The dynamics of two interacting quantum particles on a weakly disordered chain is investigated. Spatial quantum interference between them is characterized through the statistics of two-particle transition amplitudes, related to Hanbury Brown-Twiss correlations in optics. The fluctuation profile of the signal can discern whether the interacting parties are behaving like identical bosons, fermions, or distinguishable particles. An analog fully developed speckle regime displaying Rayleigh statistics is achieved for interacting bosons. Deviations toward long-tailed distributions echo quantum correlations akin to non-interacting identical particles. In the limit of strong interaction, twoparticle bound states obey generalized Rician distributions.

Anderson localization is a universal phenomenon that underlies wave physics [\[1\]](#page-4-0). It is the outcome of a destructive interference of the waves due to a random potential. In quantum mechanics, the problem is often addressed for noninteracting particles. The exponential growth in dimensionality makes it a daunting task to explore the onset of localization in an interacting multi-particle system. Interaction can lead to involved physics such as many-body localization, which has recently seen significant progress [\[2\]](#page-4-1).

Yet, a system involving only two interacting particles delivers a rich set of features [\[3–](#page-4-2)[9\]](#page-4-3). Indeed, many studies addressed the conditions in which the interaction can lead to an increase of the localization length compared to the non-interacting case [\[10–](#page-4-4)[14\]](#page-4-5). Moreover, classical and quantum correlations have been explored in those systems even in the absence of interaction [\[4,](#page-4-6) [5\]](#page-4-7). The quantum correlations in this case originate from the symmetrization of the wavefunctions to accomodate the bosonic or fermionic character of the particles [\[7\]](#page-4-8). Quantum walks of two anyons was also investigated [\[15,](#page-4-9) [16\]](#page-4-10). Other studies explored Bloch oscillations with a characteristic frequency doubling [\[9,](#page-4-3) [17\]](#page-4-11) and dissipative twoparticle dynamics [\[18\]](#page-4-12), to name a few. In addition to displaying a variety of phenomena, two-particle systems enjoy a convenient photonic implementation based on a square waveguide lattice using only classical sources of light [\[6,](#page-4-13) [7,](#page-4-8) [9,](#page-4-3) [14,](#page-4-5) [19\]](#page-4-14).

The interplay between interaction and disorder in those systems is not trivial [\[11\]](#page-4-15) and depends on a number of factors, including the property that is being measured. Most characterizations require knowledge of many wavefunction amplitudes at a time (e.g. the participation ratio [\[12,](#page-4-16) [14\]](#page-4-5)). In this letter we propose another route to obtain relevant information about the system. We are interested in the statistics of successive measurements of Hanbury Brown-Twiss type of correlations from a local standpoint. In a coupled waveguide array implementation [\[9\]](#page-4-3) that means to monitor the beam intensity in single waveguide, accounting for joint probability of

<span id="page-0-1"></span>FIG. 1. Two-particle Hamiltonian graph structure. (a) The state space of two distinguishable particles in 1D can can be mapped onto a 2D array. Diagonal vertices represent states with double occupation (bound states). (b) By exploiting the symmetry with respect to the diagonal, the basis change  $|mn\rangle^{\pm} = (|mn\rangle \pm |nm\rangle)/\sqrt{2}$  decouple the Hamiltonian into those describing identical bosons (red vertices) and spinless fermions (blue vertices). In the bosonic case, the coupling between bound states with the other vertices are renormalized between bound states with the other vertices are renormalized<br>by  $\sqrt{2}$  (thick edges). Considering a 2D photonic waveguide implementation, each of these subspaces is achieved by setting the proper relative phase between two input beams at  $(m, n)$ and  $(n, m)$ . Note that such a decoupling is valid despite the strengths of disorder W and interaction U.

finding the particles at specific locations. What we get is a speckle pattern, to which we obtain all the relevant density functions in detail. Surprisingly, the speckle contrast is able to precise the particle identity and the degree of interaction between them. It shows up as specific deviations from the Rayleigh/exponential fully-developed speckle regime.

