide just the necessary additional scattering next to the compositional disorder to power the geodynamo sufficiently. At the very least, whenever one argues the compositional disorder is important, EES must not be neglected either. Another important finding is the universal suppression of Lorenz number: thermal conductivities are affected by EES more than electrical ones [\[19,](#page-5-17) [20\]](#page-6-0). This is seen to be also an effect of compositional disorder in the Fe-O case but EES enhances this further, by supressing the contribution of states away from the Fermi energy. This is important both to properly interpret the high-pressure measurements that mostly probe  $\sigma$  and for the geodynamo, because of the distinct influence of the two quantities there.

In future studies, it would be interesting to investigate also alloying with sulfur and silicon [\[24\]](#page-6-4). Both elements affect the transport properties strongly at the DFT level because unlike oxygen that alloys interstitially [\[24\]](#page-6-4), they alloy substitutionally and therefore more strongly affect the bond disorder with perhaps different implications for electronic correlations. The silicon case was recently investigated [\[22\]](#page-6-2), and the results for CMB seem compatible with what we find at comparable concentrations of oxygen, but sulfur that would act also in an oxidizing way could potentially have a bigger effect. Whereas the sulfur concentrations are believed to be negligible in the Earth [\[46\]](#page-7-5), they are expected to be sizable in extraterrestial planets [\[47\]](#page-7-6). Finaly, both thermal disorder and compositional disorder are also important for Fe oxides that are relevant for the properties of the lower mantle, where, for example, FeO is predicted to be [\[48](#page-7-7)[–51\]](#page-7-8) in a state where electronic correlations are very strong and the influence of thermal and compositional disorder might lead to large effects there.

# <span id="page-5-18"></span>Appendix B: Effects of increased electron-electron scattering

In order to investigate how results depend on the strength of EES we performed trial conductivity calculation where we artificially set  $\Sigma \to \Sigma_{\alpha} = \text{Re}\Sigma + \alpha i \text{Im}\Sigma$ , thus increasing the scattering by a scale factor  $\alpha$ . The calculated optical conductivities and thermal optical conductivities are shown in Fig. [7.](#page-6-19) One sees a weak dependence on  $\alpha$  around  $\alpha = 1$ . As discussed in Ref. [\[21\]](#page-6-1), the dependence of conductivities on the EES is weaker than what one would expect from Matthiessen's rule. The breakdown of Matthiessen's rule was also documented as a function of the substitutional disorder [\[11\]](#page-5-9).