Tailored speckle generation finds a handful of applications [\[20\]](#page-4-17). Our main goal here, though, is to explore the following question: what can a local speckle statistics tell us about the nature of the physical mechanisms involved in its generation? This statement is particularly appealing to rogue (freak) wave phenomena in optical and quantum systems. There has been a renewed interest in the role of disorder on the generation of rare and short-lived wave amplitude spikes [\[21,](#page-4-18) [22\]](#page-5-0). In a recent work, Kirkby

<span id="page-0-0"></span><sup>∗</sup> [gmaalmeida@fis.ufal.br](mailto:gmaalmeida@fis.ufal.br)

et al. [\[23\]](#page-5-1) addressed Fock-space caustics in simple Bose-Hubbard models, which are also related to rogue events. Here we will realize that intrinsic quantum correlations due to particle identity lead to long-tailed distributions. Rogue waves are often studied as emergent phenomena in nonlinear Schrödinger equations [\[24\]](#page-5-2) (that describe, for instance, Bose-Einstein condensates [\[25\]](#page-5-3)). A bottom-up approach should therefore unveil key linear elements in driving anomalous fluctuations in quantum systems.

Let us start by considering two interacting distinguishable particles (e.g. two electrons with opposite spins) in a linear chain with  $N$  sites described by the Hamiltonian

$$
H = J \sum_{j=1}^{N-1} \left( a_{j+1}^{\dagger} a_j + b_{j+1}^{\dagger} b_j \right)
$$
  
+ 
$$
\sum_{j=1}^{N} \left[ \epsilon_j \left( a_j^{\dagger} a_j + b_j^{\dagger} b_j \right) + U a_j^{\dagger} a_j b_j^{\dagger} b_j \right], \qquad (1)
$$

where  $a_j$ ,  $b_j$   $(a_j^{\dagger}, b_j^{\dagger})$  are the corresponding annihilation and creator operators at site  $j$ . U is the local particle (respulsive) interaction strength,  $J$  is the nearest-neighbor hopping constant, and  $\epsilon_i$  is the onsite potential which we set randomly within the uniform interval  $[-W/2, W/2]$ , with  $W$  being the disorder width. The Hilbert space is spanned by  $N^2$  two-particle states  $|mn\rangle = b_n^{\dagger} a_m^{\dagger} |0\rangle$ , where  $|0\rangle$  is the vacuum state. It is known that a basis change with respect to the "diagonal" double occupancy √ (bound) states  $|mn\rangle^{\pm} = (|mn\rangle \pm |nm\rangle)/\sqrt{2}$   $(m \neq n)$ decouple the Hamiltonian in two parts [\[7\]](#page-4-8). The symmetric combinations alongside bound states interact via a Bose-Hubbard Hamiltonian accounting for two identical bosons and the anti-symmetric part behave as noninteracting spinless fermions. Figure [1](#page-0-1) depicts the statespace structure. Any local speckle pattern of the intensities will be therefore controlled by these two subspaces, each playing a distinct role.

Before we elaborate the speckle formalism for the twoparticle dynamics, it is appropriate to work out the transition amplitude statistics of a single-particle Anderson model. Consider the transition amplitude between sites m and p due to the time evolution operator  $\mathcal{U} = e^{-iH^{(1)}t}$ ,

$$
f_m^p = \langle p|\mathcal{U}|m\rangle = \sum_k a_k(m,p)e^{-iE_kt} = Ae^{i\theta}.
$$
 (2)

The phasor sum coefficients  $a_k(m, p) = v_{k,m}v_{k,p}$  read from the local eigenfunctions  $v_{k,j} = \langle j|E_k \rangle$  of the singleparticle Hamiltonian  $H^{(1)}$ . When disorder is weak (large localization length) the set of  $|a_k|$  is almost evenly distributed. The phases  $E_k t$  effectively behave as uncorrelated random variables uniformly distributed in  $[0, 2\pi)$ at distinct times given  $J\Delta t \gg 1$ . If we get enough data in a time series, the real and imaginary parts of  $f_m^p$  will obey circular Gaussian statistics. In turn, A obeys the Rayleigh distribution  $p_A(A) = (A/\sigma^2) \exp(-A^2/2\sigma^2)$ , where  $\sigma$  is a scale parameter, with the output phase  $\theta$  being uniformly distributed [\[26\]](#page-5-4). The intensity  $I =$ 

<span id="page-1-1"></span><span id="page-1-0"></span>FIG. 2. PDFs of local intensities I evaluated at distinct times for a single disordered array with  $N = 40$  sites with  $W = 0.01J$ . Statistics is taken from many operations of  $e^{-iHt}$ up to  $tJ = 10<sup>7</sup>$  in steps of size 100. (a) Two non-interacting particles  $(U = 0)$  are prepared at sites  $(m, n) = (20, 22)$  and measured at  $(p, q) = (23, 26)$ . The output for distinguishable particles is shown as green diamonds, with the corresponding K-distribution function with shape parameter  $\nu = 1$  (green curve) with contrast  $C \approx \sqrt{3}$ . When both particles are identical bosons or fermions with properly symmetrized inputoutput kets (red squares and blue circles) we get another Kdistribution with shape parameter  $\nu = 2$  (blue curve). Such a speckle profile features a contrast  $C\approx \surd 2$  as a consequence of entanglement due to wavefunction symmetrization. Gray triangles stand for two distinguishable particles occupying the same location, with  $m = n = 20$  and  $p = q = 22$ . In this case, only the bosonic subspace is involved. The correponding Weibull distribution is shown as the solid gray curve. The dashed black curve depicts the exponential density function dashed black curve depicts the exponential density function (Rayleigh regime for  $\sqrt{I}$ ). (b) In the presence of interaction  $(U = 1J)$  the distribution for identical fermions remains the same but all the others get closer to an exponential form. The bosonic distribution fits right in but that corresponding to distinguishable particles display an extended tail. This is due to an interference between Rayleigh-distributed and Kdistributed phasors. When only bound states are involved the tail retracts signalizing the onset of modes with shorter localization length.

 $A^2$  then obeys the exponential distribution  $p_I(I) =$  $p_A(\sqrt{I})|dA/dI| = s^{-1}e^{-I/s} \equiv Exp(s)$ , with mean inten-

sity  $\langle I \rangle = s = 2\sigma^2$ . A relevant measure to discriminate between speckles is the ratio between the standard deviation of the intensity by its mean, namely the contrast C. A fully developed speckle obeying exponential statistics renders  $C = 1$ . This gives us a reference to evaluate the degree of fluctuations of a given speckle pattern.

Now that we have set up the transition amplitude of a single particle as a random process, let us extended it to the case of two distinguishable particles when  $U =$ 0. Considering an input prepared at sites  $(m, n)$ , the transition to  $(p, q)$  reads

<span id="page-2-0"></span>
$$
h_{mn}^{pq} = f_m^p f_n^q = A_1 A_2 e^{i(\theta_1 + \theta_2)}.
$$
 (3)

The corresponding intensity is analogous to the twoparticle correlation function  $\langle a_m^{\dagger} b_n^{\dagger} b_n a_m \rangle$ , known as Hanbury Brown-Twiss correlations in optics [\[4,](#page-4-6) [5,](#page-4-7) [8,](#page-4-19) [14\]](#page-4-5). Each individual intensity in Eq. [\(3\)](#page-2-0) follows an exponential distribution,  $I_i = A_i^2 \sim Exp(s_i)$ . If we let  $I_1$  and  $I_2$ be independent random variables, it can be shown that their product  $I = I_1 I_2$  obeys the K-distribution [\[27\]](#page-5-5)

<span id="page-2-1"></span>
$$
\mathcal{K}(I; \mu, \nu) = \frac{2\nu}{\mu \Gamma(\nu)} \left( \sqrt{\frac{I}{\mu}} \nu \right)^{\nu - 1} K_{\nu - 1} \left( 2\sqrt{\frac{I}{\mu}} \nu \right), \quad (4)
$$

with shape parameter  $\nu = 1$ . Therein  $K_{\nu}(x)$  is a modified Bessel function of the second kind of order  $\nu$  and  $\mu = s_1 s_2$  is the mean intensity. The contrast of a speckle obeying such a of K-distribution is  $C(\nu) = \sqrt{(\nu + 2)/\nu}$ . Hence, larger fluctuations are expected when two distinguishable particles are involved, that is  $C = \sqrt{3} \approx 1.73$ , even they are not interacting. It is worth to highlight that K-distributions arise whenever some speckle intensity is known to obey exponential statistics but there is uncertainty about its mean s [\[26,](#page-5-4) [28\]](#page-5-6).

When obtaining Eq. [\(4\)](#page-2-1) we assumed that  $I_1$  and  $I_2$ were independent. This is true for most input  $(m, n)$ and output  $(p, q)$  location pairs. However, some residual correlations can be present depending on where intensity measurements are being taken. This happens, for instance, when  $|p - m| = |q - n|$  and disorder is weak. Both intensities become fully correlated  $(I_1 = I_2)$  when the transition amplitude involve only bound states, i.e.  $|h_{mm}^{pp}| = |f_m^p|^2 \sim Exp(s)$ . The intensity  $I = |f_m^p|^4$  then obeys a Weibull distribution  $p_I(y) = \alpha^{-1}(2y)^{-1/2}e^{-\sqrt{2y}},$ where  $y = I/\alpha$  and  $\alpha = 2s^2$  is the mean intensity. The contrast now reads  $C = \sqrt{5} \approx 2.24$ .

So far we have seen that the intensity speckle statistics associated to non-interacting distinguishable particles is typically long tailed. This stems from the correlations present in the spectrum of the two-particle Hamil-tonian in Eq. [\(1\)](#page-1-0). When  $U = 0$  its diagonal form reads  $H = \sum_{k_1,k_2}^{N} E_{k_1k_2} b_{k_2}^{\dagger} a_{k_1}^{\dagger} |0\rangle\langle 0| a_{k_1} b_{k_2},$  with  $|0\rangle$  being the vacuum and  $E_{k_1k_2} = E_{k_1} + E_{k_2}$ . As such the  $N^2$  phases  $E_{k_1k_2}t$  are combinations of two identical sets of N singleparticle inputs. By analyzing it through the 2D mapping (Fig. [1\)](#page-0-1), the observed non-Rayleigh statistics with higher contrasts is the result of structural correlations. We will

<span id="page-2-2"></span>FIG. 3. Local speckle contrast  $C$  against interaction strength U on a chain with  $N = 26$  sites and  $W = 0.01J$ . For a given disorder sample, the statistics is taken within three distinct time windows, namely short  $(tJ \in [0, \Delta];$  squares), intermediate  $(tJ \in [10^6, 10^6 + \Delta]$ ; circles), and long  $(tJ \in [10^9, 10^9 + \Delta]$ ; triangles), with  $\Delta = 10^5$ , in steps of 100. Contrast curves are averaged over 100 independent realizations of disorder. In (a) two bosons are loaded at sites  $(10, 11)$ , with the intensity measurements being taken at (13, 16). Panel (b) depicts the case of bound states, with the two bosons placed at (10, 10) and measured at  $(11, 11)$ . Contrast  $C = 1$  corresponds to exponential intensity statistics (fully developed speckle regime).

see shortly how those correlations are partially destroyed when  $U \neq 0$ .

Let us now discuss the speckle profile of identical bosons and spinless fermions separately. In a photonic waveguide array, each set can be explored by injecting two coherent beams at locations  $(m, n)$  and  $(n, m)$  with the proper symmetric or antisymmetric phase relation-ship [\[7,](#page-4-8) [14\]](#page-4-5). Given an input  $|\psi(0)\rangle = (b_n^{\dagger} a_m^{\dagger} \pm b_m^{\dagger} a_n^{\dagger})|0\rangle$ the transition amplitudes read  $h_{mn(B)}^{pq} = (\tilde{f}_m^p \tilde{f}_n^q +$  $f_m^q f_n^p$ ) $\mathcal{N}$ , with  $\mathcal{N} = 2^{-(\delta_{mn} + \delta_{pq})/2}$ , for bosons and  $h_{mn(F)}^{pq} = f_m^p f_n^q - f_m^q f_n^p$  for fermions. In both cases there is interference between K-distributed speckles. This is expected since we are now dealing with entangled input states. Indeed, such a quantum correlation manifests in the speckle statistics by delivering weaker fluctuations than those promoted by distinguishable particles. To see this, consider (bound states excluded)  $f_m^p f_n^q \pm f_m^q f_n^p = A_1 e^{i\theta_1} + A_2 e^{i\theta_2}$  is a two-component random phasor sum with independent K-distributed amplitudes  $A_i \sim 2\sqrt{I_i} \mathcal{K}(\sqrt{I_i}; \mu, 1)$  with mean  $\langle A_i \rangle = \pi \sqrt{\mu/4}$ and uniformly-distributed phases  $\theta_i$ . Note that we are assuming a common mean for both variables. This is a reasonable assumption for a weakly disordered chain. The output intensity speckle can be evaluated by means of a version of a modified Kluyver-Pearson formula [\[29\]](#page-5-7). It results in another K-distribution [see Eq. [\(4\)](#page-2-1)], now with shape parameter  $\nu = 2$  and mean  $\mu' = 2\mu$ , that is  $p_I(I) = \mathcal{K}(I; \mu', 2)$ . The contrast is now  $C = \sqrt{2} \approx 1.41$ , lower than that obtained for distinguishable particles √  $(C = \sqrt{3})$ . This is the entanglement due to wavefunction symmetrization modifying the classical speckle signal. Figure [2\(](#page-1-1)a) displays all the distributions obtained so far in agreement with the numerical simulations.

We are now ready to see how the presence of a local interaction between both particles modifies the speckle statistics. When  $U \neq 0$  transition amplitudes between the quantum states can no longer be expressed in terms of single-particle wavefunctions. We expect that this symmetry loss in the two-particle spectrum may drive the intensity statistics toward the (fully developed) exponential regime. However, when we expand the dynamics in terms of the bosonic and fermionic subspaces (see Fig. [1\)](#page-0-1), the latter is not affected by  $U$ . A given input  $b_n^{\dagger} a_m^{\dagger} |0\rangle$  will evolve independently in each one of those subspaces, having symmetric and anti-symmetric components. The fermionic part maintains its K-distributed profile  $\mathcal{K}(I; \mu', 2)$ . It thus suffices to examine the transition between bosonic states against U.

Figure [3](#page-2-2) shows the contrast  $C$  for several values of the interaction U in distinct timescales. When  $U \ll J$ , exponential statistics is only obtained in the long-time regime. That is, as the bosonic spectrum is slightly shifted it takes a while before the random phasor sum underlying the bosonic dynamics converges to a fully developed speckle [see Fig. [2\(](#page-1-1)b)]. When  $U$  is weak, whether or not both bosons are loaded in the same site, the short-time regime typically features higher fluctuations. Figure [3\(](#page-2-2)a) [\[3\(](#page-2-2)b)] indicates that these are reminiscent of the speckle pattern associated to the K-distribution (Weibull distribution).

At intermediate values of  $U$ , the particles are still free to access the whole bosonic subspace but the speckle signal associated to their symmetry that is present when  $U = 0$  is promptly lost. As U increases, a smaller band of N bound  $(B)$  states builds up apart from the scattering (S) part of the spectrum consisting of  $N(N-1)/2$ states [\[3,](#page-4-2) [8\]](#page-4-19). It is then convenient to express the transition amplitude as the phasor sum of the form  $h_{mn(B)}^{pq} =$  $\sum_{k \in S} b_k e^{i\phi_k} + \sum_{k' \in B} b'_k e^{i\phi'_k}$ . When  $U \gg J$ , if both bosons are injected in different sites they will display fermion-like correlations such as spatial anti-bunching [\[8\]](#page-4-19) (the phasor sum running over the bound states becomes negligible). This is heralded as the high contrast seen in Fig. [3\(](#page-2-2)a). It does not mean, however, that such a fermionic behavior will hold up at all times. Although transitions between scattered and bound states remain negligible, the speckle will eventually set as a fully developed one  $(C \approx 1)$  unless  $U \rightarrow \infty$  (hard-core boson limit).

We now realize that when loading two distinguishable particles in different locations  $(m, n)$ , the resulting speckle in  $(p, q)$  comes as an interference between Rayleigh- and K-distributed phasors. Figure [2\(](#page-1-1)b) shows that the speckle is nearly exponentially distributed aside from a pronounced tail (the contrast is numerically found to be  $C \approx 1.05$ ). Here the fermionic correlations is holding the speckle from its full development.

A noteworthy trend that occurs in the regime of strong interaction  $U$  is the decrease in contrast when only bound states are involved [see Fig. [3\(](#page-2-2)b)]. Early signs of this behavior can actually be noticed for intermediate  $U$  [see the tail retraction of the associated distribution in Fig. [2\(](#page-1-1)b)].

<span id="page-3-0"></span>FIG. 4. Distributions of the intensities associated to bosonic bound state transitions. Here,  $I = |h_{mm}^{pp}|^2$ , with  $m = 20$ and  $p = 22$ , considering a chain with  $N = 40$  sites in the strong U regime. Statistics is taken on a single disorder sample with  $W = 0.01J$  evolving up to time  $tJ = 10<sup>7</sup>$  in steps of 100. Up (right) Triangles represent the case for  $U = 200J$  $(U = 500J)$ . Solid curves are the compound Rician fittings obtained by isolating the four greatest amplitudes of the corresponding random phasor sum to build  $g(r)$  (see text). The integral  $\int R(I|r)g(r)dr$  is evaluated numerically. Note that the necessary number of phasors involved to make  $g(r)$  depends on both U and the distance between input and output locations. When the distribution is similar to an exponential one, aside from a slightly retracted tail, a standard Rician distribution with only one dominant phasor (when  $g(r)$  is a Dirac delta function) should be enough. The exponential distribution is displayed as a dashed curve for reference.

That can be readily explained in terms of the energy pulling effect taking place in the band of bound states [\[3,](#page-4-2) [8\]](#page-4-19). Even if the disorder  $W \ll J$ , the effective hopping strength within the band will eventually diminish to the point that strongly-localized bound states prevail. In a sum involving random phasors, it fosters asymmetry between their amplitudes. One or a few phasors will stand out compared to the remaining terms that amount to an exponentially-ditributed intensity with mean  $s_n$ . In the simplest case of only one dominant phasor with intensity  $I_0$ , we get the Rician distribution [\[26\]](#page-5-4)

$$
R(I;r) = s_n^{-1} e^{-(r+I/s_n)} \mathcal{I}_0(2\sqrt{Ir/s_n}), \tag{5}
$$

where  $\mathcal{I}_0(x)$  the modified Bessel function of the first kind of order zero and  $r = I_0/s_n$ . The contrast in this case or order zero and  $r = I_0/s_n$ . The contrast in this case<br>is  $C(r) = \sqrt{1+2r}/(1+r)$ . If more than one dominant phasors is set apart we can compound the distribution above over different r to obtain  $p_I(I) = \int R(I|r)g(r)dr$ where  $R(I|r)$  is the Rician distribution conditioned on knowledge of r and  $g(r)$  is its probability density function.

The above generalized Rician distributions will also display a lower contrast compared to a fully developed speckle. It ultimately depends on  $U$  as well as the distance between input and output sites given the typical spatial profile of localized modes. That is, if such a distance is large enough we expect  $g(r) \sim Exp(s_0)$  and then the Rician compound becomes an exponential distribution with mean  $\langle I \rangle = s_n + s_0$ . It is valid to mention that there is a non-monotonic relationship between  $U$  and the degree of Anderson localization disordered two-particle systems [\[12\]](#page-4-16). To see the generalized Rician distributions in activity here, let us turn our attention to the regime of strong U. Figure [4](#page-3-0) confirms the predicted statistics for transitions involving bound states.

We have seen that fluctuations associated to local intensity measurements can disclose subtle quantum correlations. Non-Rayleigh speckles can be extracted from the time evolution of two quantum particles. It ranges from low contrast forms obeying generalized Rician distributions to K-distributed speckles that display higher-thanexponential fluctuations. The two-particle dynamics can be promptly adapted to a square photonic waveguide array loaded with classical light [\[6,](#page-4-13) [7,](#page-4-8) [9,](#page-4-3) [14,](#page-4-5) [19\]](#page-4-14). The different speckle patterns is then obtained upon setting the desired input phase relationship (so as to activate bosonic and/or fermionic behavior) and controlling the detuning

Besides having immediate applications is optics, our results apply to the characterization of quantum systems in general. We have shown that local measurements in the computational basis is able to capture subtle quantum correlations involving identical particles. Even when both particles are distinguishable their resulting speckle distribution display a contrast  $C > 1$ , a property that can be traced back to fermionic correlations. The speckle corresponding to two bosonic particles also feature a higher  $\alpha$  contrast in both weak and strong U limits. It takes some time before their intrinsic correlations are washed out and we get a fully developed speckle. This is an interesting feature that allows one to manipulate the speckle statistics while maintaining the overall dynamical pattern [\[20\]](#page-4-17). This is yet another manifestation of entanglement due to particle identity that meets practical applications [\[30\]](#page-5-8). Future works may delve into the speckle response in the multi-particle level [\[31,](#page-5-9) [32\]](#page-5-10) and its relationship with other forms of entanglement.
